THE MAKING OF MEN & NATIONS

Human Nature and Society: Society and Human Nature. Men and Systems: Systems and Men. The Great Lesson of History. The Society that Endures

Continued from page 4278

By Dr. C. W. SALEEBY

LET us take a single contemporary illustration of the all-important proposition which is the central truth of sociology. There never yet was an autocracy or an oligarchy which did not depend for its existence upon an army. One man cannot defy the wills of millions merely because he is labelled emperor or king. He must have an army; as long as he has an army he will persist, and as soon as his army becomes disaffected, his knell is sounded.

The Russian Tyranny. Now, a society, if it is to produce an army devoted not only to aggression by the autocrat against foreigners, but also devoted to the control, and, if necessary, the destruction and murder of its own flesh and blood—the people from whom it has sprung—that society must be capable of producing a sufficient number of men whose nature is such that, so long as they are paid, they will not hesitate to trample upon the liberties of their own people. Thus, the very existence of a tyranny such as the Russian tyranny, which daily distresses every lover of liberty and of mankind all the world over, is in itself a demonstration of and a consequence of the existence of a certain kind of human nature among the Russian people. There is an all-important addition to be made to this proposition, and we are about to make it. Even in this present partial stage of analysis, however, the sociological phenomena presented by Russia will suffice, especially for any reader who has read the history of the French Revolution, as a fair illustration of our general proposition that human nature is the key to sociology—that the characters of a society depend upon the characters of its units in an infinitely more fundamental and necessary fashion than the characters of the molecule of a chemical compound depend upon the characters of its constituent atoms.

The Key to Human Nature. But man is a spiritual being, and not merely a dynamic mechanism like an atom. No chemist contends that there is any reaction of the molecule upon its atoms. The atoms and their relations determine the molecule, but the molecule does not modify the atoms. Immeasurably different is the case of society. Human nature, we have said, is the key to sociology, and this is true, but it is only half the truth: the complementary truth is this, that sociology is the key to human nature. That, perhaps, is a somewhat bald and imperfect way of stating the proposition, but we so state it in the hope that we may make it memorable. Our business is not to instruct, but to educate, and nothing could be more useless than that the reader should accept these propositions simply because they are to be found on this page. But here we submit them to him for his consideration and reflection: *Human nature is the key to sociology; sociology is the key to human nature.*

And now let us return to the illustration which sufficed in proof of the first proposition, but which we described as having been only half analysed. Now if the first part of our analysis was important, this is infinitely more important. It is interesting, doubtless, that the sociologist should find in human nature the key to the problems presented by societies. But we are not all sociologists, and this abstract proposition has no particular practical consequences for us. The converse proposition, however, which is the most generally and most fatally ignored of all sociological truths, concerns us all infinitely and vitally, as we shall now see.

A People Deserves What it Gets. It is an easy matter to say that the production by the Russian people of a brutal soldiery, which has hitherto been willing to militate against the happiness of the people from whom it has sprung, depends upon human nature as it is exhibited in the Russian people. It is even possible, judging by this and countless other illustrations, to say that, in general, a people deserves what it gets. For instance, only a superstitious people will be governed by such a priesthood as many of those which have darkened human life and served the devil since the dawn of civilisation.

Only a brutal people, again, can permit themselves to be dominated by a brute of their own race. Yet again, only a foolish and selfish body of voters will be led away by the lies of politicians so as to give power to unworthy, foolish, and selfish men. From democracy, autocracy, or priest-ridden societies—in short, from societies of all kinds, may be quoted proofs of the truth which leads us to say in such cases, "Serve them right." The impartial observer recognises that it does serve a people right to groan under this, that, or the other burden. It is a product of their own lack of courage, or wisdom, or honour. Indeed, to say that on the whole a people deserves what it gets—a proposition which has its light as well as its dark side, of course—is to say in other words what we have already said, that human nature is the key to sociology. This is a doctrine which everyone really admits, whether explicitly or not.

Heredity and Environment. But the thoughtful critic, looking upon the present unhappy state of Russia, and admitting that there must be brutal and ignorant elements in a people which produces an army for its own repression and grovels under superstition, will

ask *why* human nature in Russia is such and such. Now we know that the characters of any individual man or woman are determined by heredity and environment. There are inborn, inherent, innate characters with which each of us is endowed from the first: and then there are the modifications which circumstances or environment produce in us. Merely to say that human nature is the key to sociology and that the Russian people groan under the heel of the oppressor because human nature in Russia is capable of producing an army such as in all ages has been the necessary instrument of tyranny is as good as to say that human nature depends entirely upon the inborn characters with which each man is endowed from the first.

The Factors in Making Men. This, however, as we all know, is false. Environment plays its part in fashioning human nature. The body is determined by the atmospheric environment, by the nature of the food, by considerations of temperature, and the like. In this manner the inborn bodily characters are profoundly modified in every one of us. But what, pray, constitutes the all-important part of the environment of the mind? Buckle thought, as we have seen, that too much stress could scarcely be laid upon the presence or absence of mountains or earthquakes, thunder and lightning. Doubtless he recognised a truth of some importance; but nowadays we are sure that the forces which are most potent in moulding the spirit of man are themselves spiritual. Human nature is chiefly modified not by *natural*, but by *human natural* forces. It is the social atmosphere, the social environment, that is foremost in modifying the inborn characters of men. For instance, it has been finely said that genius can breathe only in an atmosphere of freedom. The superstitious régime breeds superstition; the brutal régime breeds brutality; in a military society the military spirit is fostered; and so in all other cases. After heredity, incomparably the most important of the influences which determine what a man shall be are the social influences, the social tradition, the spiritual atmosphere that he breathes.

Society Makes the Average Man. To take an instance, ambition will be all but impossible in a society where ambition is obviously futile. If there be no conceivable possibility that a man shall rise out of his class, the ambitious habit of mind will not be fostered in him. He will be different, in a word, from the man he would have become in a democratic society. Of course, we are not disputing the proposition that while most men are anvils and each must be either an anvil or a hammer, there are a few who are hammers, who make opinion, make tradition, and create new social forms and customs. Yet the fact remains that the majority of men are moulded by society into the form which suits its convenience, and tends to its own unchanged persistence.

The proposition that sociology is largely the key to human nature, as human nature is largely the key to sociology, is of profound interest to the sociologist as a pure man of science or seeker after truth. It invests his study with a unique interest and a unique difficulty. He has to study action and reaction. He cannot take the given facts of human nature, let us say, explain society in terms of them, and then be content. For the second and consequent set of facts react upon and modify the first.

Brutality Breeds Brutality. Thus, to turn to our Russian instance, the sociologist has to ask himself whether the characters of the Russian people—including the character of being able to produce a brutal soldiery—are inborn, necessary, and permanent, or whether they are not products of the brutal military régime. He has to inquire, indeed, whether any people, even the most democratic and freedom-loving—whether, indeed, such a people as ourselves, subjected for two generations to dominance by autocracy, militarism, and ecclesiasticism, would not in turn become capable of producing an army such as the Russian army. In a word, the sociologist has to deal with circles. Most of them in the past, alas! have been vicious circles. The superstitious or the brutal régime has fostered and produced the superstitious and brutal habit of mind which, in its turn, strengthens and makes possible that régime. Once we grasp the truth of the two abstract propositions upon which so much emphasis has been laid, we shall have acquired a wholly new means of passing sociological judgments. For instance, in his "Essay on Man," Pope writes:

> "For forms of government let fools contest,
> Whate'er is best administered is best."

To the untrained reader this may seem satisfying. If it be true it is a very important truth, but if it be false there is no more dangerous falsehood. The reader is well aware that, at any rate, it cannot be accepted without question, because it does not inquire into the effect of "forms of government" upon human nature.

The Failings of Democracy. Now let us see how the central sociological truths of action and reaction between society and the individual bear upon current political discussion. So far as the influence of human nature upon society is concerned, Pope's couplet will stand criticism. If there were no reactive influence such as we have described the couplet would be true. Everyone admits that forms of government, in order to be successful, or as successful as they are capable of being, are at the mercy of human nature, upon which their administration depends; and the great majority of untrained students of these subjects are content merely with recognising the half-truth which Pope recognised. For instance, sensitive people are sometimes shocked at the excesses, the blindnesses, the stupidities of which democracy is capable. Such people are apt to turn in disgust from the democratic ideal, and to declare that the best form of government, after all, would be government by a wise and beneficent autocrat, if such could be obtained. They see that democracy is liable to wire-pulling and the wiles of demagogues and the influence of wealth. They see, in short, that democracy may be very badly "administered," to use Pope's word, and they think that even

such a form of government as an autocracy would be infinitely better *if better administered.*

Government and Character. Now, we submit that all such opinions ignore the truth that different forms of government, even if all be ideally administered, differ profoundly in their influence upon human character. It is unthinkable that the same type of citizens could be produced under an ideal autocracy or hierarchy (government by priests) as under and in an ideal democracy. Different causes must produce different effects, and effects upon human character are the only important effects, perhaps, produced by any causes in the whole universe. The practical problem for the sociologist—who, as we have seen, is not merely a scientist or student of what is, but also a moralist or student of what ought to be—is to produce such a society as will make the best citizens. It is not merely his problem even to find the type of society which will keep human nature at its present level of intelligence and virtue. He knows that the average level is appallingly below the level of the highest, and he knows that, as Spencer somewhere says, what is possible for human nature here and there is possible for human nature at large.

Human Nature is Not Always the Same. The sociologist who is not a believer in evolution or the doctrine that progress is possible is, of course, a mere anachronism to-day. He is a survival from the intellectual atmosphere that preceded the idea of evolution, and, as such, is no more than an interesting and significant curiosity. If there be anything of which the sociologist is quite sure it is that, popular unwisdom notwithstanding, human nature is *not* "the same in all ages." He knows, on the contrary, that human nature is profoundly modifiable by circumstances. He knows that the ideal of human nature is vastly superior to the average reality, and yet he knows that the ideal is attainable. In passing his judgment, therefore, upon different forms of society, such as autocracy and democracy, or upon different theories of societies, such as individualism and collectivism, or upon social customs or Acts of Parliament, or, in short, upon one and all of the influences that determine the incessant changes of society, the wise sociologist asks himself what will be the effect upon the character of the citizen—the effect upon human nature.

A Nation is Made by its Units. There is one criterion alone by which the work of any and every social act is to be judged, and that is its effect upon individual character. Says Herbert Spencer, in words which should be written over the portals of every legislative chamber on earth:

"Let it be seen that the future of a nation depends on the natures of its units, that their natures are inevitably modified in adaptation to the conditions in which they are placed, that the feelings called into play by these conditions will strengthen, while those which have diminished demands on them will dwindle, and it will be seen that the bettering of conduct can be effected, not by insisting on maxims of good conduct, still less by mere intellectual culture, but only by that daily exercise of the higher sentiments and repression of the lower which results from keeping men subordinate to the requirements of orderly social life—letting them suffer the inevitable penalties of breaking these requirements and reap the benefits of conforming to them. This alone is national education. Of the ends to be kept in view by the legislator, all are unimportant compared with the end of character-making; and yet character-making is an end wholly unrecognised."

Why the Statesman Fails. The best form of government, then, is that which makes most rapidly and easily for the development of the highest worth in the individual citizen. We must later ask what is that form.

The only criterion of the worth of any society is to be found in the lives of its citizens. The great lesson of history is that other objects have been conceived as the proper objects of society, and that certain consequences have flowed from the pursuit of those objects. Let us compare and contrast the consequences which follow when other objects than the production of individual worth are sought by the statesman or the social reformer. We shall choose contrasted instances in the endeavour to show that it is utterly immaterial whether the object sought be good or bad in itself. In either case ultimate failure will follow.

History abounds with instances of societies or nations whose rulers have set certain more or less selfish objects in view and have for a time attained them. We know the history of empires; we know that, in the past, at any rate, unqualified Imperialism has always cut its own throat in the long run. We have various instances from all ages of governing powers who have set themselves to the production of powerful armies as means of conquest.

Militarism and Family Life are Eternally Opposed. To this end all legislative measures have been consecrated—or prostituted—and the end has been attained. Doubtless many other things have had to go—education has been one-sided, dealing with the body rather than the mind; moral education has dealt with the production of unquestioned obedience rather than with the production of a sense of personal responsibility for one's own actions; family life, with all that it implies in the ennobling of character, has been sacrificed, for militarism and family life are eternally opposed. Instances may be chosen on the small scale or on the large.

The reader was taught, perhaps, in his youth to admire the spirit of the Spartans who sacrificed everything to military efficiency. The Spartan mother sent out her son to war telling him to return with his shield or upon it—yet Sparta did not survive. In later times, when military warfare has yielded in part to industrial warfare, the men who have had the power to determine the form of society or of portions of society have instituted industrial régimes in which the sole consideration has been the efficiency of the

individual as a worker. These also have been successful in their way. When military efficiency was aimed at, it was often attained; when industrial efficiency is aimed at it may likewise be attained.

The Material of Empire. But the all important truth is that these objects, as such, are not worth attaining at their price. To obtain military efficiency or industrial efficiency, but to destroy the character of the people, is to achieve a temporary success at the rapidly ensuing cost of permanent failure. The material for any empire or society that is to endure is not money, nor red maps, nor mines that yield precious metals, nor treasuries mountains high, but worthy men and women. All the dead wealth on earth, accumulated and possessed and gathered into the hands of one worthless people, will not make an empire that can endure for six months. The legislator who legislates for anything less than character may be counted successful in his own day and even on the morrow; but he is not building for all time—and time will pronounce judgment upon him at the last.

The same truth is demonstrable in the case of legislation or other social action which, unlike that of the military dictator, is determined by sentiments of humanity and compassion. To-morrow as well as to-day has to be thought of, and the supreme factor of character remains supreme. It would be no more foolish than many acts which unwise people call charitable for the State at this moment to expropriate all the private wealth of the country, and to say "We will provide food, shelter, clothing, education, and a fair supply of amusements for all who please." Thereby many hundreds of thousands or millions of people, in this country alone, would be very greatly benefited indeed, for a time—they and their children too. A vast humanitarian end would have been achieved—for a time. There would be no more half-starved children—for a time.

A Passing Good and a Measureless Evil. An immediate good of some magnitude would have been accomplished; but if we are to form a final judgment upon this measure we must apply to it our criterion of its consequences upon character. The vast majority of men would not work unless they had to work—which is natural enough, since their work, unlike that of the fortunate few, affords them little or no spiritual sustenance or interest. Such men would cease to work under the measure we have imagined. Even supposing that the nation had some source of inexhaustible mineral wealth so that it could afford, as a nation, not to work, does anyone imagine that under these conditions the State would remain stable? On the contrary, the immediate good done would be as naught compared with the measureless evil which would be worked by such an act. It would involve the most appalling deterioration of character, resulting not only in the rotting away of the fibre of manhood, but also in the pursuit of pleasure by the many, under the conditions and with the consequences which are now exhibited in the case of the unemployed idle rich. Such a nation would cease to produce, or to be anything of worth, and the annexation of these islands by some Continental power would be a matter of a few years at the most. The little good accomplished would be far more than nullified by the evil influence of such a measure upon character.

Character the Sole Basis of the State. Anything that destroys the character of the individual destroys the State—which depends for its continued existence upon individual character *and nothing else*. If these propositions are true, it follows that the criterion of character-making or unmaking must be applied to all social acts by any whose concern is not with the immediate present alone. Here, again, of course, is another fundamental distinction between society and a mere chemical molecule. The present is the child of the past and the parent of the future, and to reckon with the present alone is to court destruction. The temptation may come in many guises, selfish and unselfish, but the criterion must be applied, and no measure which does not satisfy it must be allowed to pass uncondemned.

We have now completed, in so far as may be, what might be called the Philosophy of Sociology. We have tried to show the relations of the life of a society to the life of the individual; we have discussed the foundations of sociology and its relations to the lower sciences on the one hand, and to the supreme science on the other; and we have tried to distinguish between the attitude of the sociologist who asks himself merely what is and what has been and that of the sociologist who, being also a man with human emotions and aspirations, asks himself what ought to be; both of these attitudes being necessary, but neither being allowed to distort the view taken by the other.

Marriage the Central Institution of Society. We must now turn to the detailed study of our subject, and must begin with the fundamental social institution of marriage. We shall find it necessary here to begin our inquiry at a very early stage in the history of humanity. We must trace the different forms of marriage as they have been experimented with by man. We must inquire into their consequences upon society, and must determine, if possible—and it is not only possible but easy—which form of sexual relation is that best fitted to serve as the central institution of a stable and progressive society. This is a subject so important that the sociologist finds it impossible to suffer fools gladly when they discourse upon it, and being peculiarly intricate, difficult, and important, it is naturally a subject upon which fools think it well to expatiate.

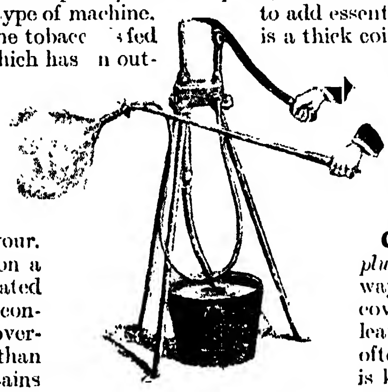
CIGARS, CIGARETTES, & PIPES

Manufacture of Roll, Twist, and Cake Tobacco. Snuff. Making and Moulding Cigars. Cigarette Machines. Clay, Briar, and Meerschaum Pipes

THE art of manufacturing smoking tobacco consists in selecting the different flavoured tobaccos and combining them to suit the various purposes for which they are required. As noted previously, ageing improves the tobacco, and sometimes the leaf is soaked in dilute hydrochloric acid to modify the nature.

Manufacture of Shag and Bird's-eye. After mixing, the leaves are damped, or *sauced*, with water in the United Kingdom, but in other countries sauces with flavouring ingredients are often used. The water is applied as a spray [7] or in the form of steam. When uniformly damped, the softened leaves are opened out, smoothed, and the midrib removed when *shag* is being made. The retention of the midrib gives *bird's-eye*. The leaves are then lightly pressed into a cake to squeeze out moisture, and cut up by a machine which works after the principle of a chaff cutter. In the modern type of machine, such as the Ajax cutter [9], the tobacco is fed continuously to the knife, which has an outward clearance movement on its upward stroke that prevents it rubbing against the tobacco, and thus avoids discolouring in the case of a bright tobacco. The cut leaf is then roasted, or panned, to dry and improve the flavour. The panning is done either on a rotating machine or on heated slabs, care being taken by constant turning to prevent over-scorching. Shag is stronger than bird's-eye, as the midrib contains a smaller proportion of nicotine than the fleshy part.



7. CLIMAX TRIPOD SPRAY PUMP

The tobacco termed *returns*, consisting of broken pieces of leaves and siftings, is similar to shag, but milder, although not so mild as bird's-eye. *Cut honeydew* is a strong smoke made from leaves of a light colour that have not been fermented to the same degree as those used for shag or bird's-eye.

Smoking Mixtures. Smoking mixtures of numerous virtues are put on the market. They are produced by mixing two or more different tobaccos. The following are examples:

Mild: York River, 4 lb.; coarse-cut British cavendish, 1 lb.

Milder but hotter: Bright returns, 5 lb.; Turkey, ½ lb.; light cavendish, ½ lb.

Full flavour: Returns, 5 lb.; cut cavendish, 2 lb.; Latakia, 1 lb.

Strong: Shag, 4 lb.; cut dark cavendish, 2 lb.

Many mixtures are much more complex than those shown in the above examples, but it will be noticed that certain tobaccos are used as bases and others for flavouring purposes.

Roll and Twist Tobacco. To make *roll* tobacco the darkest leaves are selected and stripped and sauced. They are then placed end to end, and twisted or spun into ropes of various thicknesses. The interior of the rolls consists of the small and broken leaves, the outer ones being usually bright leaves. The spinning process is effected either by hand or by a spinning machine [10], such as that used for making rope. The rope is rolled into cylinders or balls, which are enclosed in canvas and tied round with hemp cords. These masses are next stored in moist heat for some hours, and are then submitted to continuous pressure in hydraulic presses [8] for a month or so, when a slow fermentation takes place, and a good deal of the moisture is pressed out. To facilitate the spinning process and prevent the leaves caking together in the press, olive oil is used, and it is also allowable to add essential oils for flavouring. *Irish roll* is a thick coil, *pig-tail* a thin coil, and *brown tobacco* is one that has not been pressed after spinning. *Plug, bogie, nailrod, negro-head, ladies' roll,* and *target* are fancy names of roll tobacco for smoking or chewing. *Twist* ranges in thickness from the size of a bootlace upwards.

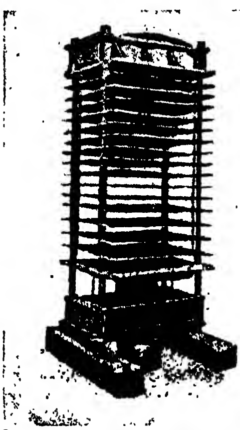
Cake Tobacco. *Cake* or *plug* tobacco is made in a similar way to that described above, the cover consisting of fine bright leaves. For chewing, the cake is often sweetened with liquorice, and is known as *sweet cavendish.* The sweetened cavendish is imported or made in bond, and can only be sold in stamped wrappers. The unsweetened cavendish is not subject to these restrictions. *Honeydew* is a light-coloured cavendish, and as *cut honeydew* is a strong smoking tobacco. *Varinas roll*, of Dutch manufacture, is not seen often now; it is a very mild cake. The twist and cake form of tobacco is much used by the working classes in Scotland and Ireland, as, besides being stronger than shag or bird's-eye, it is more economical, and also adapted for chewing.

Snuff. Although but little used at the present day, snuff-taking was formerly more in vogue than smoking. Up to A.D. 1700 snuff was used to ward off infectious diseases, but its popular use as a sternutatory is traced to a large cargo captured by Sir George Rooke off Cadiz, and sold off in English seaports at 3d. to 4d. a pound.

Snuff is made chiefly from the stalks and midribs of tobacco by a tedious process, during which fermentation is induced several times. The

coarse material of midribs and leaves is moistened with a solution of salt, and piled up into heaps containing many tons. The temperature rises gradually to about 140° F., and fermentation is allowed to proceed for some six months. At the end of this time the temperature begins to decline, and the heap is opened and the material ground to a light brown powder [11]. This powder is mixed with salt solution, and packed in large chests for six to ten months, when another fermentation occurs, and the powder develops colour and aroma. The snuff is well mixed, and sometimes submitted to a third fermentation. Finally the snuff is well sifted to make it uniform. It will thus be seen that the process extends over from 18 to 20 months, and consequently much of the nicotine is dissipated.

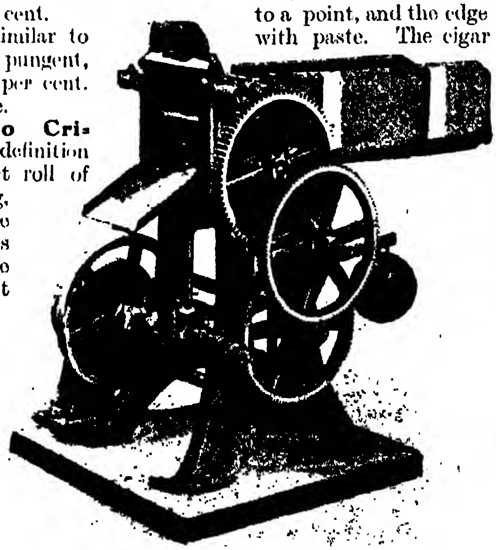
Rappee. *Rappee*, or *tabac râpé*, is a black snuff highly scented, and containing on an average 40 per cent. of moisture. The dark colour is due to long continued fermentation while in the bin. *Prince's mixture* is a rose-scented rappee, which takes its name from the fact that it was used by George IV. when Prince Regent. *Scotch and Irish snuffs* are made from stalks that have been previously roasted, which gives the characteristic smell to these snuffs. Scent is added to some varieties, and the moisture is generally about 20 per cent.



8. HYDRAULIC PRESS FOR ROLL TOBACCO

High dried snuff is similar to Scotch snuff, but more pungent, and with only about 5 per cent. to 8 per cent. of moisture.

Cigars—Colour no Criterion. The dictionary definition of a cigar is "a compact roll of tobacco leaves for smoking, one end being taken in the mouth, while the other is lit," and the word can be spelt in many different ways. A cigar consists of a core or filler, an inner cover, and an outer cover. The core should consist of the finest flavoured tobacco, and it is arranged in a longitudinal manner, so that the air can be drawn through it from end to end. It will be seen from this that the colour of a cigar is no guide to its quality or strength, which depends entirely on the quality of the filler or inside portion.

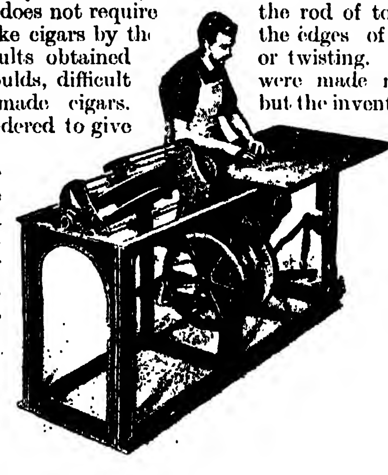


9. "AJAX" TOBACCO CUTTER

Making Cigars by Hand. In the handmade cigars workmen require years of experience before they can turn out well-made cigars; but of late years machinery and various pieces of apparatus have been employed to assist the operator. The making of cigars by hand can be thus described: The tobacco leaves are moistened by spraying to render them pliable, the stem is removed, and the leaves piled on the top of each other. The workman sits at a bench on which is a maple wood block, under which is a drawer for waste, and near him is a rack or box to receive the finished cigars. He is also provided with a knife for cutting purposes, a vessel of tragacanth paste for sticking the outer wrappers, and a cutter adjustable for various lengths—three to seven inches—with which to trim the end of the cigar to the proper length. There is a pile of wrapper leaf kept damp on one side, a supply of filler leaf on the other, and inner wrapper or binder leaf in front. A wrapper leaf is spread on the board, and cut into as many wrappers as it will make, the waste being pushed into the drawer. The binder leaf is torn into suitable pieces, and of these a large piece is laid on the board, and a smaller piece is placed on the top of it. The workman gathers up a handful of filler leaf, shapes it according to the kind of cigar required, puts it on the binder leaf, and rolls it therein. Care is needed to effect the packing and rolling easily, or a defective smoke will result. The outer wrapper is then rolled on spirally, beginning at the thick end, the mouth end of the cigar being manipulated to a point, and the edge of the wrapper touched with paste. The cigar is then trimmed to the desired length in the cutter machine.

Auxiliary Machinery. To assist the workman, suction wrapper holders and cutters are now employed, by which a saving of wrapper is obtained and a smoother appearance given to the cigar. Originally the suction tables were let out on hire, but they are now obtainable at much more advantageous rates. Some of these have a die for cutting out the leaf, but improved patterns employ a circular knife, so that the leaf is not torn at the edges [12]. Bunching machines are also employed, in which the filler is placed in a shaping cup, and by means of a concave roller and revolving apron the filler is quickly prepared in a suitable shape for binding. In another variety of bunching machine a pocket is formed in the apron, and no shaping cup is needed.

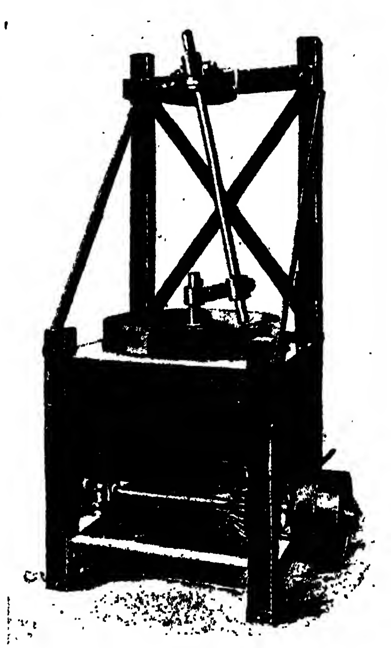
Moulded Cigars. In moulded cigars the bunches of filler are put into wooden moulds, some twenty moulds being arranged in each. The filled moulds are placed under a press for some hours, and are then ready for taking out and covering. Naturally it does not require such expert workmen to make cigars by the mould method, but the results obtained are, when using modern moulds, difficult to distinguish from hand-made cigars. The revolving mould is considered to give the best imitation of hand-made cigars. The hand-made cigar generally contains more tobacco than a moulded cigar. The moulds are obtainable in a great variety of shapes—the Miller, Dubrul, & Peters Manufacturing Co., of Cincinnati, illustrating in their list many hundreds of shapes and sizes [13]. The nearest approach to a machine for making cigars is obtained by combining bunching machines and moulds. The Reuse machine feeds the tobacco to two pairs of jaws, which form the core to any desired shape, and subsequently put on the binder and wrapper. A small mould is employed for shaping and polishing the point of the cigar. The Wartmann machine rolls the cigars between four rubber rollers, so shaped that a pocket is left between the rollers in the shape of a cigar.



10. GRIEG'S "SIMPLEX" SPINNING MACHINE

Finishing and Boxing. The cigars as turned out by the above processes are dried in the sun, or by a gentle heat, and sorted out according to colours, branded if needed with a hot brand, packed, and pressed into bundles or boxes. Before boxing the cigars a little perfume is sprinkled in the box. This perfume contains rum, lemon, cedar, vanilla, and other essential oils, the proportions of which vary, each maker having his own secret formulæ. The red cedar wood, of which the boxes are made, comes from Cuba, Mexico, and Central America, but the forests are rapidly being depleted.

Cigarettes. The consumption of cigarettes has increased so enormously of late years that it is difficult to realise that cigarette-smoking is quite a modern habit. The fashion was set by the soldiers who returned from the Crimean War, where circumstances had necessitated the use of tobacco in the form of cigarettes, and preference clung to the habit so formed when the necessity for it had vanished.

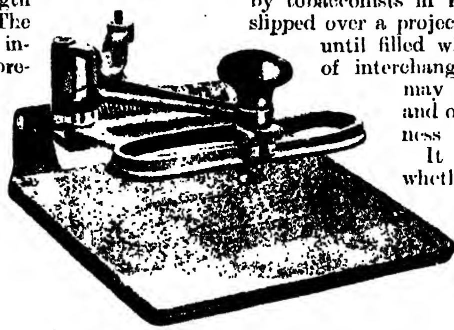


11. SNUFF MILL

Cigarette Making. The art of making a cigarette is first to prepare a sufficiency of tobacco in the form of a rod, and then to enclose the rod of tobacco in rice paper, fastening the edges of the paper together by pasting or twisting. Cigarettes up to recent years were made mostly by the smoker himself, but the invention of automatic machinery has transferred the operation to large manufacturers. The evolution of the cigarette machine is a striking instance of the perseverance of inventors and of ultimate success.

Single Cigarette Machines. The simplest type of cigarette machine is that in which single cigarettes are made, this type being divisible into two: (1) Machines in which the tobacco is prepared and encased in rice paper; and (2) machines in which the plug of tobacco is stuffed into a ready-made tube of paper. It will be noted that the efforts of inventors were very modest at first, the manufacture of cigarettes following strictly on the lines of the hand-made article. As an example of the first type of single cigarette machines may be cited the Evans Concinnum machine [14], which first appeared on the market in 1877. In this the tobacco for one cigarette was arranged on a grouping of small, corrugated rollers driven from a central wheel. The tobacco being neatly arranged, a cigarette paper was introduced, the lid closed, and then one turn of the handle wrapped the paper neatly round the tobacco. The makers of this machine claim that an expert operator can turn out 150 to 250 cigarettes per hour. A more ambitious machine on a similar principle was that of F. J. Ludington, invented in 1891. In this the tobacco was rolled and the edge of the wrapper pasted automatically. The next step is shown in the Lemaire machine, in which the cigarette filler is cut into lengths before being rolled in paper and the edges of the paper pasted, it being claimed that less waste and no loose ends result from this method. In the Williams machine the tobacco is fed to automatic mechanism and predetermined charges severed and conveyed to the rolling apron, there being mechanism for cutting the wrappers and pasting the edge, air suction being employed to

keep the papers flat. Girard, in 1895, with a view to quickening the process, devised a movable part in the mould, through which the cigarette was ejected by a jet of air. In this machine also the edges of the paper are folded. Grouvelle and Belot devised a machine for making four cigarettes at a time, the rolling being in imitation of the fingers by means of oscillating hinged levers. In Wood's machine the paper is fed to the machine from a roll, the width of which is equal to the length of the finished cigarette. The Hilgartner and Walker invention is an attempt to prepare the tobacco more carefully before cutting it into proper lengths and feeding it to the rolling table.



12. DUBRUL SUCTION WRAPPER HOLDER AND CUTTER

Plunger Type Machines. The Pierrot Minnot machine, invented in 1884, may be taken as an early example of the plunger type machine. The tobacco is brought down from a receiver between two endless bands running at different speeds to equalise the thickness of the layer. The tobacco thus carried forward enters laterally into a mould, the bottom of which rises to detach and compress the quantity to form a cigarette. A strip of paper to form a mouthpiece is twisted into form within the mould and is carried upwards with the tobacco when the mould closes. A piston then advances and pushes the contents of the mould out endwise through a tube or sheath, on which a paper wrapper has previously been arranged. Nippers hold the wrapper upon the sheath, and at the proper time allow it to pass forward, so that it may receive the tobacco within it and also the mouthpiece in its proper position as these are thrust out of the mould by the piston. The end of the cigarette is received by scissor-like cutters which remove the superfluous tobacco. The wrappers to be filled are taken from a magazine by a skewer-like instrument, which passes through a wrapper, removes it endwise from the magazine, and carries it to a sheath; then a slider on the skewer pushes the wrapper off endwise and transfers it to the sheath. The inventor claims that this machine will make 15,000 cigarettes a day. The machine has since been improved in respect to the mechanism by which the proper quantity of tobacco is detached from the mass before compression in the mould. Deconflé's machine of 1886 makes paper tubes with interlocking edges unpasted. These tubes are then placed on the end of a funnel and the tobacco contained in the funnel pushed into the tube by means of a plunger. The Georgii machines are of this type; the tobacco is rolled in an apron, and the charge pushed by a reciprocating plunger into finished paper tubes. The Ollagnier machine requires hand work to judge of the quantity of tobacco for each machine, the charges being then rolled and introduced into paper tubes. Grouvelle and Belot also adapted the plunger device for a machine making two cigarettes at a time. To the plunger type also belong the Jasmatzi, Bergstræsser, and Pederson machines. The New Transporter machine is one which is largely used by tobacconists in England. A paper tube is slipped over a projecting funnel and held there until filled with tobacco, and by means of interchangeable parts the cigarettes may be made circular or flat and of different degrees of thickness.

It is an interesting problem whether this type of machine will outlast other kinds referred to in this lesson. It is certainly at the present one of the most popular types.

Paper tubes for cigarettes are made in continuous lengths, the Bruandet machine being capable of making daily a length of tube corresponding to half a million cigarette tubes. Separate machines cut up the tubes, and in some factories a special machine is used for opening up the flattened tube before filling it with tobacco.

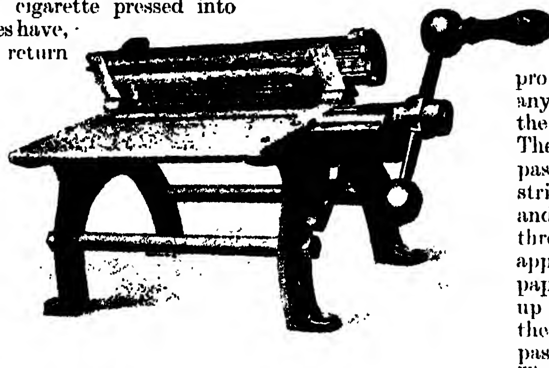
All-tobacco and Folded-end Cigarettes. All-tobacco cigarettes, in which the outer wrapper is cut from cigar leaf, are necessarily made on single cigarette machines, apparatus being provided for cutting out the wrappers. It is necessary to exercise care in cutting up a leaf of tobacco to avoid the heavy veins and midrib. A difficulty is often experienced in fastening the wrapper properly. A tragacanth paste is the best adhesive to use. The Hayden cigarette machine is one which folds in the end of the cigarette after the manner of Spanish, Cuban, or Mexican cigarettes. No paste is used on the paper wrapper, a twisting motion sufficing to hold the wrapper securely. This is done to enable the user to readily open the cigarette, as it is customary for users of this form of cigarette to roll the tobacco by hand before smoking.

13. DUPLEX LID CIGAR MOULD

Conical and Oval Cigarettes. The shape of cigarettes is not always round. One of the Bonsack machines is devised for conical cigarettes, users of this shape of cigarette contending that there is less waste of tobacco in the end thrown away. The oval, flat, or elliptical cigarette is growing in favour, the shape being better adapted for holding between the lips. The seam of the paper wrapper is generally on the flat side, but it is suggested that an improvement would be to make the seam on one of the narrow edges. The tobacco as prepared for the machine

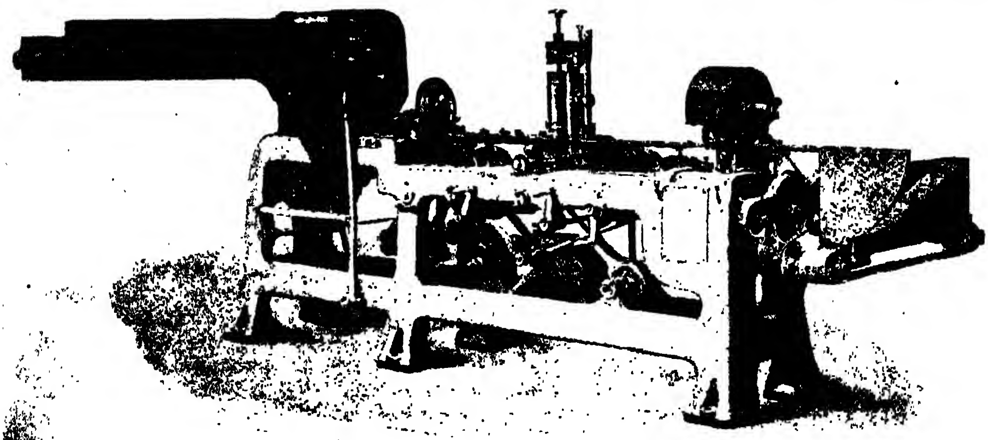
is of a round section, and must be separately moulded to the required elliptical shape. One of the Elliott machines has been adapted to this purpose, and one of the well-known Baron machines moulds the tobacco rod to an elliptical shape before wrapping. In the Braunstein and Chambon machine the tobacco is introduced into the paper tube by a spiral or screw arrangement and the finished cigarette pressed into oval form. Such cigarettes have, however, a tendency to return to their original shape.

Mouthpieces. To prevent cigarettes adhering to the lips they are provided with mouthpieces. These may be made by bronzing or waxing the end of the paper or by attaching a separable mouthpiece. Mouthpieces of stouter paper than that used for wrappers are dipped or brushed with melted paraffin wax, which gives them a translucent appearance and is quite effectual in preventing the cigarette sticking to the lips. Special machines are used for making and attaching mouthpieces, one kind also removing a little of the tobacco from the end of the cigarette and inserting a small plug of cotton-wool.



14. EVANS CIGARETTE MACHINE

Continuous Cigarette Machines. The machines in which a long row of tobacco is encased in paper—the operation proceeding indefinitely—and then cut up into cigarettes mark a distinct advance [15]. The Elliott machine, invented in 1890, started with the loose tobacco, which was spread in a layer, parted into windrows of uniform width and quantity, and pressed into continuous compact ropes or rods of tobacco. The wrapper was then applied and pasted suitably. In the Bohl machine of 1893 the tobacco is fed forward upon an endless carrier belt moving upon a horizontal table, and is brought to the middle of the belt by converging guard-plates, and then pressed sideways between two pressers moving towards each other. The tobacco then passes between converging spring guides to a series of pairs of grooved shaping-wheels on vertical shafts, by which it is pressed into an endless rope. Running along the upper surface of these wheels is a horizontal endless belt. Scrapers of special form and arrangement are provided to remove any matter adhering to the shaping wheels. The tobacco then passes on to the endless strip of cigarette paper, and the two pass through the forming apparatus, by which the paper is gradually bent up and folded round the tobacco and finally pasted and pressed. The adhesive is applied to the pasting disc by means of an endless thread running through the paste reservoir. After the endless cigarette is formed, it passes to a cutting apparatus, consisting mainly of a rapidly rotating disc cutter carried at the end of a revolving arm. In 1893 was introduced the Sloan & Barnes machine, in which the ribbon of paper is fed round the rope of tobacco in a spiral manner. The inventors likewise improved the manner of preparing the filler. The Maxfield machine also applies the paper spirally. The next step in the evolution is the abandoning of the use of paste for sticking the edges of the paper horizontally applied. Paste impares the flavour of the cigarette, and Munson's machine provided an interlocking device for the edges of the paper, the seam being afterwards crimped to make it hold. The Allagnon method of closing the edges is by two pressures on the seam, one being by means of a toothed disc. Kirshner also claims



15 DUBRUL'S PAPER-CIGARETTE MACHINE

an indenting or crimping device for holding the edges together, adaptable to the Bonsack machine.

Obviating Frayed Ends. Of the many attempts to prevent tobacco fraying from the ends of cigarettes may be mentioned Lumley & Taylor's machine. In this the arrangement for cutting up the continuous rod is so devised that it clears the tobacco away from the space about to be cut. One of the greatest difficulties that have had to be overcome in this type of machine is in the apparatus for carding or combing the tobacco to equalise it before forming it into rope. If the supply of tobacco be unequal, it gives a rope of unequal density, which shows itself in cigarettes that are difficult to draw. The Bonsack machine is one in which the mechanism in this respect has reached a high pitch, one of these machines being adapted equally for long or straight cut tobacco or granular tobacco.

PIPES AND PIPE MAKING

The materials of which tobacco pipes are made are of various kinds—clay, wood, meerschaum, asbestos, and metal. Baked clay is probably the oldest material of which pipes have been constructed, and the manufacture of clay pipes therefore will be considered first.

Clay Pipes. The clay from which pipes are made is a soft clay nearly free from iron, lime, and magnesia, so that it is colourless when baked, and very refractory. Broseley in Staffordshire, Purbeck in Dorsetshire, and Glasgow are centres of clay-pipe manufacturing. There are two main processes employed in the making of clays—namely, *pressing* and *moulding*. Pressing is mostly done on the Continent, and is rapidly dying out as the results are very unsatisfactory. In moulding, the clay is first of all weathered and matured till on the addition of water it can be kneaded into a smooth, homogeneous mass, sufficiently tenacious to hold together readily. A mould of steel or brass is prepared which represents each half of the clay pipe cut longitudinally down the centre, a brass block occupying the place of the inside of the bowl. Clay is laid in this mould and pressed, the block being inserted, so that the result is an exact half of a clay pipe. If two or more such moulds be prepared—in actual manufacture each mould consists of a great number of half pipes—and laid together so that the edges of the clay bowls and the flat sides of the shanks, which are solid, are in apposition a complete pipe is formed, a wire being passed down the centre to make the bore. The press is then opened and the pipe removed. Another workman trims off the rough edges and pulls out the wire from the stem. The pipes are allowed to dry in the air for some time, and are then baked.

Firing. The pipes are stacked in a large firing oven, similar to the ovens in which earthenware is baked, and the heat gradually brought up to a red heat. After a period of firing, which varies according to the kind of clay, the fire is allowed to die out, and when cool the pipes are removed from the oven.

Shiny clays are treated, before baking, with a lead glaze, such as is employed in glazing pottery, but some clays receive a natural glaze from the mould which is retained even after firing.

The mouth end of the pipe is tipped with sealing-wax dissolved in methylated spirit. The moulds for pipes are of various patterns. In the list published by McDougall & Co., of Glasgow, over 400 different kinds are quoted and figured. Pipe-making machines are also employed, one of the best being that invented by Mr. Young, of the firm of Davidson & Co., of Glasgow.

Briar Pipes. Wooden pipes are made of various hard woods, the chief being briar or bruyère root. This wood is used on account of its incombustibility. Briar wood has no connection with rose briers, but is the root of *Erica arborea*, a species of heath, which is grown in France, Italy, and Corsica. Centres of the briar pipe industry are St. Claude, Jura (France), and Nuremberg. The pipes are finished and fitted in London, but much briar wood is now obtained in Scotland and made into pipes in England. The roots are shaped roughly into the form of pipes, and then simmered for twelve hours in a vat, which has the effect of imparting the much admired yellowish-brown tint. A good pipe needs to be free from flaws, and as only about 10 per cent. of the pipes made fulfil this condition, it is not difficult to understand why a good briar pipe is expensive. The flaws in second quality pipes are stopped up with a composition, but the difference is apparent after the pipes have been smoked a few times. The rough blocks are converted into pipes by a process of turning and grinding.

The other woods used for pipes are the Mahaleh cherry, which grows near Vienna, the mock-orange of Hungary, the jessamine sticks of Turkey, Australian myal wood, and ebony.

The Hookah of the East. Mention may here be made of the hookah or water pipe preferred in Oriental countries. This smoking apparatus consists of three parts: (1) The head or bowl; (2) the water bottle or base; and (3) the flexible tube and mouthpiece. The smoke passes through water, and hence is quite cool by the time it reaches the mouth.

Meerschaum Pipes. Meerschaum is a hydrated magnesium silicate which, from its appearance and lightness, has become known as "sea-froth." It is found in Asia Minor (the plains of Eski-shehr), at Negroponte and Samos (Greece), and in California and Spain. The meerschaum is made into pipes at Vienna and Ruhla in Thuringia, whither it is imported in the rough state. The irregular blocks of meerschaum are scraped to free them from their red covering, dried, and polished with wax. The pipe-bowls are also soaked in melted stearine, wax, or spermaceti after they have been turned and carved. The reputation of meerschaum has declined of late years, but some smokers are still proud of the colour they have obtained on a well-smoked meerschaum pipe.

THE RAILWAY STAFF

The Three Divisions of the Railway Staff. Conditions of Entrance. Pension, Provident, and Insurance Societies' Funds

By H. G. ARCHER

THE number of persons employed by railway companies in the United Kingdom is known accurately for certain years only. The last official return is still that for 1901:

Stationmasters	8,103	Passenger guards	7,291
Brakesmen and goods guards	15,708	Signalmen and Pointsmen	28,496
Permanent way men	66,621	Labourers	53,282
Gatekeepers	3,507	Ticket collectors and examiners	3,642
Engine drivers	25,556	Mechanics	81,440
Porters	55,276	Other classes	185,216
Shunters	10,841		
Firemen	24,083		
Inspectors	6,772	Total	575,834

The Three Divisions of the Railway Staff. The staff of a railway is divided as follows:

1. Salaried officers and clerks, commonly called the clerical staff.

2. The "weekly wages" staff, sometimes referred to as the "uniformed" staff, although many of its members do not wear uniform.

3. The "daily wages" staff.

A hard-and-fast line is drawn between classes 1 and 2. If a man elect to join the "weekly wages" staff, he is seldom allowed to transfer his services to the clerical staff, although, of course, he may be promoted from the latter to the former. At certain points the two classes overlap. For instance, a first-class stationmaster is a salaried official, whereas a second-class stationmaster is in receipt of a weekly wage. If a man joins the clerical staff he is not supposed to exchange into the "weekly wages" staff; he may do so, but such exchanges are not encouraged by the authorities. The two classes do not mix.

Persons are admitted to classes 1 and 2 as juniors from 14 to 16 years of age, and as adults from 18 to 30, and in certain cases to 35 years of age.

The Clerical Staff. The clerical staff is open to all. No form of nomination is required; but some companies make it a rule to reserve a quota of vacancies for sons and near relatives of past and present officials. Again, where the latter practice does not exist, it is only natural that a claim of the above kind should carry influence.

Junior candidates for railway clerkships must produce good references, together with a medical certificate of sound health, and undergo an entrance examination (which is often competitive) in writing, spelling, geography of lines of communication, arithmetic, bookkeeping, shorthand, etc. As to what department a successful candidate is posted depends upon the nature of the vacancies at the time. A small station is the best place for a lad-clerk, as there he will learn parcels, goods, and passenger service work, together with telegraphy, etc.; in short, pick up a bit of knowledge about everything. The young railway clerk may, however, find himself posted to any one of the departmental offices—namely, that of the general manager, goods manager, superintendent of the line, or secretary, etc.

Examinations. When 18 or 19 years of age, he is called upon to pass the senior clerks' examination, and also a stiff medical examination by the company's doctor, the latter in order to qualify for admittance to the company's superannuation fund, membership of which is obligatory upon every salaried servant.

Adult candidates for railway clerkships have to pass the senior clerks' examination, and also the above medical examination, unless they be above a certain age—the usual limit being 28—in which case they are disqualified from enjoying the benefits of the superannuation fund.

"Weekly Wages" Staff. Lads are appointed to the "weekly wages" staff, provided that they have good characters and sound health, as vacancies occur. No formal educational examination is demanded of them. As a rule, a divisional inspector examines the lads in order to see that they are fairly intelligent and able to read and write. The majority of youths join the traffic department as lad porters, telegraph boys, van boys, and other similar appointments, while those who enter the locomotive department begin as bar boys or cleaners. On arriving at the age of 18 every member of the "weekly wages" staff has to undergo a searching medical examination, together with a test for colour-blindness, which is a fatal defect in a railway servant. Upon a successful issue depends his continuance in the company's service and admittance to the provident society, membership of which is compulsory. A large number of railway servants, however, join the "weekly wages" staff as adults, between the ages of 18 and 30, and they, too, have to possess a fair education, sound health, and freedom from colour-blindness.

Mechanics. In the Board of Trade return for railway employees "mechanics" constitute the largest class separately enumerated. The reason of there being so many mechanics employed is that most British railway companies build and repair their own locomotives and rolling stock, while a number also manufacture their own signalling apparatus, and one, at least—the London and North-Western—rolls its own rails, and undertakes nearly all the steel and iron work for its bridges, warehouses, etc. Therefore, our railway companies are manufacturers in a large way of business. A large proportion of the mechanics employed in the erecting shops are paid pro ratâ a daily wage.

The "daily wages" staff also comprises a number of "supernumeraries." For example, at Christmas time, additional hands have to be

engaged as passenger porters. Further, railway companies give limited employment to females. Till quite recently, female employees were confined to such posts as laundry-maids, ladies' cloak-room attendants, and barmaids in refreshment rooms. However, female clerks are now employed by the principal railway companies in the chief goods offices, and the employment of women in this branch will be augmented in the future. The Great Western Railway employs female attendants on a few of its long-distance corridor expresses. The duties of these "train maids" are the care of the toilet-rooms, the charge of children while their parents or guardians are at meals in the restaurant cars, and the chaperonage of ladies travelling without an escort. The Irish railways have some female booking clerks. It may be noted that the Continental railways go further than the British where female labour is concerned, employing women as gatekeepers at level crossings, and placing them in charge of signal cabins on main lines even. On its present comparatively small scale in the goods and traffic departments, female labour is mainly recruited by selection from among the daughters of the companies' "weekly wages" staffs.

Premium Apprentices. Most companies take "gentlemen," "cadet," or "superior apprentices" into their locomotive and engineering departments, and one or two also admit a few such premium apprentices to the clerical staff. The age at which "superior apprentices" are accepted is generally about 17 years. There is no formal examination save for sound health and eyesight, but candidates are expected to have what is known as "a good public school education." The premium payable varies with the different companies from £50 to £100, and is partly returned in wages after a probationary period has been served, the remainder of the money being devoted to the mechanics' institutes, libraries, schools, etc., organised by the companies for the benefit of their employees. Premium apprentices go through the mill in the locomotive works, carriage shops, running sheds, drawing offices, etc., just like the sons of working men and clerks who are apprenticed to a railway company without paying any premium. As a rule, no definite promise of future employment when the apprentice shall have completed his training is made. There are so few higher posts in the railway service that the companies are flooded with fully-trained gentlemen apprentices, who do not care to accept all that their employers have usually to offer them—namely, subordinate posts worth £2 per week. Consequently, the majority have to leave home railway employment and try to obtain work on Colonial railways, or in various engineering industries. The fact that a young engineer has passed with credit through the Swindon or Crewe railway works is a good recommendation, although it is not a guarantee to his finding lucrative employment in civil life.

Railway Rules. Every servant of a railway company on his appointment is given a copy of the "Rules and Regulations," which have been agreed to generally by the companies that are parties to the railway clearing system. The manual contains a compendium of the rules laid down for signalling, control and working of stations, working of trains and permanent way and works. "Every servant will be held responsible for a knowledge of, and compliance with, the whole of its contents."

Varieties of Occupation. The railway service embraces several hundreds of distinct occupations and grades of particular occupations. The following table sets forth the principal callings of railway servants as distinct from the salaried staff. The department under which each occupation falls is indicated in brackets.

Artisans (engineer's)
Ballast packers (engineer's)
Bar boys (loco.)
Boiler smiths (loco.)
Boiler washers (loco.)
Book carriers (goods)
Brakesmen (goods)
Callers-off (goods)
Canvassers (goods)
Canvassers, passenger (traffic)
Capstanmen (goods)
Carriage cleaners (carriage and waggon)
Carriage examiners (carriage and waggon)
Checkers (goods)
Clerks, booking (traffic)
Clerks, goods (goods)
Clerks, parcels (traffic)
Clerks, lost property (traffic)
Clerks, telegraph (engineer's)
Clerks, female (goods)
Conductors (traffic)
Cooks, dining-car (hotels and refreshments)
Detective inspectors (general manager's)
Detective sergeants (general manager's)
Dining-car attendants (hotels and refreshment)
Electricians (electrical engineer's)
Engine-drivers (loco.)
Engine-coalers (loco.)
Engine-cleaners (loco.)
Firemen (loco.)
Fire-droppers (loco.)
Fire-lighters (loco.)
Fitters (loco.)
Foremen, platform (traffic)
Foremen, parcels (traffic)
Foremen, permanent way (engineer's)
Foremen, shed (loco.)
Foremen, shunter (traffic)
Gangers (engineer's)
Gatekeepers (traffic)
Goods agents
Guards, passenger (traffic)
Guards, goods (traffic)
Guards, relief (traffic)
Guards, porter (traffic)
Guards, pilot (traffic)
Greasers (carriage and waggon)
Horsekeepers (horse)
Horse stablers (horse)
Inspectors, district (traffic)
Inspectors, district engineer's)
Inspectors, platform (traffic)
Inspectors, yard (goods)
Kitchen porters, dining-car (hotels and refreshment)
Labourers, miscellaneous
Lampmen (traffic)
Letter sorters (traffic)
Loaders (goods)
Number takers (goods)
Omnibus drivers (horse)
Platelayers (engineer's)
Porters, platform (traffic)
Porters, luggage (traffic)
Porters, goods, indoors (goods)
Porters (parcels post traffic)
Porters, signal (traffic-signal engineer)
Point cleaners (engineer's)
Policemen (traffic)
Rail motor-car drivers (loco.)
Rail motor-car firemen (loco.)
Rail motor-car conductors (traffic)
Road motor-car drivers (loco. or special automobile dept.)
Road motor-car conductors (traffic)
Sand driers (loco.)
Searchers (goods)
Shunters, passenger (traffic)
Shunters, goods (traffic)
Signalmen (traffic-signal engineer)
Signal fitters (traffic-signal engineer)
Signal linemen (traffic-signal engineer)
Sleeping-car attendants (traffic)
Stationmasters (traffic)
Smiths, miscellaneous (engineer's, works manager's, chief mechanical engineer's)
Surfacemen (engineer's)
Telegraphists (traffic)
Telegraph messengers, juniors (traffic)
Telegraph linesmen (electrical engineer or signal engineer)
Ticket collectors (traffic)
Ticket inspectors (traffic)
Truck markers (goods)
Tube cleaners (loco.)
Van boys (traffic)
Van drivers (traffic)
Van mechanics (carriage and waggon)
Van washers (horse)
Waggon examiners (carriage and waggon)
Waiting-room attendants (traffic)
Watchmen (traffic)
Wheel tappers (loco. carriage and waggon)
Yardmen (goods)

Some particulars as to wages are included in the following articles of the series, which deal with the work of the different departments.

The companies also provide the uniforms for all members of the uniformed staff, and also certain articles of the working clothes worn by other servants. For instance, enginemen are supplied with pilot-coats and labourers with greatcoats. Then,

lodging allowances are given and travelling expenses defrayed when men are away from home.

Advantages and Drawbacks of the Service. The advantages and disadvantages of the railway service may be enumerated.

First is permanency of employment and security of pay. Once on the regular staff a man may rely upon continuing in the company's service till incapacitated by age, provided that his habits are steady and diligent. The railway service is on a par with the Post Office and other Government spheres of employment in that its employees have nothing to fear from fluctuation of trade. The only exception is the case of the mechanics employed at railway works, who are liable to be placed on short time, but not discharged in time of slackness.

Secondly, there are the liberal superannuation, pension, provident funds, etc., backed up by well-organised benevolent societies and saving banks.

Thirdly, the man has a fair field and no favour in respect to promotion. Sir George Findlay did not exaggerate when he wrote: "The humblest railway servant, if he does not, like one of Napoleon's corporals, carry a marshal's baton in his knapsack, may at least contemplate a field of possible promotion of almost as wide a scope." It would surprise the public to hear of the humble beginnings of many of the foremost railway men of the day.

First among the disadvantages are the long hours, and secondly, where the salaried staff are concerned, the emolument cannot be described as princely. The higher posts carry with them good incomes, but the number of such posts is proportionately very small, working out to about only one-tenth per cent. of the total number of all grades employed. Thirdly, hard and unremitting application to work is demanded of all railway men. There is a fourth disadvantage, which concerns only the operating staff—that is, enginemen, shunters, guards, etc., whose duties must be placed in the category of dangerous employments.

Superannuation. Superannuation fund associations are for the benefit only of the salaried officers, and membership is obligatory as a condition of service for all who join under 28 years of age. Their object is to provide each contributing member with a superannuation allowance on his retirement from the service between 60 and 65 years of age, or at any earlier period should his health permanently fail, provided that he has been at the time of his retirement a paying member for ten years, while there is also a payment to a member's next-of-kin in the event of his death before superannuation.

Each of the larger companies has its own superannuation fund, managed by its own officers, while the Railway Clearing House has—or, rather, had—a Superannuation Fund Corporation for all less important companies who chose to join it. In 1905, unfortunately, on a valuation the latter fund was found to be not what is called "actuarially sound," and the scale of benefits had to undergo drastic revision. The Great Central Company, however, withdrew and founded one of their own. They did it on terms amicably arranged and some of the other companies affected are now seeking powers to follow their example.

The members' contributions amount, as a rule, to 2½ per cent. per annum of their salaries, being deducted monthly from their pay, and the company contributes in equal proportion. If a member elect to retire from the service of a company before superannuation, or if his services be dispensed with by the company from any cause other than fraud or dishonesty, he receives back the whole of his own contributions. If he be dismissed for fraud or dishonesty, he is liable to forfeit the whole of his contributions. If he die before superannuation, his representatives receive the equivalent of half a year's average salary, calculated over the whole term of his contributions, or the sum of his own contributions and those of the company in his behalf, whichever be the greater.

Provident Societies. The "wages" staff, both weekly and daily, have the benefits of insurance, provident, and pension societies. The object of the insurance society is to provide an allowance for the first two weeks of disablement arising from accident incurred while in the discharge of duty, and a supplemental allowance to that provided by the Workmen's Compensation Act, 1897, in cases of disablement extending beyond two weeks, and an allowance in cases of death or permanent disablement arising from accident in the discharge of duty, in those cases in which the company are not liable under the above Act, or are only liable up to a sum of £10; also an allowance in cases of death arising from other causes than accident on duty. Membership of the insurance society is voluntary, the men contributing from 1d. to 3d. per week, according to class.

The provident and pension societies are usually merged together, and membership of both is obligatory.

The provident society insures a weekly allowance in cases of temporary disablement for work arising from other causes than accident on duty; a retiring gratuity for old or disabled members in certain cases, with the same restriction as before; a death allowance to the representatives of deceased members, provided that death was not incurred through an accident on duty; and an allowance towards the funeral expenses on the death of a member's wife.

The pension fund awards pensions to old or disabled members aged between sixty and sixty-five, subject to their having been members for a period of twenty years; while when he has arrived at sixty-five any member can claim his pension irrespective of the state of his health.

The weekly premiums to the joint societies begin at 2d. for third-class members under 18 years of age, or receiving less than 12s. per week in wages, and rise to 1s. 2d. in the case of members who join the first-class from forty to forty-four years of age.

Some companies have distinct benefit societies for the locomotive staff.

TELEGRAPHY

The Training of a Telegraphist. The Morse Code. The Transmitting and Recording Instruments and their Manipulation

By D. H. KENNEDY

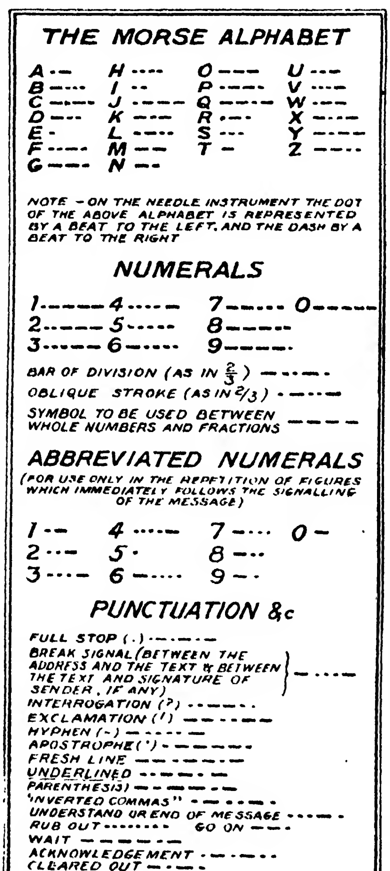
A PRACTICAL telegraphist is a person of either sex who has been trained in the art of signalling messages by electric telegraph. The length and variety of this training vary enormously, for whereas a few days' practice is often sufficient to enable the village shopkeeper to signal messages on the "Wheatstone A B C" instrument, years of training are required for the making of the all-round expert who can deal with all classes of instruments and of work such as are found in every large telegraph station.

Although the art of signalling messages was known before the invention of the electric telegraph in 1837, the enormous development which followed that epoch-making event necessitated the provision of large numbers of signallers, and opened a new career to many thousands of both sexes. In passing, we may mention that there are numerous instances of telegraphists attaining to positions of world-wide fame, noteworthy examples being Edison, the great inventor, and Carnegie, the millionaire donor of libraries.

Entering the Service. The aspirant must first enter for one of the open Competitive Examinations for Telegraph Learners. Full information is given in the Civil Service course [page 2807], and we shall assume that his visit to the Civil Service Examiners has had a satisfactory result, and that he has also passed safely through the inspection of the medical officer.

Our learner now takes up duty in the Telegraph School at the G.P.O., where he will remain until he attains sufficient expertness to deal with public messages. He will receive no pay, will practise eight hours per day, and may require from 10 to 20 weeks to reach the required standard. In most cases the learner will, on entering the school, see for the first time a telegraph instrument, but many energetic youths while preparing for their Civil Service Examination obtain also tuition in practical telegraphy at outside schools, such as that conducted at Mortimer Street, London, by the Regent Street Polytechnic. The length of time without pay is reduced accordingly.

The learner's first duty is to make acquaintance with the Morse code [1] and the time code [2], and for this purpose he is provided with cards giving the necessary information.



1. MORSE CODE

It will be seen that the letters of the alphabet are formed by combinations of dots and dashes, varying in number from one to four, while the figures in each case have five. In determining the proportionate length of the various signals and spaces, the fundamental unit is the dot. A dash is equal in duration to three dots. The space between the elements of a letter is equal in length to one dot. The space separating the letters of a word is equal to three dots, while the space between words is equal to six dots.

The time code is used principally to indicate the time at which a telegram was handed in. Each figure on the clock has an assigned letter, so that A stands for 1 o'clock, C for 3 o'clock, AC for 1.15, CA for 3.5, and so on. For the four minutes which intervene between every two five-minute points, the letters r, s, w, and x are used, so that CAr means 3.6, and ACw means 1.18.

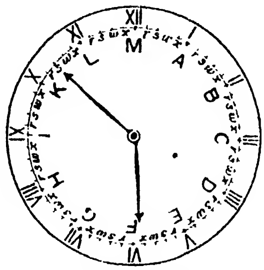
The Sounder Instrument. After studying this card the learner will take his place at a sounder set [5], consisting of a single-current key and a sounder. They are *short-circuited*—that is, arranged so that the key controls the sounder. There he will spend many hours practising the formation of the letters, and familiarising his ear with the sounder.

Much care and patience are necessary, for a bad style once formed cannot easily be improved. C is usually found to be the most difficult letter, while H and V also require special

attention. When he has made some progress the learner is allowed access to the inkwriter [3]. Here, in addition to hearing the sounds, he has a printed record of his efforts, and is able to see from the inked slip which letters require most attention with a view to improvement.

Before introducing any other instrument, it will be well to explain the adjustments of those already mentioned. Further details of the theory and construction of all the apparatus will be found in Telegraph Engineering. The telegraphist is concerned only with the working adjustments.

Adjusting the Key. The single-current key is made up of a brass lever which is mounted on an axle so that it oscillates between two contact points. At the front upper side of the lever there is a horn or ebonite knob which is shaped so as to be conveniently held by the thumb and first two fingers of the right hand. The brass bridge and contact points are fixed on a suitable wooden base. Normally the lever is held in connection with the rear contact point by the tension of the spiral spring.



2. TIME CODE

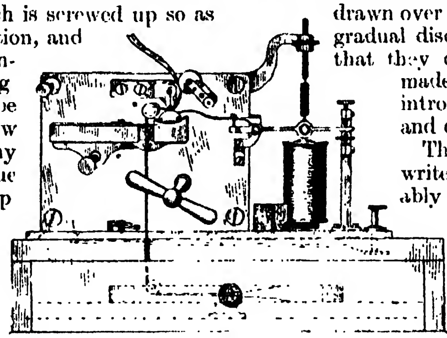
There are only two adjustments, one to determine the amplitude of the oscillation—commonly called the *play* of the lever—and the second to regulate the tension of the spiral spring. The former adjustment is made by means of the long screw which passes through the rear end of the brass lever. The screw has a cylindrical head containing small holes, so that it can be turned by a capstan spike, a little tool better known to the telegraphist as a *tommy*. It will be observed, however, that the end of the brass lever is split, and on one side of the lever there is a blue metal screw which is screwed up so as to tighten up the split portion, and prevent the adjustable contact screw from moving. The blue screw must first be opened; the contact screw can then be altered to any desired position, and the blue screw again tightened up. The usual amplitude is about $\frac{1}{32}$nd of an inch. The adjustment of the tension is made by raising or lowering the screw nearest the axle. For this purpose a screwdriver is necessary. Oil is never necessary, and it should be remembered that oil is an insulator, and that its presence on electrical apparatus usually leads to trouble.

Adjusting the Sounder. We turn now to the sounder. It is a little more complicated than the key. It consists of an electromagnet and a movable armature. The electromagnet—two bobbins of insulated wire, having iron cores connected at the lower end by a yoke piece of iron—is fixed to the brass base. The armature—a piece of blue annealed soft iron—is fixed by a screw to a bent lever of brass, the latter being provided with axle pins, and mounted in a brass bridge.

The bottom end of the armature lever is attached to a spiral spring. The other end of this spring is connected to the milled adjusting screw which can be seen in front of the cores, and normally the spring tends to hold the armature away from the electromagnet.

The upper end of the armature lever carries an adjustable stop which passes through it, and strikes against the angular bridge piece, when the armature is attracted. The uppermost adjusting screw forms the banking stop for the lever in its normal or upper position. Both of these adjusting stops, and the two axle screws are provided with check nuts. In adjusting a sounder it is first necessary to see that the lever is properly centred, and the axle screws neither too tight nor too loose. The lower adjusting stop should then be fixed so that the distance between the armature, when depressed, and the iron cores is about $\frac{1}{100}$th of an inch. It must be specially noted that if the armature be allowed to touch the cores it will not work properly. The upper stop should next be adjusted, and, finally, the tension of the spiral spring.

Adjusting the Inkwriter. The *inkwriter* [3], now but little used in comparison with the large number of sounders, was, in this country, the predecessor of that instrument. It is practically the same instrument, but with the armature lever lengthened to carry an ink-wheel rotating in an ink-well and arranged so that when the armature is attracted the wheel makes a record on a paper tape which is drawn over a roller by clockwork. The gradual discovery by expert operators, that they could interpret the sounds made by the armature, led to the introduction of the much simpler and cheaper sounder instrument.

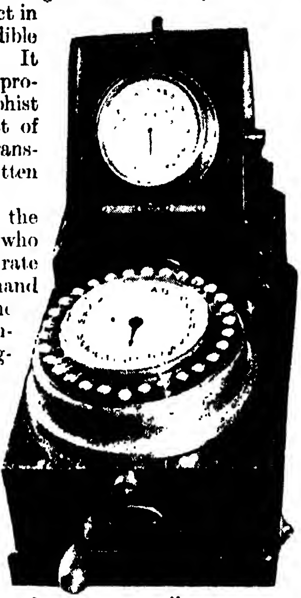


3. INKWRITER

The adjustment of the inkwriter, however, differs considerably in detail from that of the sounder. The end in view is the same in each case, but whereas with the sounder we begin from the fixed electromagnet and bring the other parts into proper relation, in the case of the inkwriter we have to begin with the ink-wheel, which must first be properly arranged for marking the paper when the armature is attracted. This is achieved by regulating the bottom banking stop of the armature lever. The upper stop limiting the play next receives attention, and finally the electromagnet is brought up to the proper distance from the armature by turning the adjusting screw near the base of the electromagnet. The tension of the antagonistic spring is adjusted in the same way as for the sounder.

Acquiring the Art. Generally speaking, the learner progresses in "sending" much more rapidly than in "receiving." A large amount of practice is needed to enable the ear to recognise rapidly each combination of signals, and for the brain and the hand to act in unison, and so to translate the audible signals into the written message. It will be observed that the mental process in which the receiving telegraphist is engaged is very similar to that of the shorthand reporter—each is transforming audible sounds into written symbols.

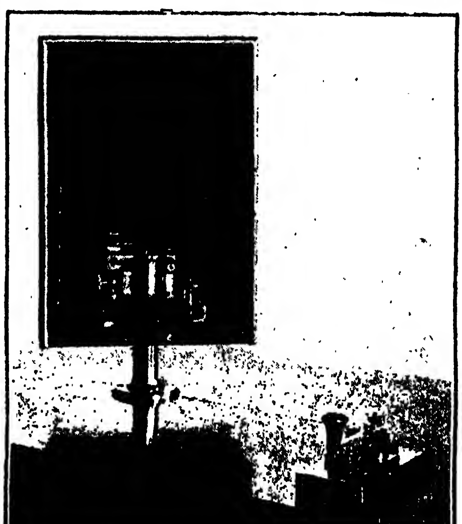
In each case the writer is at the mercy of some other individual, who sets the pace. Fortunately, the rate at which it is possible to send by hand on a telegraph key is about the same as that which can be maintained by an expert writer of longhand. The average rate maintained by good operators is about 25 words (125 letters) per minute. In occasional cases, the rate goes up above 30 words per minute, and may reach 35, and in extraordinary cases 40 words per minute. Learners usually find the greatest difficulty at the stage from 15 to 20 words per minute. Not only have they at this point to mend their pace in the matter of writing, but at this speed it is quite impossible to set down letter by letter as received, and difficulty is experienced in following up because the writing is necessarily some way in arrear of the signalling. All these difficulties, however, give way before application and perseverance, and it is marvellous how expert the telegraphist ultimately becomes.



4. THE "A B C" MACHINE

It is the special virtue of the sounder system that, as only the ear is employed in the reception of the signals, the eye and hands are left free for writing.

In order to lighten and diversify his labours, the learner is also introduced to the A B C needle and punching instruments at an early stage, and thenceforward a certain amount of practice is had on each daily, the sounder receiving the greater share.



5. THE SOUNDER INSTRUMENT

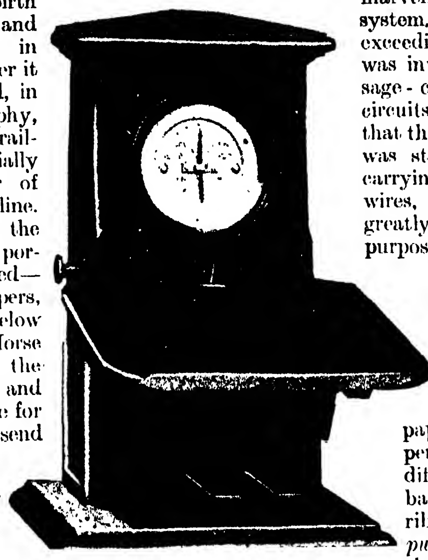
A B C System. But little need be said of the A B C [4]. This instrument was one of the many ingenious inventions of Sir Charles Wheatstone. The method of operating is simplicity itself. Each station consists of two instruments the communicator and the indicator. The latter stands upon the rear portion of the first-named. The communicator dial is surrounded by 30 keys. The rearmost key is marked + (sometimes called zero), then follow the letters A to Z, and the three punctuation marks (, ;.). On an inner circle the numerals appear twice, once from A to J, and again from P to Y. The indicator dial is marked in the same way. Normally, both pointers stand at the zero +. In order to send, the little crank in the front side of the communicator is turned at a uniform and fairly quick rate, and the letter keys are depressed one after another in the order required to make up any given word. The depression of each key automatically raises the key which had last been depressed, and the communicator pointer follows round. The end of each word is indicated by depressing the zero + key. If any figures occur, the telegraphist signals ";". The signals which succeed this are read from figures on the inner circle, and the finish of the group of figures is also indicated by the signal ";".

In recent years, however, the Post Office has found it necessary to abandon the use of the dial numerals, and to substitute a system of spelling out figures, prefacing the group of figures by the signal FI, and following by the signal FF. As the communicator needle travels from point to point, the indicator needles, both at the home and the distant station, move in exact synchronism, and so the message can be read and set down letter by letter by the distant operator. Usually the receiving clerk acknowledges the receipt of each word by sending one revolution. When from any cause the needles get out of synchronism, the communicator needle must be turned to the zero, and the indicator needle brought to the same point by oscillating the little adjusting key which can be seen just below the dial. No other adjustment can be made without the aid of a lineman or mechanic. Any person of average intelligence can send and receive messages on this instrument after an hour or two's practice. The rate of working is, however, always very slow. Ten words per minute is a good average

speed, 20 is quite exceptional. Its use is now practically restricted to village offices where messages are so infrequent as to render the retention of a skilled operator unremunerative.

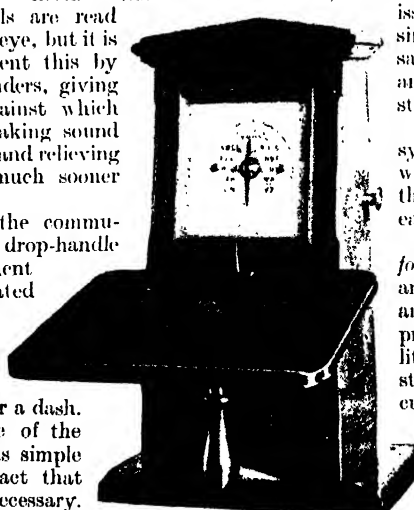
The Single Needle. The single needle [6], invented at the very birth of telegraphy, still survives, and possesses features which, in special circumstances, render it very valuable. In England, in addition to postal telegraphy, it is very largely used by railway companies. It is specially suitable where a number of stations are grouped on one line.

In the Post Office form, the *commutator*—as the sending portion of the instrument is called—consists of two keys or tappers, which project forward below the writing desk. The Morse code is used, modified to the extent of substituting right and left deflections of the needle for dashes and dots. Thus, to send the letter A, the left key is depressed, followed immediately by a depression of the right key. Simultaneously the needles at all stations will deflect first to the left stop, and then to the right. The spacing between letters and words is similar to sounder working; but as the time required for the "dash" element of a signal is the same as for the "dot," it is possible to send at a higher rate on the "needle" than on the "sounder." The signals are read from the needle by the eye, but it is now usual to supplement this by providing two tin sounders, giving out different notes against which the needle beats, so making sound reading quite possible, and relieving the eye, which tires much sooner than the ear.



6. SINGLE-NEEDLE TAPPER FORM

For railway service the commutator is usually of the drop-handle form [7]. The instrument can then be manipulated by one hand. The handle has three positions—centre or normal, to the right for a dot, and to the left for a dash. One special advantage of the single needle, due to its simple construction, is the fact that adjustment is rarely necessary. It is sometimes, though only rarely, affected by earth currents, which give the needle a bias to one side or the other. To meet such emergencies the dial is arranged so that it can be rotated through a large arc of a circle. It is accordingly turned round until the needle is properly centred between the stops, when working can be resumed. What may be called the workshop adjustments of the single needle will be dealt with in the Engineering section.



7. SINGLE-NEEDLE DROP-HANDLE FORM

High - speed Telegraphy. Having earned his spurs at the various manual systems, our learner will be allowed to approach the marvellous Wheatstone automatic system. When wires were few and exceedingly expensive, this system was invented to increase the message-carrying capacity of long circuits. Wheatstone early realised that the quickest manual signalling was still a long way below the carrying capacity of telegraph wires, and he sought a means of greatly increasing it. For this purpose he designed three instruments—the perforator, the automatic transmitter, and the Wheatstone receiver.

By means of the *perforator* [8], messages are transferred to a long thin paper ribbon. Of course, several perforators may be used by different operators preparing a batch of messages. The paper ribbons, commonly called *punched slips* [9], are passed through the automatic transmitter. Controlled by the slips, the transmitter sends signals exactly similar to the human operator, but with the accuracy proverbial of a machine, and at speeds up to 600 words per minute. At the distant station the messages are received on a blue ribbon, which issues from the receiver in a fashion similar to the printer, but with the same difference as to accuracy and speed as prevail at the sending station.

One sees at a glance that this system deals with messages on the wholesale principle, and enables the labours of several operators at each end to be applied to one wire.

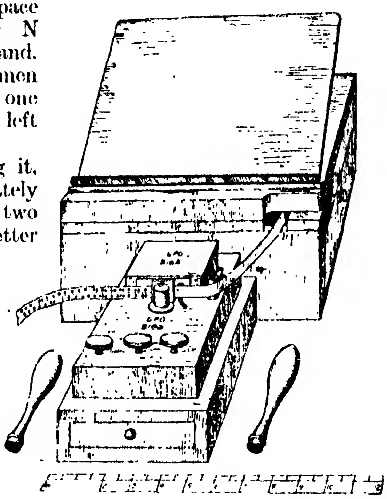
The Perforator. The *perforator* [8] is a little mechanical arrangement in which three keys are arranged so that when depressed by striking them with little rubber-shod iron punching-sticks, they operate levers and cutters which make certain holes in a white paper ribbon. The left key corresponds to dots, the centre key is the spacing key, and the right key makes the dashes.

In the operation of punching both hands are used, but the keys corresponding to the required dots, dashes, and spaces must be struck in proper order, and under no circumstances simultaneously. After punching the dots and dashes to form a letter, the centre key is depressed once, before commencing the next letter, and

after the last letter of a word, the space key is struck twice. Here, again, a good beginning is valuable. The badly-taught "puncher" does all the spacing with his right hand, and gets along very slowly in comparison with the man whose style has been formed on right lines.

The golden rule for punching is—space with the hand not required for the last stroke of each letter. Thus, after A (·—), space with the left hand; after N (—·) space with the right hand. The word shown on the specimen below [9] is a favourite one for practising right and left spacing,

Punching. In punching it, the hands come down alternately throughout, except where the two dots come together in the letter "d." Very good punchers carry the alternating use of both hands a stage further by using them on one key for the letters "H" and "O." The average rate which a good "puncher" can maintain is about 25 words per minute. The work is not unpleasant, and good operators usually consider it a pleasant change from their other duties. At the receiving end the slip comes from the receiver marked in the dash-and-dot style, which our learner has already met in the inkwriter. Daily practice in writing up slips will complete his round of school duties. The beginning of the slip to be transcribed is held in the left hand. The next foot or so is laid flat on the desk between the left hand and a "slip conductor," a sort of paperweight with a little upright pillar. The remainder of the slip usually extends to the floor. By the aid of the thumb and first finger of the left hand, the slip is pulled along as quickly as the eyes can read and the hand write. Twenty-five to 30 words per minute is the usual average rate.



8. PERFORATOR

Telegraph Instrument Room. What becomes of our learner when he has been judged ready for practical work will depend on the varying needs of the service. If the demand for telegraphists is great, he may be put on practical work at once; if not, he will probably be employed half-time on telegraphy practice, and half-time collecting—that is, carrying message forms from point to point in the instrument room.

As being the best case to enable us to take a bird's-eye view, we shall suppose that we follow him into a large provincial office. On the door of the instrument room is a notice warning all and sundry that the room is strictly private, and can be entered only by those having the permission of the secretary of the Post Office. Our fledgling telegraphist, remembering that he has already appeared before a magistrate and taken the oath of secrecy, presses forward with only a slight hesitation.

It is the middle of the morning, and immediately our ears are assailed by such a buzzing and clicking and humming that we at once think of a beehive. Across the room run long, narrow tables crowded with apparatus. Sitting at one side only, and all facing towards the centre of the room, we see rows and rows of men and women operators. Many youths are hurriedly carrying messages from point to point. Older men are dotted about the room, evidently each in charge of two or three tables, while near the middle of one long wall we see a sort of pulpit-desk, where sits the presiding bee, keeping watchful eyes on his many workers. In a telegraph office there are no drones.

The Test Box. Opposite the pulpit, on the other long wall, our eyes are entrapped by a projecting wall of dark, polished wood, about 20 ft. long and 7 ft. high, with a yard-wide frieze of brass screws along the eye line and a square check pattern, still in brass screws, further down. This is the *test box*, where all the lines from distant towns and from the sets of apparatus in the instrument room are concentrated, each on its proper brass screw, numbered and labelled.

Further along the same wall, made conspicuous by some hundreds of small pigeon-holes, each containing quantities of the familiar buff envelopes, is the delivery department, where young ladies are engaged in enveloping telegrams.

The man to whom a telegram rarely comes learns with surprise that in every large town there are firms whose daily average of telegrams runs into two, and sometimes three figures. For such folk the Post Office finds it economical to have supplies of envelopes with printed addresses, hence the many pigeon-holes. Here one also notices the ingenious little machines employed for numbering the messages.

REST, SLEEP, AND EXERCISE

The Proper Place of Athletics. Their Danger and Abuse. Exercise and Health. The Value of Rest to Young and Old. Holidays

Continued from page 4258

By Dr. A. T. SCHOFIELD

IT is the undoubted duty of every man to see that, as far as possible, his body is in a sound condition; and it is beginning to be recognised that not only is one's own health imperilled by neglect, but that a stunted physique may result in a degenerate offspring. Athletics rightly pursued, or their equivalent in exercise, become, therefore, a duty, binding in various measures on every man, woman, and child.

Exercise and Physique. In the manufacturing districts, the general physique had so degenerated a few years ago that the average stature of a man was but 5 ft. 1½ in., and his weight 106 lb.; whereas, in certain northern counties, in country districts, where bodily exercise was the rule, the men averaged 5 ft. 11 in., and weighed 199 lb. Possibly other circumstances favoured the difference. We may be sure, however, it did not end with the physique, but affected every part of the mortal being.

The development of athletics is of recent date. Thirty or forty years ago our daily papers took no notice of any sport but horse-racing, which can hardly be included under athletics; there were no crowds at boat-races, or at Lord's. Though it seems strange to say so, it is only an insignificant minority that actually engage in outdoor games; and, so far from their being overdone, the pressing need of the day is still more and more outdoor exercise for our urban population. The outcry that has arisen against athletics is rather against the betting, the gossiping, the reporting and general puffing, than the actual playing.

"Sportsmen" who Never Play. We distinctly say now, in 1906, as Dr. Warre so well pointed out at the Health Congress in 1886, that the value of outdoor games is *not* yet understood. The interest in sports is great, but the players are few, and the value of the exercise is only experienced by those who play—not by those who look on. At Lord's, out of 2,375 members, only 118 played on the ground in one year. In all London there are not probably 4,000 football players out of the population of 800,000 men. Probably not more than 1 per cent. of men between twenty and forty play games at all, and still fewer young women, whose physique is of such national importance to our race. Their chests usually show conspicuous want of development of lung power, solely from lack of physical exercise. It is true that among a few of the rich the love of outdoor exercise is carried to excess, but these are small exceptions. On the other hand, the real importance, and indeed necessity, of physical culture is beginning to be more realised. In children especially it is becoming better understood, and they are getting straighter backs and broader chests. Attitudes in school hours are studied, and games and drills are fostered; so that while the general physique of the lower classes is still very poor, that of the educated classes is greatly improved. Indeed, we may say that a boy at Harrow or Eton will average 3 in. taller and a stone heavier than a boy of the same age in a London County Council school.

The Average Man's Exercise. Generally speaking, the muscular system is in good condition when the person is about his right weight, and takes plenty of exercise. Games, however valuable, have certain drawbacks in over-developing various parts of the body, which regular gymnastic exercise is always seeking to correct.

A remarkable instance of this is seen in the connection of lateral curvature of the spine with the attitude of writing. A very large proportion of these deformities are caused during school life by the twisted position of the body that was in vogue, especially in girls' schools, in the days of the old sloping, angular handwriting. Ambidexterity in school life, and afterwards in some professions and trades, tends to correct this. When the muscles of the limbs that meet the eye are kept in condition, we know that those muscles that we cannot see, and on which our life depends, such as the muscles of the heart and internal organs, are also strong. Exercise is therefore essential for health, and the amount required by the average human being has been roughly stated as a mile walk a day for every stone weight. In this is included *all* exercise taken, such as walking upstairs or about a room.

Exercise, the Beautifier. What exercise can do in the way of beauty has been so graphically described by Sir F. Treves that it may be quoted with its wealth of adjectives entire: "Physical exercise is capable of healthfully transforming the meaningless, monotonous, purposeless curves of the physically uneducated, who are mainly muscular paupers, whose limbs are little better than burlesques, composed as they are of shapeless masses of flabby, doughy tissue, covered with dull, loose, lustreless skin, into the beautiful, classical, muscular outline of ancient statuary, clothed with the polished, fresh, elastic skin of perfect health." Who would not take exercise after this?

Exercise varies with age and sex. In childhood, games and musical drill are best; in boyhood and youth, games and field sports and general athletics, always avoiding what leads to extreme exhaustion or breathlessness,

such as prolonged runs at "hare and hounds." We must remember, too, that these sports bring only health to the actual players, not to the mere onlookers. Riding, walking, rowing, and cycling are pre-eminently of value to all classes.

For girls and young women games and sports are good, omitting the most violent, such as football. They conduce to growth, beauty and health.

Looking on is not Athletics. Men of mature years depend on walking, riding, cycling, for exercise, with sometimes cricket—but never football—and often, and increasingly, golf. Of the physical value of golf for maturity and old age there can be no doubt; but we question very much whether its solitary nature and its absorbing character does not often develop unpleasing traits and tend to selfishness.

All through mature life, ten minutes' brisk exercise after the daily morning bath is good. At least two hours a day should be spent where possible in really active exercise.

A revolution has been going on and is still progressing in the medical profession with regard to exercise. More and more the natural therapeutics of exercise and rest, of fresh air and quiet, are coming to the front.

Exercise on some such lines is indispensable to health, and is far too little thought of amongst town-dwellers and sedentary workers. These are constantly getting out of sorts for want of sufficient brisk exercise. It is well if, at least once in the day, one glows all over with active exertion, so that the whole stream of life is quickened in every organ—and this can never be achieved by a lazy stroll or by watching a cricket match.

A rigid examination into the physical condition of our youth and manhood has shown a great lack of physical culture, and has dissipated the hollow fallacy that looking on at sports is "athletics." Watching games has largely taken the place of playing them, and it certainly saves labour; or, rather, it substitutes unhealthy brain excitement for healthy bodily exercise. The whole tendency is in this direction, and both motor-cars and motor cycles contribute directly to it. Nevertheless, we must not be pessimists, for, in spite of all, the race is evolving. The civilised portion, as judged by the size of old armour and the like, is said roughly to be increasing at the rate of 1¼ inches in height in every 1,000 years.

The Finest Exercise for Girls. Our girls have certainly benefited in stature and general physique by the increased attention to games and sports; and, after all, the body of the woman is of more value than that of the man. For the mothers of the race a fine physique is imperative. This Nature clearly teaches, for we see that in times of famine more boys are born than girls (in the siege of Paris almost all the births were boys), while in times of plenty girls predominate.

Lawn tennis is undoubtedly one of the greatest boons ever bestowed upon our girl population. What this one game means to the future of the race in England—especially if we could get it more widely extended amongst our sedentary population of work-girls, dressmakers, governesses, clerks, etc.—we can never know. There is no sight that speaks more for the future welfare of England than a group of well-made English girls returning from a tennis lawn, their every movement instinct with healthy life and vigour. It is in vain, therefore, to set against this a sprained arm or ankle, or even a strained heart, as occasionally may occur among the weak.

But the mental value of athletics is also very well marked and quite undeniable. This is perhaps largely due to their increasing social character in the present day. Social athletics and crowded pleasure grounds and matches are no doubt largely due to the increase of town populations and the facilities of travel. Hence, clubs and recreation grounds and parks with gymnasia, and cricket grounds are multiplied everywhere.

The playing of games together in friendly competition tends to develop self-control, firmness, manliness, unselfishness and general goodfellowship, while it lessens self-consciousness. It also develops nerve force, on the one hand, while it lessens nerve strain and nervousness, which is really nerve weakness, on the other. Athletics, rightly used, develop patience, perseverance, self-restraint, friendship and humility, and increased will power.

Dangers of Athletics. Lest, however, we should be accused of holding a brief for one side only, let us now consider what evils are connected with athletic exercise. These, like the advantages, are twofold—physical, and mental or moral. The former may arise from athletics directly or indirectly. Amongst the direct physical dangers are sprains and strains of the muscles, accidents to life and limb, and internal injuries.

Sprains and strains are very common, and arise from overtaxing one's power, as in severe competition; from pure accident; from want of training, and from excessive violence.

Accidents to life and limb are still more serious; and we fear, in spite of what its apologists may say in its favour, a grave case can be made out against football, and particularly when played by men's clubs according to Rugby rules.

From September, 1889, to the third week in January, 1890, the direct deaths from football were 13; the fractures of legs, 15; of arms, 4; of collar-bones, 11; and severe internal injuries, 7. A great deal might be made out of the fact that the mortality from football in three months is nearly double that of hydrophobia in England for three years, there being eight deaths from this cause in that period.

Internal strain and injuries may arise from over-exertion, or very commonly from want of training. Clergymen who go Alpine climbing in the autumn, and young schoolgirls who take exhausting cycling journeys, often suffer in this way. The heart, lungs, or any other organ may thus be severely injured.

Indirect dangers arise mainly from improper clothing or carelessness. The safe clothing for all athletics is flannel; and yet we see fashion requiring some of our public schools to play in linen shirts under a blazing sun.

Athletic Training. Turning to the moral evils of athletics, we are bound to say they are all excrescences, and that from athletics themselves, rightly conducted, no moral evil can ensue. The betting and gambling that disgrace so many of our grounds are beginning to be tabooed at some of those more recently opened, notably Paddington Recreation Ground. But there is great mental risk whenever men give themselves up to physical exercise and nothing else. This is especially seen in the case of prizefighters. Exclusive training of any one part of a man is necessarily very injurious to the rest. It is here, perhaps, in the devotion of every spare hour to physical exercise that to many young men the chief danger lies. There are other claims, associations that cannot be safely ignored. The most healthful life gives each duty its place, and looks for a wise proportion in all things.

The present system of training is the most healthy and natural imaginable. All the former fads of raw beefsteak diet and other absurdities have disappeared, and given place to a most sensible and regular mode of life. Without going into regular training, it would be well if those whose lives are sedentary, and who contemplate active exercise at any time or during the holidays, would make it a rule always to give themselves a little preliminary canter. For instance, in football, if a man is going to play who has not played for some time, it is astonishing what a help it is to take a little preliminary practice at kicking, stooping, running, and tumbling about.

No hard exercise should be taken without preparation. Before going to Switzerland the body should be hardened by prolonged walks and climbs at home. For want of this the holiday often does more harm than good.

Cycling, Walking, and Rowing. Cycling is such an admirable and delightful exercise that for hygienic reasons it is a great pity it has been invaded by the nerve-destroying motor cycle and the motor-car. Walking, after all, perhaps next to riding, remains the best all-round exercise, while rowing has a very special value in the form of sculling, and is especially good for young women, in that it gives the arms and chest and back free play while the rest of the body is still, and also because it is one of the few exercises that are not one-sided. Nearly all games use one side of the body at the expense of the other, hence the value of a few minutes' regular gymnastics each day to restore the balance.

It is important at all ages in exercise to stop short of exhaustion, such as, in the case of children, long walks, such games as hare and hounds, and paper-chases; in the case of young men, severe competitions. In old age excess is common—in running to catch trains, in over-cycling, etc., but moderation in all things is the golden rule, both in exercise and rest. 173.

In health exercise and rest go hand in hand; but of the two, perhaps, we can do better without exercise than without rest, though no one can really be well and strong who does not enjoy both.

Rest During Illness. In almost every accident and disease rest is not only an instinct but a necessity, and it is well to remember this. In the case of accidents, for instance, there is the general rest required after shock, severe internal injuries, and great operations. For all these rest in bed is the great resource. It is not too much to say that in such cases rest alone is worth more than all the other remedies put together. General rest, which is always best secured in bed, is required in fevers, which so rapidly exhaust the strength, in wasting diseases, especially consumption, in fits and faints, in painful diseases, such as rheumatism, heart disease, and all nervous breakdowns. These all are greatly relieved by simple rest and by the more elaborate "rest-cures."

It is most important to understand the value of local rest. If a man has broken his leg, it is not enough to put him to bed; local rest must be secured for the two fragments of bone, otherwise they will never knit. Nearly all cases of ununited fracture arise from want of complete local rest. Putting it in position is indeed all the doctor does when he sets the bone, for the splints and bandages are used simply so to fix the parts as to give them absolute rest. The same is the case with dislocation. The joint must be kept at perfect rest for some time, till the torn ligaments have united.

Bad sprains of any part of the body are cured by local rest. When an ankle is twisted, not only is the foot kept off the ground, but it is fixed on a splint. In all bad wounds and bruises, the part heals better and more rapidly if it is kept at rest; otherwise it will heal more slowly, or not at all. With inflamed joints, rest is the one thing needful. Knee or hip joint cases, which get little relief by the patient being put to bed, at once begin to improve when the inflamed part is absolutely at rest in proper splints.

"Local" Rest. Local rest is also required in all diseases of the internal organs. If there is an ulcer in the stomach, the only way to heal it is to give the stomach complete rest from food. If there are ulcers in the bowels, as in typhoid fever, the only way to heal them is to keep the patient at perfect rest in bed, and the bowels at rest by giving nothing but liquid food. In brain fever, the head is kept at rest by the avoidance of light, by the maintenance of quiet, by the use of a soft pillow, and, if necessary, by sedative medicines. When the pleura or covering of the lungs is inflamed, as in pleurisy, the pain is great each time the ribs move up and down in breathing. This is relieved by tightly strapping the ribs, so that they cannot move; thus the pleura gets rest. When the heart is diseased, although it cannot be put to rest entirely, its work is made as light as possible by the patient

lying in bed with the head low, and by perfect stillness. So we might go on through all the varieties of diseases, and show that in each and all of them the first great desideratum is rest.

If rest in illness is so important, rest after illness is hardly less so. The way in which men, after a severe and weakening illness suppose themselves strong because they are no longer ill, and at once resume work, shows how little this point is understood. Hardly less important than the hospitals are the convalescent homes, of which there are now some hundreds in England.

Rest in Health and Convalescence. In this case, however, the rest is only comparative, for the patient is no longer in bed, but strolls about in the sun and open air. It is difficult to lay down a general law as to the period of convalescence; perhaps the best that can be said on the subject is that only after very slight illnesses should work or study be immediately resumed, and that after all exhausting illnesses and fevers, a period of further rest should be allowed of not less than one fortnight, preferably more. In still more serious cases, when life has been in danger, the period of convalescence should equal the period of illness.

It is usual in all schools, and in most trades, to allow more time for meals than is absolutely required, this extra time being given for rest. It may be half an hour or an hour; whatever it is, it is of the greatest service, and those trades and professions are certainly injurious to health where it is not allowed.

Children at school may be allowed to play at this time, since it is their minds, not their bodies, that have been worked at school; but in the case of girls growing rapidly, or of weak health, it is far better to insist on their lying down during the spare time. For young children, the mid-day hour in bed is of immense value, and should be kept up till schooldays begin The mother's time for rest is generally in the afternoon, after the children have returned to school and the house is tidied up. An hour or two then on the couch, or better still, if possible, in the quiet bed-room, with the window open, gives her the rest she needs after the hard work of the morning, to brace her up for the remaining duties of the day.

How Long should we Sleep? There are some trades requiring night shifts, and occupations, like nursing, which reverse the natural order, and require the work at night and the rest by day. Such callings are never healthy, and sooner or later leave their mark. We must have night nurses and night watchmen, but it is well to know that the less night work there is, the better for health. For a short time of service, not exceeding three weeks, night work does not matter. When rest is taken in the day by a man working out of doors, as in ploughing, harvesting, and the like, we constantly find it spent in sleep, for there can be no doubt that nothing produces sleep better than hard work in the open air. Sleep, indeed, is always more enjoyed by body workers than by brain workers. The best rest after hard brain work is, not sleep, but exercise for the body, which acts as a rest or restorative to the mind.

With regard to rest at night in sleep, there are several points to be noted. The importance of sufficient sleep to any man cannot be overrated; when he gets it, he should rise in the morning with the strength and vigour of a veritable resurrection, the cares as well as the fatigues of the past day being gone, and the body well braced for the toils of another day. But what is sufficient sleep? The old adage, six hours for a man, seven for a woman, and eight for a fool, is very wrong. Eight for a man, nine for a woman, and ten for a child, would have been nearer the mark. Sleep must be not only sufficient, but refreshing. To ensure this, the principal ablutions with working women should take place at night. A right understanding of the extreme importance of health, of periods of relaxation, alone enables a hard-working woman to preserve her looks and spirits to a green old age. The right time for the father's ablutions is immediately on his return home at night, or, at any rate, after his evening meal.

When and How to Sleep. In close connection with the daily rest is the nap after meals. Many who are advancing in years resist this tendency by every means in their power, believing that it is a bad habit. On the contrary, it is a good one, though not needed by the young. The perfect rest it brings greatly favours digestion, and for the old it is really needed.

With regard to the rest at night, the bed-room should, if possible, be large and airy, and above the ground floor. Separate beds are healthier than double ones. They should be firm and comfortable, but not soft, preferably made with spring mattresses. The bed-clothes should be light and porous, but sufficiently thick to keep the person quite warm all night. The pillow should be soft, and high or low, as wished. But all these points are unimportant for giving perfect refreshing sleep compared with the question of sufficient fresh air. Unfortunately there still exists, generally without the slightest reason to support it, a singular prejudice against night air. Except in a few cases, where houses are built in low-lying grounds or marshes, or near rivers or canals, and in some exceptional cases of storm, wind, and rain, the window may be safely left open at night, for the air is then healthier and purer than in the day; and this is of the first importance to health while sleeping.

The Bed-room Windows. Out of one hundred parts of oxygen—the breath of life—which we absorb in the twenty-four hours to support existence, only one-third is taken in during the day, and two-thirds at night. No bed room ought, therefore, to be used by people in health that has not a direct communication with the open air. The top of the window should always be open, in summer as widely as possible, and in winter in such a way that a direct draught does not blow down upon the sleeper. The air should be directed upwards towards the ceiling by one of the many simple contrivances elsewhere described. [See pages 4019–4020.]

For children to sleep in pure air is, if possible, more essential still, and they should be thoroughly accustomed to sleeping with the window well open. It is only the habit of sleeping in close, stuffy rooms that renders a person liable to catch cold from an open window. Children should sleep on firm (not hard) beds, singly, if possible, with light but sufficient clothing. They should not sleep on the back or on the face. If a child persistently sleeps on its back, a towel should be tied in a knot in the middle and then fastened round the child's waist with the knot exactly on the spine; the child will never sleep on its back then. Children, especially when at school, require at night more fresh air than others do.

The Week-end. The custom of having no school for children on Saturday, and no work after two or three o'clock for men, is gaining ground everywhere, to the great advantage of the health of the rising generation. To children the boon is inestimable, and parents should make the most of it. The first point to remember is that as the child has been cooped up indoors all the week, therefore "out of doors" must be the rule on Saturday. This is the way to get the most good out of the day's rest. Children in town should spend the day in the nearest park, the country or the fields. Let no parent consider Saturday as a lost day to the child. If the other days are of importance for the child's mental development, Saturday is the day for the development and health of the body.

And what about men? How are they to get the most good out of their hard-earned half-holiday? Not certainly by spending it in some close room, but by taking that amount of relaxation that gives the most rest. Some are so hard-worked that a couple of hours' doze is essential before they are fresh and vigorous enough for a turn out of doors at all. Those engaged in much bodily labour should not undertake long and wearisome excursions on this day, but should remember that the watchword for the day is rest, and that this is the first consideration. Care should be taken, therefore, not to make a toil of a pleasure. Somehow it is usually the mother who gets least rest. To her is generally committed the task of looking after the children the livelong day, which, to her, is no change of occupation, and, therefore, anything but rest.

When the Body Rests. In all things connected with man, work and rest alternate at varying intervals. The very cells of the body are believed to have their time of rest. The heart itself rests four-fifths of every second; the lungs are at rest between each of the seventeen breaths that are drawn every minute, the stomach during the intervals between the digestion of the various meals, the brain between the intervals of study, the body at various periods during the day, partially, and completely at night when in bed. Some have cycles of work and rest, some complete in a single second, others in a minute, others in an hour or in a day, and others again in a week or even longer periods. The institution of the Sabbath, or one day of rest in seven is as old as man himself, and though it had to do primarily with the Ten Commandments, it is not necessarily kept from religious reasons alone, but also on hygienic grounds.

What Holidays Should Be. Most people, especially in towns, look forward to an annual break in the daily routine, by going away for a week or a fortnight, or a longer time, either to some seaside resort or to some country place. This practice is a good one, though it is often attended with drawbacks. Perhaps the railway journey is so long as to weary everyone both in going and coming; or the place is so crowded that there is no proper sleeping accommodation, and thus health is injured. The principle, however, when there are means to carry it out properly, is a good one, and infinitely better than that terrible rush some hundred or more miles on a bank holiday that is supposed to be "rest." When pleasure becomes hard work, and means rising at 5 a.m., and returning at 11 p.m., there cannot be much rest in it, or much health derived from it.

The rest obtained by living away from one's work in the country is somewhat dearly bought by the daily run to business; and when this means an hour by rail, the price is too high, for eventually the health is undermined.

With women who are overworked it may be remembered that twenty-four hours' rest in bed will often ward off an illness, and save a doctor's bill; and if the overwork is chronic, the mere fact of not coming down till after breakfast may make all the difference.

In old age, too, after 65, there should be a great increase of rest, and life should be taken more leisurely. Of course, the wisest maxims cannot always be obeyed, and necessity knows no law. Nevertheless, it is well to impress the therapeutic value of rest on all sections of the community, for not the least hard worked are the determined votaries of pleasure.

One point may be made in conclusion, that only those who work *can* rest; those who never exert themselves do not know the true meaning of the word.

NOTE. On page 3719 the table in the paragraph headed "Water Vapour" should read:

1 cub. ft.	of air	at 30°	Fahr.	can contain	2	grains	of water

HISTORY OF ART continued from page 4302

ART IN MODERN TIMES

Gainsborough, Reynolds and Romney. Landseer and Wilkie. The Pre-Raphaelites. French Impressionism. Rodin, Meunier, and Stevens. The Art of To-day

By P. G. KONODY

Foreign Masters in England. At a time when Italy, Flanders, Spain, Germany, and France were witnessing the rise of great national schools of painting, England had to be content with deriving her art from foreign sources. Not that there was not an abundant supply of native talent from the days of Henry VIII. to the beginning of the eighteenth century, when Hogarth (A.D. 1697–1764) appeared on the threshold of a brilliant period of artistic activity, but the leaders around whom these painters gathered, and from whom they took their style, were of foreign blood and birth. Holbein was the first of the foreign masters who worked at the English Court and determined the manner of a whole generation of portraitists, especially of miniature painters, and Van Dyck, the Court painter of Charles I., may, with good reason, be called the father of English eighteenth century portraiture. His influence was enormous and lasting, though two other foreign masters stand between him and Gainsborough —the Germans, Sir Peter Lely and Sir Godfrey Kneller. Antonio Moro, Daniel Mytens, M. Mierevelt, Rigaud, La'gillière, and Canaletto all worked in England, and had their followers — capable artists like Dobson, Walker, and Samuel Scott, who have left us many works of merit without adding a single new page to the history of art.

90. THE SHRIMP GIRL, BY HOGARTH *Mansell*
(National Gallery, London)

William Hogarth. The first original word uttered by a British artist was spoken by Hogarth. Before him, painting in England had been altogether aristocratic and stately. His art was robust and healthy and democratic, almost plebeian. There is much of the English puritanical spirit in his scathing satires on the vices and weaknesses and immoralities of his contemporaries. He is, above all, a moralist —a preacher who uses his art as a weapon in the cause of virtue and righteousness. But these inartistic subjects are painted with consummate artistry. If the anecdotal painter generally fails, it is because a commentary is so often needed to make his work intelligible. Hogarth never supplies illustrations to other people's ideas, but tells his own stories with unmistakable directness in the language of paint. He conceives them as pictures, and, if one has eyes to see, one needs no explanation either of the story or of the moral to be drawn from such picture cycles as the "Mariage à la Mode," the "Rake's Progress," "The Idle Apprentice," and "The Industrious Apprentice." At the same time, Hogarth never allows his literary intention to interfere with the purely artistic consideration, never sacrifices beauty of arrangement and harmonious colour to the clearer telling of the story. The mastery of his brushwork can best be judged from a picture like the "Shrimp Girl" at the National Gallery, where the sheer beauty of paint can be enjoyed without the distraction of a moral sermon [90].

Gainsborough. The second half of the eighteenth century witnessed the rise of the great school of British portraiture, of which Gainsborough, Reynolds, and Raeburn are the brilliant luminaries. Of the two first-named, Gainsborough may be said to be the representative of the aristocratic and Reynolds of the democratic tradition. Gainsborough is, above all, the painter of the graceful elegance of contemporary society—his ladies are beautiful, distinguished, refined; his men slightly dandified; and his very technique, his deliciously cool colour schemes, and the negligent but sure elegance of his touch, reflect the character of his sitters.

Van Dyck is his real master, and his affinity with him appears clearly in such a picture as the famous "Blue Boy," which was painted in defiance of Sir Joshua's dictum that blue cannot be made the dominating colour of a successful scheme [91].

91. THE BLUE BOY, BY GAINSBOROUGH

Sir Joshua Reynolds. Reynolds, unlike Gainsborough, who had never left England or made a profound study of the old masters, had steeped himself in the art of the past and based his designs, his style, and his colour on the Italian masters. He was for ever proclaiming his allegiance to the "grand style," and his more ambitious compositions hold more than an echo of Tintoretto and Titian, of Correggio and Michelangelo, and even of Guercino and the later Bolognese. But not on these does his fame depend. With a curious perversity, which we find to an even greater degree in Romney, he set little store by his portraiture, which he considered mere drudgery, and pinned his faith to painting "histories" in the grand manner of the later Italian masters. With all their noble qualities of colour and design, they would to-day not suffice to secure Reynolds the eminent position he holds in the art of his country. This position is due to his powers as a portrait painter. And, as such, he is the antithesis of Gainsborough. He is as intellectual and searching as Gainsborough is elegant and superficial, and his sitters were not so much the society beauties of the day, but the aristocracy of intellect—men of letters, politicians, actors, philosophers, and scientists. In the place of the cool musical colour of Gainsborough applied in loose, thin touches, he prefers a hot, sumptuous scheme carried out with firmness and energy in a thick impasto. As likenesses, his portraits are far more convincing than those of his rival. He particularly excelled in portraying the innocent charm of childhood, and may, in fact, be said to be the first artist who painted children *as* children, and not as miniature men and women [92].

92. THE INFANT SAMUEL, BY REYNOLDS
(National Gallery, London)

George Romney. George Romney, whom fashion has placed beside these two masters, scarcely deserves to be held up as their compeer. His sense of beauty and technical skill were certainly second to none, but he fell into a mannered convention which, while searching for prettiness—and finding it—lost in character and sincerity. The vast number of portraits left by his brush might all have been painted from members of the same family. Raeburn (A.D. 1756-1823), the greatest master produced by Scotland, has, unlike Romney, met with comparative neglect, though he is now rapidly gaining the recognition which is his due as the father of the modern Scottish school, a daring colourist of rare strength and virility. As regards summary expressiveness and breadth of brushwork he is unapproached by any of his contemporaries. With broad sweeps of the brush he suggests all the subtleties of modelling and drawing. Hoppner, Opie and Cotes must be mentioned among the masters of these halcyon days of English portraiture, while Sir Thomas Lawrence connects these days with the period of academic sloth from which English painting was only liberated in the Forties by the Pre-Raphaelite revolt.

Landseer and Wilkie. Only landscape painting [see page 4299] made giant strides in this period, and Constable and Turner showed the way to the Barbizon men and the impressionists; while soapy and insipid portraiture, uninspired relating of anecdotes in paint, theatrical scenes of history, and such like held the public, and academic painting erred further and further in the path of bituminous gloom. Even where there was real talent, as in the case of the animal painter, Landseer, concessions had to be made to the public demand for humorous anecdote. David Wilkie must be mentioned among the great artists of that period, a real master in the handling of pigment which with

him retains an extraordinary richness of quality in spite of the minute precision of his detail. He was influenced chiefly by the Dutch small masters, and his skill in composing and arranging groups of figures and in massing the light and shade deserves the greatest admiration. William Blake, a mystic whose weird, fantastic imagination defied all laws of Nature, belongs to this time, but was an isolated appearance in the history of art.

93. LORENZO AND ISABELLA, BY SIR J. E. MILLAIS, BART., P.R.A.
(Walker Art Gallery, Liverpool

The Pre-Raphaelite Brotherhood. On the whole, English painting was at its lowest ebb in 1848, when a few ardent young spirits, led by D. G. Rossetti, J. E. Millais, and W. Holman Hunt, resolved to renounce the artificial academic formula of the day, and to follow the example of the Italian primitives, to approach Nature in a humble, naive spirit, and to do away with theatrical posing and bituminous shadows and ready-made recipes for making pictures. The famous picture, "Lux Mundi," is reproduced in colour opposite page 625, and another excellent example is the "Lorenzo and Isabella," by Millais [93]. Every detail, every grass blade or flower, stone or furrow, was made the object of careful study from Nature—so much so, that at times the larger truth was lost sight of in the passion for microscopic truths. As regards subject, romance and poetry were put in the place of the trivialities which then had the applause of the public.

The works of the Brotherhood aroused a storm of indignant abuse, but a powerful defender of their aims appeared in Ruskin, who threw himself heart and soul into the movement. The Brotherhood, as such, was short-lived, but the influence has been lasting, and is still to be felt in the art of to-day in spite of the growing supremacy of French ideas and techni

Art Under "The Empire." In France, which we have left at the threshold of the Revolution, more perhaps than in any other country, the political and social conditions are reflected by the currents of artistic evolution. The lascivious art of an immoral Court was followed by the chilling classicism of a Louis David, a true child of the Revolution, who, in his reconstructions of Ancient history, glorified the self-sacrificing patriotism of the Roman Republic, and then, as Court painter to Napoleon, became the originator of the Neo-Greek "Empire" style. With Napoleon's victorious campaigns arose an important school of battle painters, of which Gros and Gérard were the leading spirits. But neither art nor literature flourished during the first Empire, and only after the Restoration the intellectual life of France began to flow again in many contending currents. The first great battle was waged between Ingres, the head of the classicist school, who based his art on the imitation of the antique and perfect draughtsmanship, and Delacroix, the leader of the Romanticists, a truly inspired artist, with a glowing sense of colour and a powerful imagination. Then came the revolt of the Barbizon men, then the struggle of the freelight painters, and finally of the impressionists, whose aims have already been set forth in the article on "Landscape Art."

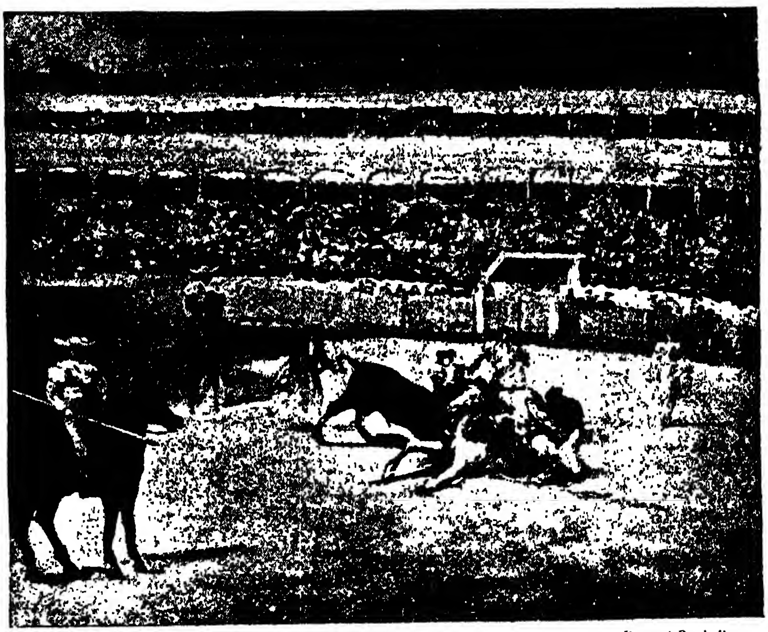
Impressionism in France. But impressionism has another aspect besides that of which Claude Monet is the chief exponent. As conceived by such masters as Manet and Degas, it substitutes beauty of character for beauty of form, and turns the attention of the artists to scenes of contemporary life. Classicism and academic art in general sail in lofty regions far removed from the bustle and strife of everyday life. The impressionists maintain, and frequently prove by their works, that the meanest subject is worthy of pictorial treatment if it is seen by the eye of an artist. As the word conveys, *impressionism* is concerned with the impression of a scene, which can only be recorded in its completeness by summary suppression of all the details which cannot be grasped at a rapid glance. The academic painter loses the freshness of an impression by using his *knowledge* of the form of things to penetrate the mysteries of distance or deep shadow. The impressionist loses outline and form where they are lost in Nature, and thus attains greater verisimilitude. The academic painter, in

treating the figure, loses the sense of movement through overcarefulness in drawing. The model is turned to stone, as it were, in the act of running, or wrestling, or dancing; while the impressionist, sometimes through accentuation, which is not, strictly speaking, correct, or through the effacing of contours, often succeeds in conveying an extraordinary suggestion of movement. Thus, in the ballet scenes by Degas, the dancers seem to be actually circling and pirouetting round the stage. As an example of Manet's work a reproduction is given of "A Bull Fight" [94].

Four Great Masters. Like the Pre-Raphaelites in England, the French impressionists had to fight a hard struggle before their views found acceptance, and there is no doubt that the extreme manifestations of impressionism frequently degenerate into absurdity and ugly caricature, and fully deserve the ridicule that has been heaped upon them. Yet it has remained one of the leading factors in modern art, not only in France but throughout Europe and America. Its influence has not always been beneficial, for the incompetent frequently sails under its flag to conceal lack of training and deficient draughtsmanship; but on the other hand, it has enriched the world with the masterpieces of a Monet, a Manet, a Degas, and a Whistler.

Nineteenth Century Art. In the rich artistic life of nineteenth century France, impressionism was only one, though the most important, phase. The academic school continued to flourish in the art of accomplished painters like Meissonier, Bouguereau, Delaroche, Fleury, and many others; the Orientalists, who found their subject-matter in the sumptuous picturesqueness of the East, are chiefly represented by Decamps, Fromentin, and Marilhat; decorative wall painting attracted masters like Puvis de Chavannes and, more recently, Besnard; Bastien-Lepage stands at the head of the freelight painters; while the most recent group, the intimists, include Le Sidaner, one of the most fascinating artists of the present time.

Rodin and Stevens. In sculpture, France took an uncontested lead during the nineteenth century. Rude (A.D. 1784-1855) was the first to return to the national tradition which the followers of Canova had forsaken for cold classicism. Barye (A.D. 1796-1875) stands unapproached as a sculptor of animals. Carpeaux, Frémiet, Dalou, and Falguière must all be reckoned among the masters of their art. They all went to Nature for their inspiration, instead of continuing the imitation of the antique that was so prevalent in the early part of the century. Rodin, finally, achieved the introduction of something like impressionism in sculpture. Of the masters of the past, Donatello is the one with whom he shows the greatest affinity, though Rodin's style is entirely original and personal. Through the accentuation and amplification of certain planes, he not only succeeds in suggesting movement, but a curious softening of the silhouettes, which makes his statues and groups appear as if they were bathed in atmosphere. Rodin, like all great reformers, met with bitter opposition, but to-day his pre-eminence in the field of sculpture is admitted by those who are most competent to judge. An example of his work is to be found on page 1675. In Belgium, Constantin Meunier has created, in stone and bronze, a mighty epos of Labour. His aims and achievements in sculpture are almost identical with Millet's in paint. The one great sculptor produced by England in the middle of last century was Alfred Stevens, whose Wellington Memorial in St. Paul's Cathedral is worthy to be placed beside the masterpieces of the sculptors of the Italian Renaissance. The last decades of the century witnessed an important advance in plastic art, and English sculptors of to-day have little to fear from comparison with their Continental contemporaries.



94. A BULL FIGHT, BY MANET

HISTORY OF ART *concluded; followed by* GLASS

Group 15 HISTORY 31 Continued from page 4322	MEDIÆVAL EUROPE Spain from Ferdinand II. to the Spanish Armada. The Netherlands' Struggle for Independence. Germany, Switzerland, and Hungary in the Middle Ages

By JUSTIN McCARTHY

SPAIN

We have already told how the Moorish dominion in Spain was brought to an end in the reign of Ferdinand II., and how Spain thus became, for the first time, one united sovereignty, and one nationality. Ferdinand married Isabella of Castile, which marriage helped effectually to bring about the union of the two kingdoms. Isabella was the sister of Henry IV. of Castile, and on his death most of the Castilian nobles refused to acknowledge the legitimacy of his daughter, Juana, and proclaimed Ferdinand and Isabella rulers of Castile. A civil war followed, in which Ferdinand was successful.

The reign of Ferdinand was remarkable for many events. He did much to restore peace and order to the country, and to diminish the power of the nobles. In his reign occurred the discovery of America by Christopher Columbus. There were many wars and civil struggles during his time, and throughout his reign he was ably assisted by the celebrated Cardinal Ximenes, who was, indeed, practically the ruler of Spain until the accession of Charles V.

The Inquisition. Ferdinand's reign has, however, left a dark memory behind it because of his establishment of the Inquisition and the cruel persecution of the Jews and of those Moorish inhabitants who had remained in Spain, led to remain there by conditions promised but never made good to them. Isabella died in 1504, and in the following year Ferdinand married a niece of Louis XII. of France. He ruled as regent for his daughter, Juana—who was insane—on the death of her husband, son of the King of the Netherlands, who died in 1506. Ferdinand died in 1516.

The destiny of Spain was for a time greatly influenced by the fact that Charles V., Emperor of Germany, succeeded to the Spanish crown. Charles inherited from his father, Philip, the Low Countries, Burgundy, and the Imperial throne; while from his mother, the daughter of Ferdinand and Isabella, he became heir to the rulership of Spain, Naples, and Spanish America. Charles, who was born in 1500, went to Spain in 1517 and was for a time joint ruler of the country with his mother, who afterwards became insane. In 1520 he was crowned Emperor of Germany, and soon after presided at the Diet of Worms, where Martin Luther's opinions were condemned, and in 1526 he married Isabella, sister of John III. of Portugal.

A great part of the European Continent soon became a scene for the display of the rivalry between Charles and Francis I. of France. Charles claimed the Duchy of Burgundy and that of Milan, while the King of France maintained that he was the sovereign of those regions.

The war at first was a success for Charles. He had the support of Henry VIII. of England, and also of the Constable Bourbon, one of the most powerful subjects of the French King. Charles drove the French out of Italy, and invaded Provence. Soon after, the King of France was defeated and taken prisoner, as already related in our French history. No sooner was this accomplished than the alliance which was called the Holy League was formed against Charles by Pope Clement VII, who had as his allies Henry VIII., King Francis, and the Venetians.

Imprisonment of the Pope. One event in the struggle which followed was that in 1527 an army of Italians, Spaniards, and Germans, led by Bourbon, entered and occupied Rome, and imprisoned the Pope. Bourbon himself was killed in the attack upon the city. Charles disclaimed all part in the movement against Rome, and repudiated any sympathy with the imprisonment of the Pope. A peace was finally made—the Peace of Cambrai—in 1529, by the operation of which Charles became practically the ruler of Italy. It was then that, for the first time, he went to see and study Italy for himself, and he was crowned at Bologna as Emperor of the Romans and King of Lombardy.

The struggles with France still went on, until in 1538 the new Pope, Paul III., the Sovereign of France, and Charles agreed to a truce for ten years. Among his other military and naval operations, Charles found time to head in person a maritime expedition against the celebrated corsair Barbarossa—the pirates of the North African ports were then an incessant trouble to southern Europe. He completely subdued Barbarossa, and captured Tunis. A later expedition of his against other Algerian pirates was less fortunate in its results, for the fleet which he conducted was brought to complete wreck by heavy storms.

The Triumph of the Protestants. The league which Charles had made with the Papal Government aroused the Protestants into armed resistance of his power, but the two campaigns which followed proved unfavourable to the arms of the Protestants, and a truce was agreed upon. But Charles's stern maintenance of the terms he had imposed, and the severity with which he treated his prisoners, among whom were the Elector of Saxony and the Landgrave of Hesse, turned many of his own supporters against him, all the more because it was now clear that his ambition was to become absolute ruler of Germany. Maurice of Saxony, a Protestant, who had up to this time supported Charles, now turned against him, and proved himself so well supported that Charles was compelled to recognise the Protestant claims, and treaties were made which ended in the Peace

of Augsburg in 1555. Charles was disappointed in some of his most cherished purposes by this and by other events, and he appears to have grown weary of rulership. He was breaking down in health, and suffering much pain, and in 1555 he resigned his position both as Emperor and as King, handing over the crown of Spain to his son Philip. He spent the remainder of his life in monastic seclusion at Yuste, where he died on September 21st, 1558.

Don John of Austria, who afterwards made himself famous by his wars against the Moors and against the Turks, was a natural son of Charles. In the great battle of Lepanto, October 7th, 1571, he conducted the combined fleets of Spain, Venice, Genoa, Malta, and Rome, defeated the whole arrayed naval power of the Turks near to Corinth, and put, for the time, a complete stop to the aggressive movements of Turkey.

Philip II. of Spain. Charles V. was succeeded by his son, Philip II. of Spain, a sovereign who made for himself a deep mark on the world's history. Philip was born at Valladolid in 1527. In 1543 he married Mary of Portugal, who died three years after, and in 1554 he became the husband of Mary Tudor, Queen of England. The abdication of his father consigned to him a vast dominion, including Spain, the two Sicilies, Milan, the Low Countries, Mexico, and Peru. The resources of the State had been much exhausted by previous wars, and Philip had but little opportunity of making good these losses, even if he had been a sincere and capable economist. The first war of his reign was made against the league formed by Henry II. of France and Pope Paul IV. Philip won two decided victories over the French, and Henry of France was compelled to agree to a peace. On the death of his wife, he married Isabella of France.

"Dictator to Europe." Philip was a man of narrow mind, although of much political capacity, and ambitious of extreme power. His resolute aim was to reign as a despot over his own dominions, and to make himself a dictator to Europe in general. He put himself at the head of the Catholic party, and worked deliberately for the suppression of all free institutions within his own states. He made full use of the machinery established by the Inquisition for the purpose of extinguishing all religious sects throughout his territories; but he overdid the work. In the Low Countries his tyrannical policy roused the whole people of the Netherlands to a revolt, which ended in the independence of that country. The great failure of Philip's life came from his extravagant attempt to conquer England. The destruction of the Spanish Armada is one of the memorable events of European history. His whole reign was, in fact, a series of failures which greatly increased his financial troubles at home, and his persecutions brought him enemies far and wide. His later years were a period of utter disappointment, of breakdown in health and hope. He died on September 13th, 1598. With the revolt of the Netherlands and the defeat of the Spanish Armada, the history of Spain as a great, and sometimes a domineering, power in Europe may be said to have come to an end.

THE NETHERLANDS

The struggle for independence and the final success of the Netherlands gives to the history of Europe one of the most interesting and important of its chapters. That portion of the northern Netherlands known as Holland was governed for some centuries by a line of counts under the over-rule of the German sovereigns. It was annexed to Austria, and finally came under the dominion of Philip II. of Spain.

The Revolt of the Netherlands. The people of the Netherlands were among the earliest and the most resolute to join the Reformation, and Philip made merciless use of all the forces of the Inquisition in the futile effort to coerce the indomitable Dutchmen into a renunciation of their new faith. It is said that about 100,000 human beings must have lost their lives during Philip's campaigns of persecution. The people of Holland were not, however, to be persecuted out of their religion or their nationality, and as Philip was evidently determined not to mitigate his policy, they saw that there was nothing left for them but to rise in rebellion. The leading men among the Dutch kept firmly in their minds the fact that they had, as their last resource, an ally against which even the power of Philip II. could not contend—the sea, which rose above the level of their shores, and had to be kept from washing over them by gigantic and elaborate dykes and other such artificial means of protection. In 1566 the Dutch nobles formed a confederation called "Les Gueux" ("The Beggars"), a name which had its origin from an epithet given in contempt to a body of 300 deputies from the Low Countries, headed by two nobles, who ventured to present the petition for the abolition of the Inquisition in Holland and Belgium. This name, thrown out in scorn, was taken up by the deputies and accepted defiantly as their title. The peaceful deputation soon changed into a warrior band and made the name of the "Beggars" to ring in renown throughout Europe.

William the Silent. One of the leading men of that era was William Prince of Orange, who succeeded to large estates in Holland, and showed even in his earliest years so much military and statesmanlike capacity that he was appointed by Charles V. Commander-in-Chief of the Netherlands when only twenty-two. William is known to all history as "William the Silent." It is, however, certain that among other great qualities he was an accomplished orator, who never failed to make use of his powers of speech when any great object was to be served.

On one memorable occasion, in 1560, William was put in possession of a State secret by Henry II. of France, at a time when he was a hostage in Henry's dominions. This secret, which was a project concocted by France and Spain for the destruction of all the Protestants of France and of the Netherlands, was confided to him while hunting in the forest of Vincennes by the King of France, who assumed that the Prince of Orange, like most other men of rank at that time, had no sympathy [illegible] the

Protestant cause. William of Orange was then a Catholic, though he became a Protestant soon after. Had William entered into any controversy on the subject, he knew that means would be taken to prevent him from spreading alarm as to the intended policy of extirpation.

He listened, therefore, in absolute silence, and was able to forewarn his countrymen and prepare measures of national defence. He began by opposing the persecutions started by Philip, and in 1567 resigned all his offices of state, and openly avowed himself a member of the Protestant Church. Philip of Spain sent the Duke of Alva to the Netherlands at the head of a large army, and with unlimited power to maintain the Government of Spain there. The Duke of Alva did his best to carry out the King of Spain's wishes by merciless bloodshed. William was proclaimed a traitor by Alva, and as the whole country was now rising in revolt, the proclaimed traitor was at once chosen by the Hollanders as their commander by sea and by land, and under his guidance the revolt of the Netherlands was successfully carried on. Until the rising of the Gueux, the Spaniards had held unchallenged mastery over the Netherlands, but from that time a revolt went on gaining in strength with every day.

Union of the Northern Provinces. The union of all the northern provinces was thoroughly established in 1579, and in five years more the whole united Netherlands had renounced for ever their allegiance to the power of Spain. Much was yet to be accomplished before the absolute independence of the new state could be forced upon the recognition of Spain. The Dutch were determined to fight on to the last, and it was one of their resolves that, should the worst come, they would destroy the dykes which kept out the sea. 173.

Long before the struggle had gone so far as to call for such a policy of self-destruction, the gallant Hollanders had suffered a heavy loss by the death of their illustrious leader, William the Silent. The King of Spain, through the Duke of Alva, proclaimed William of Orange a traitor, and set a price upon his head—the sum of 25,000 gold crowns, and as a result of this measure an assassin named Balthasar Gerards shot William with a pistol bought with money the Prince had given him in alms, and killed him at Delf, on July 10th, 1584. Nothing can give better evidence of the strength of the national cause and of the enthusiasm with which William had inspired his fellow countrymen than the fact that his death only seemed to nerve the Hollanders to fresh effort.

Much sympathy was felt in England for the Dutch in the struggle which they were carrying on, and in 1585 some 6,000 men were sent to help them. Spain had made many enemies for herself throughout Europe, and Queen Elizabeth of England was always ready to lend a helping hand to any opponents of Spanish policy, although the continual rivalry between the two great powers had not yet reached to that form of open war it was soon to assume. The Dutch knew well how to maintain their struggle, and how to avail themselves in the most effective manner of any help offered to them. It became evident that there was no possible means of reducing the Dutch once again to servitude under the King of Spain. The northern provinces of the Netherlands achieved their independence, and thus became a new self-ruling European state. Those provinces of the Netherlands which we now know as Belgium remained, for a time, under the dominion of Spain or of Austria.

GERMANY

The German populations were, about the tenth century, forming themselves into something like cohesive and powerful states, although many of them yet remained in a condition which showed uncertainty as to whether they were destined ultimately to form part of a people subject to a foreign power, or to lose their nationality by becoming absorbed into the dominions of some larger state. Austria, the name of which signifies "Eastern Kingdom," had undergone many invasions and occupations since the days when it was part of the Roman Empire. Charlemagne, in re-establishing the various states over which he had acquired dominion, made Austria a margraviate, ruled over by a margrave. Later on the margraviate was raised to a duchy, and still later to an archduchy.

Frederick II., who reigned over the Empire of Germany from 1212 to 1250, was one of the most remarkable sovereigns of the Middle Ages. With his son Conrad, who reigned for four years, ended the Hohenstaufen line, and he was succeeded by many princes who ruled—sometimes contemporaneously—during a period known as the Great Interregnum, which lasted till 1273, when Rudolf I. of the Austrian House of Hapsburg, came to the throne. For nearly two centuries from this time the history of the German Empire is but the record of a succession of rulers.

Maximilian I. succeeded his father, Frederick IV., in 1493, and his marriage with Mary, daughter of Charles the Bold of Burgundy, involved Maximilian in European politics. He made many improvements in the laws and the internal affairs of the Empire—originating the Imperial Chamber and the Aulic Council.

The Reformation. In his reign began the Reformation movement, to which he was opposed, and the success of Luther's preaching, but the establishment of the Protestant religion in Germany did not take place until the reign of his grandson, Charles V, grandson, also of Ferdinand and Isabella of Spain, who reigned from 1519 to 1556.

For a long time the Emperors of Germany retained also the title of Emperor of Rome, by which Charlemagne was crowned in 800, by Pope Leo III. Otho the Great, who was crowned by Pope John XII., in Rome, in 962, was the first who was called Sovereign of the Holy Roman Empire. The Empire, under its various denominations, was made up of all manner of European states enclosing within the one ruling system several different nationalities. Nor did these populations seem to be held together by any influence more successfully assimilating them than the strength of the German ruling power. For some time the Netherlands became part of the Empire of Austria by the marriage of the

Austrian Prince Maximilian with the daughter of Charles the Bold, and not long after Spain became a dominion attached to Austria by the marriage of Philip of Spain with the heiress of Aragon and Castile.

SWITZERLAND

Helvetia, or Switzerland, after the rule of the Roman Empire had ended, was ravaged by the Huns, and in 450 was invaded by the Burgundians and the Alemanni. In the fifth century it was ruled by the Franks of the Merovingian line, and somewhere about this period many of the famous monasteries were founded. Much of what is now Switzerland was, in the Middle Ages, part of the Holy Roman Empire, and was therefore, in the thirteenth century, under the rule of Rudolph of Hapsburg, the Sovereign of Austria.

The men of some of the Swiss cantons, Uri, Schwyz and Unterwalden, early in the fourteenth century formed a league and covenant against the rule of Austria—more, indeed, against the rule of the subordinates of the Emperor than against the Emperor himself—and other cantons quickly joined the *Eidgenossen* (the confederates), as they were called. In 1307 three of the leaders of the confederates met by the Lake of Lucerne, and swore to free their country from the tyranny of Austria, and in the following years many other cantons joined the confederation. In 1315 they put to rout the army of Leopold of Austria. By the middle of the century most of the cantons had joined the confederates, and the Austrians were defeated in 1386 at Sempach, in 1388 at Näfels, and in 1393 the Swiss drew up the famous Convention of Sempach.

In 1476 the Swiss encountered Charles the Bold on the French frontier. They defeated him at Grandson, and again at Morat, and in the following year, before the walls of Nancy, in which engagement Charles the Bold was slain.

The Story of William Tell. The story of the Swiss uprising is so much associated with the name of William Tell that we will mention the legend here in passing. The story tells how Gessler, the representative of Albert II. of Austria, tried to compel the Swiss to do homage to the hat of the prince set up on a pole in Altorf; how William Tell, refusing to offer this homage, was ordered to shoot an apple off the head of his son. Tell accomplished this feat without injuring his boy, but avenged himself by putting the village tyrant to death. Then broke out the movement which ended in securing the entire independence of Switzerland.

In the sixteenth century the Protestant Reformation, led by Zwingli, arose in Zurich, and quickly spread over many of the northern or German cantons of Switzerland. Some of them, however, remained Catholic, and in 1531 war broke out between the followers of the two faiths. Zwingli was killed, and the Zurichers were defeated at the Battle of Kappel. Four years later Geneva became a Republic with new civil and ecclesiastical laws, under Calvin, and after this Protestantism spread into the west of the country. During the Thirty Years War Zurich and Berne helped to maintain the neutrality of Switzerland, which was recognised as an independent state by the Treaty of Westphalia in 1648. This independence Switzerland has ever since maintained.

HUNGARY

Hungary was first formed into a kingdom by Stephen in 1000. The title of "Apostolic King" was conferred on him by Pope Sylvester II. for his work in the spread of Christianity, and the crown he then received was worn by all kings of Hungary since. After his death in 1038, unsuccessful efforts were made to re-establish paganism. Stephen founded many religious and civil institutions—the Ecclesiastical Organisation, the Municipal Councils, and the National Council—afterwards the Diet of the State.

In 1222, during the reign of Andrew II., the "Golden Bull," the Magna Charta of Hungary, was granted, and nine years later its privileges were much extended. Hungary was invaded by the Mongols in the reign of Béla IV., and German colonists were introduced by him, as the country had been much depopulated by the Mongol massacre. Andrew III., who died in 1301, was the last sovereign of the House of Arpád, and on his death the succession was contested. Seven years later, Charles Robert of Anjou became king, and reigned until 1342. He did much to improve the condition of his adopted country, and under his rule and that of his son, Louis the Great, Hungary took a high place among the nations.

Matthias of Hungary. When Ladislaus Posthumus died, in 1457, he was succeeded by Matthias, the son of the great Hunyady—the famous general whose life was one long crusade against the Turks. The reign of Matthias saw the greatest era in the history of Hungary. He went to war with Bohemia, and became king of it and of Moravia. He made war with Turkey, and regained the Southern Provinces which Turkey had held. In 1485, he made Vienna the capital of Hungary.

Matthias was also renowned for his statesmanship, his justice, and his encouragement of arts and letters. On his death the country was given over to internecine strife, and rapidly declined in prosperity. It was invaded by the Turks in the reign of Louis II., and Louis himself was killed. The crown was then contended for by John Zapolya and Ferdinand II. of Austria. As Ferdinand had the support of the Hungarian nobles, Zapolya had to renounce his claim, and Hungary thus came under the sway of the House of Hapsburg. Since that date the history of Hungary is connected with that of Austria. Under a succession of Austrian sovereigns there were many wars with Turkey, and much strife between the Catholic kings and their Protestant subjects. There were many risings, also, against Austrian rule, and these conditions lasted until 1825, when the National Diet, which was convoked by Francis I., opened a new era in the history of Hungary.

Continued.

THE NAVAL OFFICER

From Cadet to Admiral. Entrance Examination. Naval Colleges. Midshipman. The Ladder of Promotion. The Officer's Pay

By C. DUNCAN CROSS

We have shown how a seaman may rise in the Navy from a second-class boy to commissioned rank; we shall now proceed to explain how a boy more favoured with fortune's blessings rises from midshipman to Admiral of the Fleet. It will be observed that we deal in this section only with the executive branch of the Service, the Paymaster branch being dealt with in the Civil Service sections on page 3195.

Efficiency of the Naval Officer. To-day the cry of the Navy, as in every other profession, is for the life-trained officer, for there is so much to learn in our complicated boxes of machinery that to know even a part means a life study. For a man who is to lead men, also, the training in the habit of obedience and discipline cannot begin too early. In the case of other services, charges are sometimes levelled that the training methods are inefficient, and that the living is extravagant. This, however, cannot be said of the Navy, where the keynote of naval education is thoroughness, and where economy of living is the watchword. From the moment a boy joins the training college he is taught that strict attention to work is the only avenue to promotion, and his allowance of pocket-money would compare badly with that of a public school boy of his own age. After reaching the rank of lieutenant, a young man can live fairly comfortably on his pay.

It must be understood that at present the representatives of two systems of education are working side by side in the Navy. Under the old system boys entered for whatever branch of the Service they fancied—executive, Engineers, or Royal Marines. The result was a race of specialists—each man excellent in his own department, but knowing very little about the work of other branches of the Service. To remedy this state of things a new system has been introduced to produce a type of officer with a more comprehensive knowledge and wider sympathies. The age of entry has been lowered, so that to-day a boy must decide practically on leaving his preparatory school that he desires to enter the Navy.

The Preliminary Examination. The training begins at Osborne College. To be admitted, a boy must be of pure European descent, and the son of natural born British subjects, or of parents naturalised in the United Kingdom. An application for nomination should be addressed to the private secretary of the First Lord of the Admiralty, and should not be made before the boy is eleven years old. On receiving a nomination from the First Lord, the candidate is required to present himself before a committee, not for an examination of his book knowledge, but so that the committee may have an opportunity of judging from his conversation and manner what sort of a boy he is, and whether he is likely to make a good officer when he is grown up. The candidate is required to produce a certificate of birth or its equivalent, a certificate of good conduct from the master of the school or schools at which he has been educated for the two previous years, and proofs of good health and freedom from constitutional disease or hereditary taint of any kind. A severe medical inquiry has to be faced, and then the qualifying examination, which embraces the following subjects:

English: Dictation, simple composition and reproduction of the gist of a passage read twice by the examiner.

History and Geography: The whole outline, with special reference to the British Empire.

Mathematics: Arithmetic (simple), including decimals, fractions, mensuration of area and capacity, money, proportion, etc. Algebra, up to simple and simultaneous equations. Practical geometry (angles and constructon of angles, squares, parallelograms, and division of straight lines into equal parts). Theoretical geometry (definitions, the substance of theories contained in Euclid Book I, propositions 4—6, 8, 13—16, 18, 19, 26—30, 32—34, and very simple deductions from these).

French or German: Simple examination, with great stress on the *vivâ voce* part.

Latin: Easy passages for translation, English-Latin and Latin-English, and simple grammatical questions.

Specimen examination papers can be obtained.

Cost of Training. This examination successfully passed, the lads have to present themselves in uniform at Portsmouth Dockyard on the appointed day, and are taken across to Osborne by a Government launch. Here the foundation of the life-work is laid.

Beyond the cost of the kit, which consists of bed-linen and towels as well as clothes, the cost to the parent is at the rate of £75 per annum in three (advance) instalments of £25. Over and above this, to cover the miscellaneous expenses, such as washing, instruments, books, sports, and pocket-money, another £8 per term should be expended. In a few cases the Admiralty allow the sons of officers in the Army, Navy, or civil servants under the Admiralty to enter at a reduced payment of £25.

Osborne College. The Naval School at Osborne is organised on the lines of the best public schools, special attention being directed to fit the cadet for his career, not only as a skilful

seaman, but also as an officer and a gentleman. Examinations are held at the end of every term, and should a cadet fail to satisfy the Lords of the Admiralty his parents may be asked to withdraw him at any time. A declaration of willingness to do this has to be signed at the time of the boy's joining, together with a declaration of willingness that the boy shall enter that branch of the Service for which he may seem to be best fitted, whether engineering, marine or general executive. At Osborne, a splendid workshop has been fitted up, and the cadets spend quite half of their time in practical and theoretical work connected with engineering or in studies closely bearing upon it. There is a ship attached to Osborne in which the cadets go for cruises lasting six weeks for practical instruction in seamanship. Physical education also is well looked after.

Dartmouth College. After two years, the cadet passes on to Dartmouth College for another two years, to complete his preliminary studies. The course of this four years' training has included the study of mathematics, mechanics, heat and electricity, the theory and practice of engineering; English and French composition and literature, together with some German; history and geography, navigation, and the elements of seamanship; religious knowledge; physical education. The cadet at Osborne has already had a course lasting some six weeks, and, leaving Dartmouth, he goes to a training cruiser for more practical instruction in navigation, seamanship, and engineering than can be obtained ashore. Until he reaches the rank of sub-lieutenant his parents are required to make him an allowance of £50 a year.

Midshipman. At the end of two terms on the training cruiser he is drafted with a batch of youngsters of his own seniority to a sea-going ship as midshipman. This, however, does not mean that his education is complete. True, he is no longer under a civilian instructor but he devotes his whole time to learning his professional duties under one or other of the officers, about one-third of his days being spent in the engineering section. On completing three years' service as a midshipman, a serious examination has to be passed for acting sub-lieutenant in seamanship and practical engineering; he attends the next examination in navigation and general subjects, and he attends short courses of gunnery, torpedo work, and pilotage at the depôts, each of which is followed by an examination on the work studied in the course. Those who show aptitude and special ability are then allowed to go through a further and more comprehensive course, lasting six months, at Greenwich Naval College, which fits them for specialising in any particular branch.

The sub-lieutenants who do not qualify for the extra course are immediately sent to sea, and are joined by the Greenwich students at the completion of their course. Sub-lieutenants must serve at sea for at least one year before being promoted to lieutenant, and must obtain from their captain a certificate that they are efficient in the duties of officers of the watch.

Under the new scheme of education the lads who have all been trained under the same system are now apportioned to the branch for which they are most fitted, and they become specialists in engineering, in gunnery, torpedo, or navigation, being denoted by the letters E, G, T and N, while some go to the Marines, whom we shall call M. The rest become general service lieutenants, available specially for watch-keeping, discipline, and seamanship.

Lieutenant. On promotion to lieutenant, the dividing line comes. Officers for gunnery go to Portsmouth for a year; for torpedo-work, to the Vernon Torpedo School; for navigation to Greenwich; for engineering to Keyham, to increase their practical knowledge and to study dockyard work and repairs. Lieutenants (M) go to one of the Marine divisions to learn their special military duties.

Of these specialists a few of the best are allowed a further course of instruction to fit them for the higher grade of lieutenant, which, for the sake of clearness, will be called G 2, T 2. For these the higher course lasts for one year while for E 2 the course is two years. Of the general service lieutenants a few are selected for instructional purposes and undergo a short course to fit them for their work.

Branches of the Service. Now it has been explained how the lads trained together in the same system as far as the rank of lieutenant have been broken up into three main divisions—engineers, Marines, and what we shall call, for want of a better term, general executive officers, which divisions have been subdivided into specialists and non-specialists. It remains to be shown what these young men will do with their careers. Will the specialists continue as specialists to the end of their days, or do they foster the hope of one day commanding a fleet?—for it is still open to the engineer to revert to the main channel and go through the ordinary course of promotion.

In exceptional cases, it is possible for the lieutenant (E 2) to revert, but it is most unusual, and indeed, undesirable, for he is throwing away his special education and his chance of quicker promotion. He will, therefore, look to the engineer branch to provide his fortune, and he will rise in the ordinary course to commander (E 2), captain (E 2). And although he

PAY OF OFFICERS IN THE ROYAL MARINES

will go to sea from time to time to keep in touch with modern practical engineering, the Admiralty will be glad to make use of his services ashore and in the higher ranks of the dockyard advisers. The Marine lieutenant, in some cases, will revert to the general executive and be appointed commander in his proper turn; for he is to-day not only the musketry officer but he can also take his turn in watch-keeping and the general duties of the ship. On the other hand, he may qualify for commander (M) and then revert to captain in command of a ship. A third possibility, of which a few will avail themselves, is to continue discharging the duties of Marine commander, and look for promotion in the Marines to the higher rank of captain (M), major (M), and colonel to general.

The Ladder of Promotion. For the rest, the general service lieutenants, there is a long, weary wait for their next step. After five years' service in the rank the officer has to pass an examination in naval law, court-martial, naval history, strategy and tactics, besides the examination in the general professional subjects. In due course his turn for promotion comes and he is promoted to commander, probably in ten or twelve years. It must not be supposed that the time has been monotonously spent. He has been changing from ship to ship, has been in torpedo boats, destroyers, cruisers and battleships, and has served at home and abroad. He has attended qualifying and requalifying courses and has every year been learning something of the management of ships, of guns and of men. So that at about the age of thirty-five he is a man of wide knowledge and experience besides having passed about twenty severe examinations. Another four to six years as commander should see him promoted to captain, though still he has not completed his education, but must go to Greenwich to learn the higher teachings of strategy. In the end he is promoted at last to admiral after eleven to fifteen years in command of ships.

We have not yet touched upon two important branches of the Service—the medical and the clerical. They are, however, of purely technical interest, and are open only to men who have already received a special education. It suffices, therefore, to say that a proof of professional knowledge must be produced in the form of a degree, and that promotion is gained by seniority tempered by a certain amount of selection. Doctors enter as surgeons and rise through staff-surgeon to fleet-surgeon; and there are one or two good appointments for the fortunate both at home and abroad.

For chaplains there is little promotion in the ordinary sense, but their pay increases by length of service; and there are a few livings ashore belonging to the Admiralty which are given to men who have been naval chaplains as a reward for good service. The pay of a chaplain or naval instructor ranges between £219 and £401 10s. per annum.

CHEMICAL ANALYSIS

Apparatus used in Chemical Analysis. Qualitative and Quantitative Analysis. Examinations and Confirmatory Tests

Continued from page 4319

By CLAYTON BEADLE and HENRY P. STEVENS

THE word *analysis* is derived from the Greek ἀναλυω (analuō), to loosen; and, like so many general terms of this description, can be used in several different senses.

In a chemical sense we refer to the loosening or breaking down of a substance, or mixture of substances, into their ultimate constituents; just the reverse of what is understood by *synthesis*, which means the building up of a substance from simpler constituents. The meaning which we shall attach to the words Chemical Analysis in this article is somewhat narrower. We shall break down or resolve substances merely for the purpose of ascertaining of what they consist and in what proportions the constituents are present. Put shortly, the objects of a chemical analysis are (1) the identification of a substance, (2) the detection of the components in a mixture of substances, (3) the determination (estimation) of the amounts in which they are present.

Qualitative and Quantitative Work. Thus, supposing we are analysing a silver coin, we might be required to identify the metal of which the coin is made, in this case silver; secondly, to detect the presence of other substances, such as copper; and thirdly, to estimate the quantities of silver and copper alloyed together in the coin. The identification and detection of substances and mixtures are operations which naturally precede the estimations of the proportions in which they are present. We may, therefore, regard analysis as comprising two branches, *qualitative* and *quantitative*. We shall start with the qualitative analysis, in which we "convert the unknown constituents of a body into certain known forms of combinations; and we are thus enabled to draw correct inferences respecting the nature of these unknown constituents" (Fresenius).

In what follows, the student will find given an outline of some of the more important methods of analysis, which will enable him to form a general idea of how such analyses are performed. In some cases, methods of analysis are fully described, but in most cases it has been found impossible to do this. For full details the student may consult the "Qualitative and Quantitative Analysis" of Fresenius, and the "Volumetric Analysis" of Sutton. These are the standard works on the subject, and on them most of the smaller treatises are based. The student may also consult Clowes and Coleman, who have compiled useful textbooks on both qualitative and quantitative analysis. The latter, with which we are well acquainted, is a particularly useful book for the student. The theoretical side of analysis is beautifully worked out in Ostwald's "Analytical Chemistry." No amount of reading can, however, replace practical work in the laboratory; and, in doing accurate work, there are numerous precautions to be taken and difficulties to be overcome, which will not be realised merely by reading these articles, and which are met with only in actual practice. We have, however, where possible, drawn the student's attention to the more obvious pitfalls, and with some personal instruction he should, without much difficulty, be capable of carrying out those analyses where full details are given.

Theoretical Considerations. Substances are identified by their properties which appeal to our senses. It is, of course, impossible to take all these properties into consideration, but if we prove that two substances agree completely in a few instances, it is usually sufficient. Thus, a black solid giving purple vapours when heated and a blue colour with starch paste is almost certainly iodine. We know of no other substance coinciding in all these three properties with iodine, and may therefore take these coincidences as sufficient proof of identification. On the other hand, we are acquainted with several white solids which give colourless vapours, and to distinguish between them we must note other of their properties. By taking as wide a range as possible, we reduce the possibility of error. The properties we make use of are of two kinds: first, the inherent properties—those peculiar to the substance itself, such as colour, odour, density (mass per unit volume); secondly, what for want of a better word, we may term *reactions*—that is, those changes brought about by treating with other substances, as well as those due to changed environment.

Reactions. The second class is the more important for our purpose and includes a wider and more varied range of phenomena, among which is included the *chemical and physical reactions*. By these we understand changes brought about by altering the conditions under which the body exists. Thus, in identifying iodine, we obtained it in the form of a purple vapour by changing one condition—namely, temperature. By varying the temperature and noting the behaviour of the substance under examination, a great deal of information may be gained, and the applicability of this method is further extended by using instruments (thermometers) for accurately measuring temperatures. In addition to observing a change in the state of aggregation—say, from solid to liquid—on raising the temperature, we may note the exact temperature at which the change takes place (melting point). This principle is one of those most commonly used in identifying organic substances.

Numerous other instances might be cited, and the student will meet with other examples in what follows. The changes we have considered may be classed under the heading of *physical reactions.* The chemical reactions are of equal, or of even greater, importance. In order that such may take place, two substances must be brought into intimate contact with one another, and in the case of solids, this is most generally effected by dissolving them in a common solvent, such as water. On dissolving each separately, and mixing the solutions, a "precipitate" will be formed if, by their mutual reaction on one another, they are capable of forming a substance insoluble in water (the precipitate), which promptly separates out in a finely divided state.

Precipitates, and What They Teach. As to chemical apparatus, we require little else for qualitative analysis beyond a basket of test tubes, a test-tube stand [1] to hold them, some watch-glasses [2] and stirring rods, a platinum wire and Bunsen burner [3] and a set of reagents—that is, chemical substances usually in solution, which bring about characteristic reactions with the substances which we are testing. In addition, a funnel and filter paper will be required. Fig. 4 shows the different shapes in folding a filter paper and fitting it into a funnel. The most common method, and that most generally applicable, is to add the reagent to a solution of the substance to be tested, and note whether or not a precipitate is formed. Thus, a solution of hydrochloric acid added to a silver salt, produces a white precipitate of silver chloride. As, however, hydrochloric acid produces a white precipitate with other substances besides silver salts—as, for instance, salts of mercury (mercurous) and lead—it is usually necessary to examine the precipitate further in order to make certain that the substance is what we imagine it to be. The white precipitates formed from silver, mercurous, and lead salts, differ in their properties, so that we can distinguish between them. Thus, the lead compound known as *lead chloride* is soluble in hot water, separating out again on cooling, in tiny needle-shaped crystals. The lead chloride precipitate is seen in 7. Being heavy, it rapidly settles to the bottom of the test tube. Fig. 8 shows the needle-shaped crystals obtained by dissolving in hot water and setting aside to stand. It is not changed in appearance by adding ammonia to it, while on the other hand, mercurous chloride is turned black by this treatment, and silver chloride is dissolved. Where possible, the precipitate should be washed before applying the latter tests, as other substances in solution might interfere with the reactions and complicate them. Washing is effected by filling the test tube with water, allowing the precipitate to settle to the bottom, carefully pouring off the water, leaving as much precipitate behind as possible, adding more water, and repeating the process once or twice. Fig. 6 shows a "clotted" precipitate of silver chloride which has been washed in this manner.

Some substances when heated with acids evolve gases, and this property may be made use of in analytical work. Thus, carbonates, such as chalk, give off carbon dioxide gas when treated with hydrochloric acid. Here also, it is necessary to go a step further and to identify the gas. It happens that sulphides also give off a gas when treated with hydrochloric acid; but the gases have different properties. Thus, carbon dioxide gas may be poured off into a test tube containing lime water, when a precipitate of calcium carbonate will be formed on shaking the liquid up with the gas. It is, moreover, odourless. On the other hand, sulphuretted hydrogen has a peculiar, offensive odour, and produces a metallic stain on a piece of filtered paper saturated with a solution of the silver or lead salt.

Insoluble Substances and Preliminary Work. Sometimes substances are insoluble in water and acids, and appear to be very inert. The identification of these substances is difficult. However, as there is only a limited number of them, their individual properties can be learnt, and they must be tested for separately. Of course, the identification of simple substances such as simple salts is a much easier operation than the detection and identification of a number of substances mixed together. As, however, in technical work pure substances are seldom met with, a technical chemist has to deal with mixtures even though some of the constituents are present in small quantities as impurities. The reactions of different substances with reagents have been carefully studied and tabulated, so that a systematic examination may be made. It is usual, however, before proceeding with the systematic examination, to make a preliminary examination, which often furnishes valuable clues to the nature of the substance. As we have already shown, any property of a substance, and any reaction in which it is capable of taking part may be made use of for its detection and identification, so that a knowledge of analysis, and a knowledge of general chemistry go hand in hand, and it is therefore impossible to be an expert analyst without a wide knowledge of chemical reactions.

Group Reagents. In the course of systematic analysis it will be found that hydrochloric acid produces a white precipitate with silver, mercury or lead, owing to the formation of the chlorides of these metals, and as they behave alike in this respect, and differ from the salts of all other metals, they are classed together in Group 1, of which hydrochloric acid is the "group reagent." If no precipitate is ob[illegible] the student passes on to Group 2, of which sulphuretted hydrogen is the group reagent. This forms a precipitate with the salts [illegible]

metals in Group 2; the other groups have their corresponding group reagents.

Observation and Experiment. It is not possible to proceed mechanically in making an analysis, as the general rules which we shall give are modified by varying conditions. Even in the detection of simple salts the student may make serious errors unless he reason out his methods carefully, and take the trouble to understand thoroughly what he is doing.

We remember that on one occasion a student was given a yellow-coloured solution to test smelling somewhat of sulphuretted hydrogen. Taking no notice of these data, he proceeded blindly to test for metals of the first group by adding hydrochloric acid, and, obtaining a whitish precipitate, immediately concluded that a salt of silver, mercury, or lead was present. If he had thought a moment, and taken trouble to examine the precipitate, he would have seen that it differed totally in appearance from the chlorides of any of these metals. As a matter of fact, he had been given a solution of an alkaline sulphide to identify, and the hydrochloric acid added neutralised the alkali, precipitating sulphur, which he mistook for the chloride of a metal of Group 1. The sulphur precipitate is seen in **5**; its appearance may be contrasted with **6** and **7**. The incident mentioned was a very obvious case of want of care in observation and lack of knowledge or forethought; but similar things can happen, and happen more easily in difficult analyses, if the student does not understand thoroughly what he is doing.

4. GLASS FUNNEL AND FILTER PAPER

Hints for Practical Work. When working in the laboratory only small quantities need be used, both of the substance to be tested and of the reagent. If a quantity of the liquid to be tested sufficient to fill the test tube to a depth of ½ in. or so be taken, that will be ample. Compare **5** to **12**. The reagent should be added gradually, especially in the case of strong acids. The contents of a test tube should not be thrown down the sink directly after adding the reagent if a precipitate be not immediately apparent. Some precipitates, such as sulphate of calcium or strontium form slowly. Others, as aluminium hydroxide, are very transparent and gelatinous in appearance, and may easily be missed. The precipitate of aluminium hydroxide becomes denser and settles on boiling [**9**]. When a precipitate is formed, its appearance should be noted before throwing it away. Thus, it is advisable to replace the test tubes in the stand until the condition of the precipitate is properly understood and carefully noted. The appearance of precipitates varies very much. Thus, a flocculent, or "clotty" precipitate of silver chloride [**6**] is very characteristic, and easily distinguishable from a fine, granular one, such as sulphate of barium [**12**]. After boiling, the precipitate settles more readily [**11**]. When heating the contents of a test tube in a Bunsen flame, the tube should be held with the mouth pointing away from the operator, and the tube constantly shaken; there will then be less likelihood of cracking the tube, and if the contents boil suddenly and spurt out, as they sometimes do, there is less danger of them striking the face.

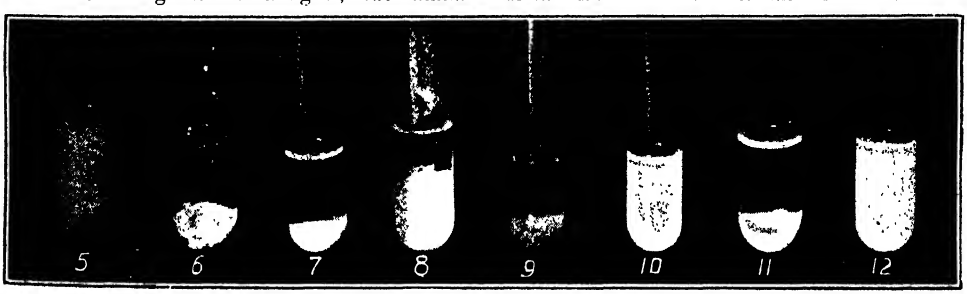
With these remarks, we proceed with the preliminary examination.

Preliminary Examination. The substance is assumed to be in a solid state. Note the colour and general appearance. Many metals have coloured ions and form characteristically coloured salts – for instance, *copper*, blue and green; *cobalt*, blue and pink; *ferrous iron*, green; *ferric iron*, red to brown; chromium, yellow to red. *Mercury*, *lead* and some other metals give characteristically coloured compounds, while those formed from others, such as *aluminium*, *barium*, etc., are generally white.

Heat a little in a dry tube, preferably a narrow hard-glass tube, but a test tube will do, and note what happens.

The following conclusions may be drawn:

(1) If it changes colour—to black (carbonisation), *organic matter*; to brown, *cadmium*



TYPICAL PRECIPITATES

5. Sulphur recrystallised **6.** Silver chloride precipitate washed **7.** Lead chloride freshly precipitated **8.** Lead chloride **9.** Aluminium hydroxide **10.** Silver chloride freshly precipitated **11.** Barium sulphate after boiling **12.** Barium sulphate before boiling

carbonate; to yellow (while hot), *zinc oxide* or *carbonate*.

(2) If it sublimes, note colour and appearance of sublimate—that is, the substance that condenses from the fumes. The sublimate may be white, *ammonium salts*, *mercury*, *antimony* or *arsenic*; metallic mirror or globules, *mercury*, *arsenic*: yellow or reddish globules of molten sulphur, *sulphur*, *sulphides*.

(3). If it give off a gas, these conclusions may be drawn:

Oxygen, *chlorates*, *nitrates*, and *peroxides*; carbon monoxide, *oxalates*; carbon dioxide, *carbonates*; nitrogen peroxide, *nitrates*; ammonia, *ammonium salts*; sulphur dioxide, *sulphites*, *thiosulphates*; sulphuretted hydrogen, *sulphides*; hydrocyanic acid, *cyanides*; chlorine, *hypochlorites*; chlorine peroxide, *chlorates*. The gases are identified by their properties and reactions.

Warm a little of the substance in a dry test tube with strong sulphuric acid, and note if a gas be given off. The following conclusions can be drawn according to the nature of the gas:

Sulphur dioxide, *sulphites*, *thiosulphates*; sulphuretted hydrogen, *sulphides*; hydrocyanic acid, *cyanides*; oxygen, *chromates*, *peroxides*, *permanganates*; carbon dioxide, *carbonates*; carbon monoxide, *oxalates*, *formates*, *ferrocyanides*; chlorine, *hypochlorites*; chlorine peroxide, *chlorates*; hydrochloric acid, *chlorides*.

It is often stated that sulphuric acid acts in this manner in virtue of its strength. Being a "stronger acid" than, say, sulphurous acid, it is said to be capable of turning this latter acid out of its combination with a metal such as sodium, forming sodium sulphate, and liberating sulphur dioxide gas. This is not correct. Sulphuric acid is certainly one of the "strongest" acids, but it is not in virtue of its "strength" that it acts in the manner above described, but because it is more stable, and less volatile than sulphurous acid. Sulphuric acid is itself turned out of combination by the "weaker" but less volatile phosphoric acid.

Flame Tests. A number of metallic salts impart to a colourless Bunsen flame a characteristic coloration. It is necessary that the salts should be volatile, and the reaction is usually carried out by moistening a little of the solid substance with hydrochloric acid on a watch-glass, dipping a platinum wire into it, and holding the wire in the flame. The platinum wire must be thoroughly cleansed before use by repeatedly dipping into pure hydrochloric acid and holding in the flame until it no longer shows a reaction. The following is a list of the more characteristic colorations:

Sodium salts, yellow; *potassium* salts, violet; *barium* salts, pale green; *strontium* salts, bright crimson; *calcium* salts, dull red.

In addition to these a green colour is obtained with some *copper* and *manganese* salts.

Mere traces of these substances may be detected by using a spectroscope, which resolves the light into a number of coloured bands, the position and intensity of each being characteristic of the substance under examination.

The Blowpipe. For blowpipe analysis the student should be provided with an ordinary mouth blowpipe [13], in the use of which he will require some little practice before he is able to handle it properly. The airholes of the burner should be closed, so that a small luminous flame is obtained. The nozzle of the blowpipe is placed in the centre of the flame, resting on the top of the burner, and, on blowing steadily, a long, pointed, non-luminous, very hot flame will be produced. The flame consists of two zones—an outer, almost colourless at the tip, termed the *oxidising* flame, and an inner, or blue zone, termed the *reducing* flame. For an explanation of the terms oxidation and reduction, see page 1295. A little of the substance to be tested is mixed with carbonate of soda, and placed in a small hollow in a lump of charcoal. The reducing flame of the blowpipe is then directed on to it, with the result that if *silver*, *lead*, *bismuth*, or *antimony* be present, tiny globules, or beads, of these metals will be produced. If a little potassium cyanide be mixed with the potassium carbonate, *tin* and *copper* salts will also be reduced to metallic beads. *Iron* is also reduced to a metal by this treatment, but the temperature is not high enough to fuse it The resulting metallic powder is magnetic. The same applies to *nickel* and *cobalt*. The salts of *zinc* and *cadmium* yield in each case the corresponding oxide, which is white in the case of *zinc*, and brown in the case of *cadmium* If compounds of *zinc*, *aluminium*, and *magnesium* be first heated on charcoal in the blowpipe flame, and then moistened with a solution of cobalt chloride, and finally reheated, the mass turns green in the case of *zinc* compounds, blue with *aluminium*, and pale pink with *magnesium* Certain *phosphates* also give a blue colour.

Borax Beads. If the end of a piece of platinum wire be bent into a small loop, heated in the flame, and dipped into powdered borax, a little of the latter will adhere to the wire, and may be fused to a colourless bead in the blowpipe flame. Small quantities of metallic salts impart the following characteristic colours to these beads when reheated:

Blue, *cobalt* and *copper*; green, *chromium*; yellow, *iron*; amethyst colour, *manganese*.

Theory of Solution. Most of the tests we have so far considered belong to the class of "dry reactions." In the systematic examinations we depend on "wet reactions"—that is to say, tests made with *solutions* both of the "reagent" and the substance to be tested. It will be as well before proceeding with the systematic examination to consider the form in which substances exist in solution, and the chemical mechanism involving the formation of a precipitate, in order that what follows may be better understood. All substances belong to one of two classes—they are either crystalloids or colloids, although a substance can appear in both forms. [See PHYSICS.] The wet reactions we are about to consider apply only to crystalloids. If a substance appear in a colloided form (silica, some metallic sulphides, hydroxides of iron and aluminium and other

bodies have this tendency) we must treat it in such a manner as to alter its condition [see Analysis of Silicates], because only crystalloids form true solutions.

Acids, bases, and metallic salts, when dissolved in water, are more or less split up (dissociated) into their components (ions), and it is by an interchange of ions that precipitates are formed. Berzelius, the Swedish chemist, originated a dual theory of the constitution of chemical substances; but since his day the dual theory has been considerably modified, and the modern theory of electrolytic dissociation explains in a truly marvellous manner the numerous chemical reactions with which we have to deal. It will suffice if we confine ourselves to the following essentials, leaving out all reference to electrolysis and kindred subjects.

It will be noticed that the kation hydrogen is characteristic of the acids, and the anion hydroxyl of the bases. On mixing together an acid and a base in solution the hydrogen of the acid combines with the hydroxyl of the base to form water $H + OH \rightarrow H_2O$, which is not dissociated (or so slightly so that we can leave it out of account). There is left the anion of the acid and the kation of the base. In other words, we have now in solution a salt, thus:

$$\overset{+}{H}\overset{-}{Cl} \text{ and } \overset{+}{K}\overset{-}{OH} \text{ yield } H_2O \text{ and } \overset{+}{K}\overset{-}{Cl}.$$

Possibly the salt is only slightly soluble in water (no substances are absolutely insoluble in water) in which case it separates out—that is, a precipitate is formed. What happens is that the ions composing the insoluble salt cannot exist together in the free state, or only in very

Acids, Bases, and Salts. For our purpose we may regard these three types as composed of two ions, a positive or *kation* (metals including hydrogen and metal-like radicals, such as ammonium, NH_4), and a negative ion or *anion* (non-metals including the hydroxyl OH, the halogens and the acid radicals SO_4, NO_3, CO_3, etc.). Using the signs + (plus) for kation, and – (minus) for anion, the state of some of the commoner salts, acids, and bases in solution may be written graphically as follows:

$$\overset{+}{H} - \overset{-}{Cl},\quad \overset{+}{H} - \overset{-}{NO_3},\quad \overset{+}{HH} - \overset{-}{SO_4},\quad \overset{+}{HH} - \overset{-}{CO_3}.$$

$$\overset{+}{K} - \overset{-}{OH},\quad \overset{+}{NH_4} - \overset{-}{OH},\quad \overset{+}{Ca} - \overset{--}{OHOH}.$$

$$\overset{+}{K} - \overset{-}{Cl},\quad \overset{+}{KK} - \overset{-}{SO_4},\quad \overset{+}{NH_4} - \overset{-}{NO_3},\quad \overset{+}{Ca} - \overset{-}{SO_4}.$$

dilute solution; most of them combine, and, as the combination happens to be insoluble in water, the substance is precipitated. Such an occurrence is, however, much more commonly met with in mixing solutions of two salts together. In the mixed solutions we shall have four ions, and if by combination of two of them an insoluble substance is possible, it will be promptly formed, and a precipitate will appear. We may represent the two cases graphically as follows:

$$\overset{+}{H}\overset{-}{Cl} \text{ \& } \overset{+}{Ag}\overset{-}{NO_3} \text{ give } AgCl \text{ (precipitate) \& } \overset{+}{H}\overset{-}{NO_3}.$$

$$\overset{+}{K}\overset{-}{Cl} \text{ \& } \overset{+}{Ag}\overset{-}{NO_3} \text{ give } AgCl \text{ (precipitate) \& } \overset{+}{K}\overset{-}{NO_3}.$$

Mixtures of Soluble Salts. If on mixing solutions of two salts, say, potassium chloride and sodium sulphate—all possible

combinations are soluble in water—no precipitate will be formed; but if we concentrate the mixed solutions by evaporating off the water, a point will be reached when one of the salts will begin to separate out. This may be any one of the four following: Potassium chloride, sodium sulphate, sodium chloride, or potassium sulphate. It will depend entirely on which is the most insoluble in the solution at the temperature of the liquid. *This most insoluble salt will separate out*, whether it be one of those originally added or not.

It is evident that there is no object to be gained by asking which of the four salts were originally in solution. They were all there potentially

Degree of Dissociation. A salt is not, however, wholly dissociated, except in an infinitely dilute solution, so that both molecules of the salts as well as ions are present in the mixed solutions.

Strong acids, bases, and the salts prepared from them, are the most completely dissociated of substances in solution. Indeed, the strength of acids and bases will be proportional to the number of free hydrogen and hydroxyl ions respectively. Thus, solutions of acids of strengths proportional to their molecular weights will contain a larger or smaller number of hydrogen ions according to the strength of the acid, and anything that tends to reduce the proportion of hydrogen ions will reduce the strength of the acid. So, for instance, sulphuretted hydrogen gives no precipitate with zinc chloride in the presence of hydrochloric acid; but, if an excess of sodium acetate be added, a precipitate is formed, because the concentration of the hydrogen ion, or hydrion, is reduced. First, acetic acid replaces hydrochloric acid, and, being a weaker acid, there is a smaller proportion of hydrogen ions; and, secondly, the excess of sodium acetate still further reduces the degree of the dissociation of the acetic acid, and a liquid is obtained, which for all practical purposes is neutral. Yet, note, this result has been obtained, not by adding a base to neutralise the acid, but by merely adding an excess of a *neutral salt* - sodium acetate.

The All-important Ion. It is of the greatest importance for the student to realise that the properties of "electrolytes" (acids, salts, and bases) are the properties of the ions. It is the *ions* that react; consequently, the behaviour of the substance depends upon the nature and the number present. This fact simplifies very much the problems of analysis. We have not to learn the properties of the salts but merely of their ions. The ion chlorine will always combine with the silver ion to give a precipitate of silver chloride, whether derived from hydrochloric acid, potassium chloride, or any other soluble salt. On the other hand, no precipitate of silver chloride is obtained, say with potassium chlorate ($KClO_3$), because it does not contain the chlorine ion, but the chlorate ion (ClO_3). Examples of this sort could be multiplied indefinitely. It was formerly the custom to regard potassium platinochloride—the precipitate obtained from potassium chloride—as a double salt ($2KCl, PtCl_4$), yet it contains no chlorine ion, and does not yield silver chloride with silver nitrate solution, but rather the silver salt of chloroplatinic acid (H_2PtCl_6), dissociated thus $\overset{+}{H}\overset{+}{H}\ \overset{-}{PtCl_6}$.

Our systematic examination will therefore comprise the reactions of the ions. As the old nomenclature is that still generally used, we shall still adhere to it; thus, for instance, we shall speak of tests for chlorides instead of chlorine ions, for chlorates and not (ClO_3) ions, and for salts of silver, mercury, and lead, and not silver, mercury, and lead ions. Professor Ostwald has written a treatise on analytical chemistry, mostly from the theoretical standpoint, in which the theory of electrolytic dissociation is employed systematically throughout. The student is referred to this for full information on the subject. He will find it most interesting reading.

SYSTEMATIC EXAMINATION

The metals are conveniently divided into five groups. We give below the group reagent and a confirmatory test for each metal.

Group 1. *Silver, mercury (mercurous)* and *lead* salts. All these metals give white precipitates of the chlorides with hydrochloric acid. We have already noted the properties of these precipitates. As confirmatory tests: *silver*—sodium hydroxide produces a light brown precipitate of silver oxide (Ag_2O); *mercury*—sulphuretted hydrogen produces a black precipitate of mercury and mercurous sulphide; *lead* potassium iodide produces a bright yellow precipitate of lead iodide (PbI_2).

Group 2. Where no precipitate was formed on adding hydrochloric acid, or the precipitate, if formed, has been filtered off, the addition of sulphuretted hydrogen to the clear solution precipitates as sulphides:

Mercury (mercuric), lead, bismuth, cadmium, arsenic, antimony, and *tin*. As the sulphides of these metals are differently coloured, the precipitate formed will help the student to distinguish between them. If the sulphuretted hydrogen be added very gradually, the precipitate with *mercuric* salts is at first whitish, then changes rapidly from red and brown to black. *Lead, bismuth*, and *copper* form black precipitates (PbS, Bi_2S_3, CuS); *cadmium*, bright yellow (CdS); *tin* (*stannous*), dark brown (SnS); *stannic*, yellow (SnS_2); *antimony*, orange (Sb_2S_3); *arsenic*, yellow (As_2S_3). Sulphides of the last three metals differ from the preceding ones, as they are soluble on warming gently in ammonium sulphide solution. If *lead* has been present in quantity it will already have been detected in Group 1.

Confirmatory Tests. *Mercury (Mercuric)*: potassium iodide produces a bright red precipitate of mercuric iodide (HgI_2). Strong solutions of *bismuth* salts, when diluted with much water, produce white precipitates, owing to the formation of basic salts. Thus, bismuth chloride yields bismuth oxychloride ($BiCl_3 \rightarrow BiOCl$).

This reaction may be thus represented:

$$BiCl_3 + H_2O \rightleftarrows BiOCl + 2HCl.$$

The double arrows are intended to show that the reaction may take place in either direction. The proportion of $BiCl_3$ (soluble) to BiOCl (precipitate) will depend entirely on the proportions of hydrochloric acid and water.

The group BiO plays the part of a metal, and the chloride may be contrasted with silver chloride, thus: (BiO)Cl and AgCl.

Copper: a piece of iron, such as the blade of a penknife, dipped into a solution of copper salt becomes coated with a red deposit of metallic copper.

Tin (stannous): a solution of mercuric chloride, produces at first a white precipitate of mercurous chloride (Hg_2Cl_2), which, on warming with an excess of tin salt, turns grey, owing to the formation of metallic mercury. The reactions are thus represented:

$$2HgCl_2 + SnCl_2 = Hg_2Cl_2 + SnCl_4$$
$$Hg_2Cl_2 + SnCl_2 = Hg_2 + SnCl_4$$

Antimony and arsenic: very minute traces of these metals may be detected by means of Marsh's test. A current of hydrogen gas is produced by allowing a dilute solution of sulphuric acid to act on *pure* zinc, to which a drop or two of platinum chloride has been added, to promote by galvanic action the evolution of the gas, which is led through a narrow glass tube. When the hydrogen has expelled all the air from the apparatus, the gas is lit at the end of the tube, and a small quantity of the test solution is then added to the flask. The flame becomes coloured, as it carries with it the gases AsH_3 or SbH_3, and, on holding a cold porcelain basin to it, a metallic deposit of arsenic or antimony will be formed. A black stain indicates the presence of *antimony*, and a brownish and shiny mirror, *arsenic*. If this deposit be treated with a little sodium hypochlorite solution the *arsenic* stain will be rapidly dissolved, whereas the *antimony* stain will be unaffected. By heating the tube through which the gases pass with a flame, a metallic deposit is formed on the walls, and is further from the flame in the case of arsenic than with antimony.

The hydrogen gas should always be tested before starting the experiment to see that it is pure and free from arsenuretted hydrogen (AsH_3), as arsenic is a common impurity in zinc. Marsh's test can also be applied to organic substances suspected to contain arsenic, and thousands of these tests were made after the cases of arsenic poisoning from beer a few years ago. This test is also one commonly employed in detecting minute traces of arsenic or antimony in the viscera in post-mortem examinations of persons suspected of having been poisoned.

Group 3. This group may be separated into two subdivisions. The first of these comprises the metals *iron, aluminium,* and *chromium,* which are precipitated on adding to a fresh solution of the substance to be examined an excess of ammonium chloride followed by ammonia.

In the case of iron (*ferrous salts*), the precipitate is whitish to dark green ($Fe(OH)_2$). In the case of *ferric* salts, foxy red in colour ($Fe_2(OH)_6$); *aluminium* is precipitated white as aluminium hydroxide ($Al_2(OH)_6$). Chromium is only partially precipitated. All these precipitates consist of hydroxides of the metals. If no precipitate is formed, add a little ammonium sulphide, when precipitates will be formed of *zinc sulphide* (ZnS) (white); *manganese sulphide* (MnS), (flesh coloured); *chromium hydroxide* ($Cr_2(OH)_6$) —not the sulphide—(bluish green), *nickel* and *cobalt sulphides* (NiS and CoS) (black).

Confirmatory Tests. *Iron (ferrous)*: potassium ferro-cyanide produces a white precipitate ($K_2Fe_2(CN)_6$), which turns blue on shaking in the air through oxidation to Prussian blue.

Iron (ferric) salts; potassium ferrocyanide produces a dark blue precipitate, Prussian blue. At first, the idea of testing for an iron salt with another compound of iron may seem strange; but it is easily explained when we remember that the iron salts in question contain ferric ions, while potassium ferrocyanide contains another and more complex ion ($Fe(CN)_6$), which, of course, reacts as a whole, and has different properties to the ferric ion.

Aluminium: ammonium sulphide produces a white flocculent precipitate of aluminium hydroxide ($Al_2(OH)_6$), the sulphide possibly first formed being decomposed.

Zinc: sodium hydroxide produces a white precipitate ($Zn(OH)_2$), soluble in excess. Some of the best confirmatory tests for metals of this group have been given under Blowpipe Analysis.

Group 4. This comprises three metals—*barium, strontium,* and *calcium*—all of which are precipitated as carbonates on adding ammonium carbonate solution to the liquid to which ammonia and ammonium chloride have already been added. In all cases the carbonates are white precipitates. ($BaCO_3$, $SrCO_3$, and $CaCO_3$)

Confirmatory Tests. *Barium:* potassium chromate produces a yellow precipitate of barium chromate ($BaCrO_4$), while calcium sulphate ($CaSO_4$) produces a white precipitate of barium sulphate ($BaSO_4$). *Strontium:* potassium chromate produces a yellow precipitate in concentrated solutions only, while calcium sulphate produces a white precipitate of strontium sulphate ($SrSO_4$) on standing (the strontium sulphate is formed in solution immediately on adding a soluble sulphate, but does not begin to separate out at once from dilute solutions owing to the phenomena of "supersaturation"). *Calcium:* ammonium oxalate produces a white precipitate of calcium oxalate (CaC_2O_4), insoluble in acetic acid.

Group 5. We now come to the metals which are not precipitated by any of the foregoing reagents. They differ from those already considered in that most of their salts (including carbonates) are soluble in water. Metals of this group comprise magnesium, potassium, ammonium, and sodium. *Magnesium* differs from the others in that it forms an insoluble phosphate. A solution of magnesia salt, containing ammonia

and ammonium chloride gives a white crystalline precipitate with sodium phosphate. This precipitate consists of magnesium ammonium phosphate ($MgNH_4PO_4$), and as it is slightly soluble in water it does not separate very rapidly from dilute solutions (supersaturation). The contents of the test tube should be shaken vigorously, or the sides of the test tube rubbed with a glass rod to induce formation of the precipitate.

Confirmatory Tests. To a solution of a *potassium* salt add one of platinic chloride, and stir well with a glass rod; a yellow precipitate (K_2PtCl_6) separates out. All *ammonium* salts smell of ammonia gas when warmed with alkalies. *Sodium:* there is hardly a sodium salt which is not readily soluble in water, so that for all practical purposes we may say that sodium salts give no precipitates with reagents.

The flame tests already mentioned will be found useful in testing for the metals of this group and the preceding one.

EXAMINATION FOR ACIDS

Besides the preliminary tests already described there are a number of wet reactions for acids of which we give below the more important. These tests apply to salts of the acids in question, and generally to the free acids as well. We can subdivide them into groups as in the case of the metals.

Group 1. This group comprises *sulphuric acid* and *hydrofluosilicic acid*. The latter is very seldom met with. These acids and their salts, with barium chloride solution, give white precipitates (such as barium sulphate, $BaSO_4$), which are insoluble in hydrochloric acid, so that the precipitate may be formed in the presence of hydrochloric acid, or it may be added subsequently, when it will be noticed that the precipitate will not dissolve.

Group 2. This group comprises acids which are precipitated by barium chloride, but these precipitates are soluble in hydrochloric acid, so that acid added to the precipitate rapidly dissolves it. The group includes the acids *carbonic, oxalic, boric, phosphoric, hydrofluoric, arsenious, arsenic, sulphurous, thiosulphuric, chromic,* and *iodic*.

Confirmatory Tests. The student should note that when he applies a reagent and makes himself acquainted with a test, he is learning at the same time a test for the reagent. Thus, we have explained how calcium salts can be tested for by means of a solution of ammonium oxalate. *Oxalates* can equally well be tested for with a solution of calcium salt. Thus in testing for an oxalate it is necessary merely to add calcium chloride to a neutral solution, when we obtain a precipitate of calcium oxalate whose properties we have already described.

Boric acid: a piece of tumeric paper is dipped into a solution of a borate, such as common borax, acidified with hydrochloric acid, and afterwards dried. Boric acid is indicated by a red-brown colour.

Phosphoric acid: a solution of ammonium molybdate in the presence of excess of nitric acid gives a yellow precipitate on warming gently. Very little of the substance and an excess of ammonium molybdate solution should be taken. The test is a delicate one.

Hydrofluoric acid: heat a little of the dry substance in strong sulphuric acid, when hydrofluoric acid (HF) is evolved. The liquid in the test tube shows a characteristic oily appearance. If the reaction be carried on in a platinum crucible covered with a piece of glass, the glass will be etched by the action of the acid vapours.

Arsenious and *arsenic acids:* solutions of acids must be first carefully neutralised with a little ammonia, when, on adding silver nitrate, a yellow precipitate of silver arsenite (Ag_3AsO_3) will be formed with the former, and a brown with the latter acid (silver arsenite, Ag_3AsO_4).

Sulphurous acid: nothing is more characteristic than the smell of the gas when driven off on warming the solution with a little mineral acid. It has, moreover, the power of turning a red solution of potassium bichromate green (reduction to a chromium salt). The test may be performed by lowering a glass rod with a drop of the bichromate solution on the end into the test tube, avoiding touching the sides. On removing the rod a little later, the drop hanging from the rod will be seen to have turned green.

Thiosulphuric acid: mineral acids precipitate finely divided sulphur, while at the same time sulphur dioxide gas is given off.

Chromic acid: salts of this acid are well coloured. The precipitate with barium chloride is yellow. We may reverse the test for sulphurous acid, a little of which turns the yellow or red solution of the chromates green.

Iodic acid: iodates are decomposed on heating. The residue readily yields vapours of iodine on warming with strong sulphuric acid. These violet vapours are very characteristic of the element.

Group 3. Acids of Group 3 are precipitated by a solution of silver nitrate. We shall consider only those which are not precipitated by barium chloride. These comprise *hydrochloric, hydrobromic, hydriodic, hydrocyanic,* and *hydrosulphuric* acid. The precipitates, consisting of the silver salts, are white or yellow, with the exception of silver sulphide, which is black. Silver chloride we have noticed when testing for silver. The precipitate is insoluble in nitric acid, but soluble in ammonia solution.

Silver bromide is yellowish in colour. It is almost insoluble in nitric acid, but dissolves in strong ammonia solution.

Silver iodide is yellow, and differs from bromide in that it is very sparingly soluble in ammonia solution.

Silver cyanide, which is white, behaves almost exactly like silver chloride, but does not dissolve so readily in ammonia. It dissolves in excess of potassium cyanide giving $KAg(CN)_2$.

Confirmatory Tests. *Hydrochloric, hydrobromic,* and *hydriodic acids* may be identified by the liberation of the corresponding elements—chlorine, bromine, and iodine—by heating with sulphuric acid and a little powdered oxide of manganese. For the appearance and properties of these elements see page 1444.

Cyanides are decomposed by hydrochloric acid, with the liberation of hydrocyanic acid (HCN), which has a peculiar odour, said to resemble bitter almonds, but, as a matter of fact, its smell is characteristic and not exactly like anything else. As it is extremely poisonous, care must be taken not to inhale too much of it.

Group 4. This group comprises a few acids which are not precipitated by barium chloride or silver nitrate. They include *nitric*, *chloric*, and *perchloric acids*. *Nitric acid* is easily detected by its action on copper. Copper shavings are readily dissolved either by the free acid or by a mixture of a salt and a little sulphuric acid, with the evolution of brown vapours (oxides of nitrogen) and the formation of a blue solution (copper nitrate). Another very characteristic test is to mix the solution to be tested with a solution of ferrous sulphate. A little strong sulphuric acid is carefully poured down the side of the tube, so that it sinks and forms a layer underneath the aqueous solution. The test tube is held under the tap to cool it thoroughly, and on holding it up to the light a brown ring will be seen at the juncture of the two liquids. The action of the sulphuric acid on the nitric acid is to liberate oxides of nitrogen, which give a dark brown or black colour with ferrous salts.

Insoluble Substances. There are a number of insoluble substances which are very inert and require to be tested for carefully.

Although insoluble in water and acids, silica is dissolved to a certain extent on boiling with strong alkali solutions, or better still by fusing it with a mixture of equal weights of the carbonates of soda and potash (fusion mixture). The fused mass is dissolved in water and acidified, when gelatinous silica separates out either at once or on concentration of the solution.

We have omitted to mention all rare elements—some of which, however, are of considerable and increasing importance—as by doing so we should be introducing too many complications. For these the student must refer to larger works, specially devoted to the subject.

Tests for Organic Substances. There are a number of organic substances to which routine tests are applicable. One or two of the more important may be mentioned here.

Tartaric, citric, and *malic acids:* these acids, like oxalic acid, yield precipitates of the calcium salts—for instance, with calcium chloride in neutral solution.

Tartaric acid can be further identified by the fact that a strong solution shaken with potassium chloride gives a white crystalline precipitate of acid potassium tartrate.

Benzoic acid gives a yellow-brown precipitate with ferric chloride. The acid volatilised by heating in a tube emits a vapour of characteristic odour, which condenses again in the cooler parts of the tube.

Carbolic acid. Ferric chloride produces a violet colouration, but a similar colour is obtained with *salicylic acid.* These two substances are related, and a smell of carbolic acid is evolved on heating salicylic acid with lime.

QUANTITATIVE ANALYSIS

In our discussion of qualitative analysis we have given an outline of the methods of ascertaining the *nature* of a substance; in this section we shall show how to determine the *amount* in which it is present, whether by itself or in admixture with other substances.

This portion of our subject is divisible into two sections—analysis by weight, or *gravimetric* analysis, and by volume, or *volumetric* analysis. Volumes are also measured in the analysis of gases, but this is usually treated under gas analysis.

Gravimetric Analysis. "Gravimetric analysis has for its object to convert the known constituents of a substance into forms or combinations which will admit of the most exact determination of their weight, and of which, moreover, the composition is accurately known" (Fresenius). Thus, we shall suppose that one of the known constituents of a substance we are dealing with is sulphuric acid or a soluble sulphate, and that we require to determine (or estimate) its amount. We proceed to convert it into a substance of known composition, say the barium salt or barium sulphate, which can be separated and accurately weighed. As one equivalent of sulphuric acid will produce one equivalent of barium sulphate, we can calculate the amount of sulphuric acid present from the weight of the barium sulphate found. We have special reasons for choosing the barium and not some other salt such as the calcium salt. We have seen in our study of qualitative analysis that barium sulphate is very insoluble in water. It is, as a matter of fact, one of the most insoluble substances known, and consequently well adapted for our purpose.

Sulphuric Acid Estimation. We shall proceed to make an estimation of sulphuric acid. We may suppose that a careful qualitative analysis has already been carried through, and that the precipitate obtained with barium chloride solution in the presence of hydrochloric acid was fairly copious, pointing to a considerable proportion of sulphuric acid or sulphate present.

About one gramme of the substance is accurately weighed off on a chemical balance [see page 61]. Substances to be weighed must never be put directly on to the scale-pan, but are weighed on a watchglass [2] or in a weighing bottle [14], whose weights must first be determined and deducted from the total weight found.

Enter the weights in your book thus:

Weight of watchglass + substance	=	1·9472 gr.
Weight of watchglass	...	·8315 „
∴ Weight of substance taken for analysis	=	1·1157 „

The weights down to one gramme are made of brass [15]; below one gramme usually of platinum [16]. For weights less than a centigramme, the rider attachment situated over the beam of the balance is used.

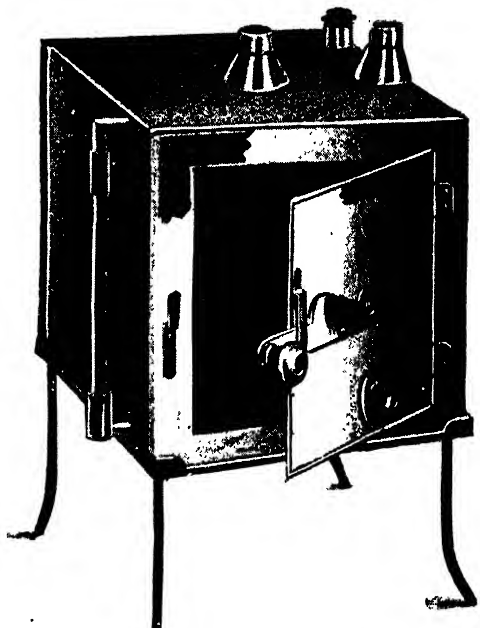
A weighing bottle should be employed if the substance to be tested is "hygroscopic"—that is to say, has the power of absorbing moisture from the air; otherwise a watchglass will usually be preferred.

Removal of Insoluble Matter. Having weighed out the substance, it is dissolved in pure (that is, distilled) water in a beaker [17]. Sometimes the water should be heated to get the substance dissolved more quickly. We assume here that it is soluble in water, or at any rate that we are estimating only the sulphuric acid in the soluble portion. If there be an insoluble portion, it should first be filtered off. For this purpose a circular filter paper is folded in four in the form of a quadrant [4], the flap opened and fitted into a glass funnel. The paper is then moistened with distilled water from a wash bottle [18] and fitted evenly against the sides of the funnel. The liquid is then poured down a glass rod into the funnel, which should not be filled above three-quarters the height of the filter paper. When the whole has run through, the beaker is washed out three times with water, the washings being poured through the filter paper so that the whole of the soluble matter is collected in a vessel, such as a beaker, placed under the funnel.

Precipitation as Barium Sulphate. Hydrochloric acid is added to the liquid, which should not more than half fill the beaker. It is heated to boiling on a tripod [19], and sufficient barium chloride solution added to precipitate the whole of the sulphuric acid as barium sulphate. For this purpose more than the theoretical quantity of $BaCl_2$ will be required. The liquid is kept boiling for a minute or two and the precipitate allowed to settle. When precipitated from a boiling solution, barium sulphate settles more rapidly and is easier to filter. Compare **11** and **12**; both are barium sulphate precipitates which have been standing together; **11** has been boiled and has rapidly settled, while **12**, precipitated in the cold, only just begins to show signs of settling. The clear, "supernatant" liquid is poured off through a close-grained filter paper. The "filtrate"—the liquid which passes through—should be boiled for a few minutes after adding two or three drops more barium chloride solution to make sure that the whole of the sulphuric acid has been precipitated. With the aid of a jet of hot water from a wash bottle [18] the precipitate is transferred from the beaker to the filter paper and washed further by means of a hot-water jet from the wash bottle until the filtrate is free from chloride (a few drops should give no cloudiness with silver nitrate solution).

Igniting the Precipitate. The filter paper is allowed to drain and is then transferred bodily with the precipitate to a previously-weighed platinum crucible [20] lying on a pipe-clay triangle [21] on a tripod [19]. Care must be taken not to tear the paper or lose any of the precipitate. The lid is placed on the crucible, and a Bunsen burner [3] with full flame set underneath. There is just a little spluttering at first; the lid is then removed, the crucible tilted a little to one side, and the paper charred and eventually burnt off to a white ash. After heating to redness for a short time, nothing but a small quantity of white substance—sulphate of barium and filter paper ash—remains at the bottom of the crucible. Any dark portions left point to unburnt carbon from the paper. As the carbonaceous matter is liable to reduce the barium sulphate into sulphide, it is moistened when cold with a drop of nitric acid to convert any sulphide into sulphate, reheated, cooled, and weighed.

Weighing and Calculating. For most purposes the weight of the ash may be neglected or allowed for and deducted from the weight of the precipitate if great accuracy be insisted on. Packets of pure filter paper for quantitative work generally have marked on them the average weight of the ash. The crucible is lifted off the triangle by means of a pair of crucible tongs [22], best made of nickel, and deposited in a desiccator [23] to cool. The desiccator consists of a glass jar with cover having strong sulphuric acid or calcium chloride at the bottom so that, the air above being dry,



25. STEAM DRYING OVEN

the crucible and contents cool without absorbing moisture and increasing in weight. The crucible and contents are then weighed.

Enter the results in your notebook thus:

Weight of crucible + barium sulphate	= 19·4377 gr.
Weight of crucible	= 18·4312 ,,
∴ Weight of barium sulphate	= 1·0065 ,,

This quantity of barium sulphate is equivalent to $1{\cdot}0065 \times \frac{80}{233} = {\cdot}3456$ gm. (SO_3);

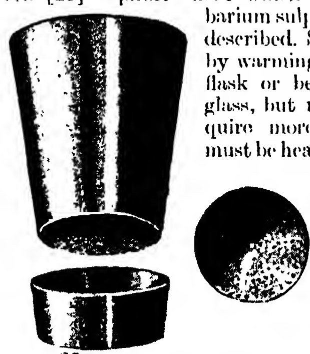
or, expressed in percentages:

$$\frac{{\cdot}3456}{1{\cdot}1157} \times 100 = 30{\cdot}9 \text{ per cent.}$$

In the foregoing we chose the estimation of sulphuric acid, and have given a full description of the chemical manipulations, as it is a determination which has to be made in the technical laboratory as often as any other. Moreover, if

is the universal method for the determination of sulphates. No satisfactory volumetric method has been devised. Of course, this does not apply to solutions of the free acid.

Analyses of Other Substances. We are unable in the short space at our disposal to give specific instructions as to the carrying out of other gravimetric estimations, and must content ourselves with mentioning a few points in which modifications of the above method are necessary or convenient. Platinum crucibles [20] cannot always be used, as some substances, such as compounds of lead, attack and alloy with the platinum. In these cases a porcelain crucible [24] should be taken. As instances where this is necessary, we may mention: *lead*, as lead carbonate ($PbCO_3$) precipitated from solutions of lead salts by ammonium carbonate in presence of a small quantity of ammonia; *zinc*, as zinc carbonate ($ZnCO_3$) precipitated with sodium carbonate; *silver*, as silver chloride ($AgCl$) precipitated with hydrochloric acid. The precipitates in such cases as these cannot be put wet into the crucible, but must first be dried in a steam oven [25] and the dry precipitate separated as much as possible from the filter paper and ignited apart from the latter in the crucible. This operation should be performed with the crucible standing on a piece of glazed paper. The precipitate may be detached by the aid of the clean blade of a penknife, and any substance spilt on the paper may be afterwards swept into the crucible with a camelhair brush. The filter paper is folded up and securely held by wrapping a long piece of platinum wire round it; the end of the wire is fused into a glass handle. The paper is burnt in the cage of wire formed in this manner and the ash is allowed to drop into the crucible containing the already ignited precipitate, so that all are weighed together.



26. GOOCH CRUCIBLE

The Gooch Crucible. The method just described is somewhat tedious, and unless the greatest care be taken, some of the precipitate is sure to be lost. Such determinations as those of silver and chlorine are rapidly made in a Gooch crucible [26]. It consists of a platinum crucible the base of which is perforated with numerous small holes; it fits into a filtering flask similar to that shown [27]. Some short-fibred asbestos thoroughly extracted with acids is poured into the crucible, and as the water drains away it leaves a plug of fibre on the bottom. This is then covered with the perforated plate seen on the right of the illustration [26], and on connecting the flask with an exhaust pump, most of the water is sucked out and fresh water may be drawn through, so that the asbestos is thoroughly washed. The crucible is then detached, dried in an air oven at 110° C., and weighed. The silver chloride is precipitated in the ordinary manner, and the liquid poured into the crucible. The aqueous liquor is sucked through into the filtering flask and the precipitate left entangled in the asbestos. It is washed with distilled water in the usual manner, after which the crucible is removed to the oven, dried and weighed. The difference in weight represents silver chloride. Results just as accurate are got by drying at 110° C. as when silver chloride is heated to fusing point. There is no need to put in fresh asbestos each time a determination is made, as the crucible can be used several times before the accumulation of precipitates necessitates cleaning it out.

More Important Estimations. We will indicate briefly the method of analysis in some instances not already treated of.

Iron and *aluminium*: precipitate as hydroxides with slight excess of ammonia and ignite wet.

Copper: precipitates as oxide with caustic potash or soda. If the liquid contain any organic matter it must be destroyed by concentrating in an open dish or basin [28], with the addition of soda and nitre, and then fusing, redissolving, and precipitating.

Sulphur, whether present as sulphides or free or contained in organic matter, must be oxidised with nitric acid to convert it into sulphuric acid which can then be estimated as barium sulphate in the manner already described. Sulphides are readily oxidised by warming with strong nitric acid in a flask or beaker covered with a clock-glass, but many organic substances require more drastic treatment. They must be heated with nitric acid to a high temperature—200° C. to 300° C.—and this can be accomplished only by sealing them up with nitric acid in a strong glass tube [29] (Carius method) and placing the tube in a special oven or furnace [34]. The latter illustration shows the ends of the oven raised and the iron tubes in which the glass ones are placed, so that no damage will be done should they burst—a thing which not infrequently happens, when they go off with a report, leaving nothing but a little powdered glass behind. In sealing the glass tubes care is taken to leave a fine capillary at the end [29] so that after a couple of hours, when the reaction is complete, the tubes are opened and the accumulated pressure released by fusing the end of the capillary without taking the glass tube out of the iron one. All danger is thus avoided. The pressure released, the tube is cut into halves and the contents washed out into a beaker and precipitated with barium chloride in the usual manner.

Chlorine in soluble salts may be precipitated directly with silver nitrate, but when contained in organic substances it must first be liberated in the form of chloride by heating with nitric acid in a sealed tube in the manner just described. A crystal or two of silver nitrate is put into the tube, so that on opening, the silver chloride has only to be washed out into a Gooch crucible and weighed.

Magnesium. Soluble salts are heated with ammonium chloride, and made very slightly

alkaline with ammonia. An excess of sodium phosphate is added, and the liquid is stirred for a minute or two. When the precipitate has formed, add more strong ammonia, and put aside to stand till the next day. Filter off, wash with ammonia solution (1 in 12), and ignite. The precipitate of magnesium ammonium ($MgNH_4PO_4$ $6H_2O$) is converted by ignition into magnesium pyrophosphate ($Mg_2P_2O_7$), in which form it is weighed, all the volatile water and ammonia being driven off.

Phosphates may be estimated by the above process for magnesium.

Antimony may be estimated by precipitating it from an acid solution as the sulphide (Sb_2S_3) by saturating with sulphuretted hydrogen gas. Strong solutions of antimony chloride are precipitated on dilution with water; tartaric acid added to the liquid prevents this. There are certain difficulties in the way of weighing sulphide of antimony, as it decomposes when heated in air. It must either be dried by heating in hydrogen gas (which can be conveniently carried out in a Gooch) or else oxidised with nitric acid, which converts it into the oxide (Sb_2O_3). This is then ignited and weighed.

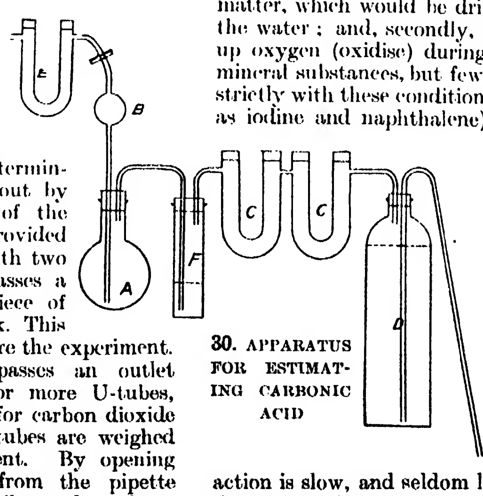
28. PORCELAIN BASIN

Arsenic is precipitated as sulphide (As_2S_3), collected in a Gooch, and dried at 100° C.

Tin is also precipitated as sulphide, and on igniting is converted into the oxide (SnO_2), in which form it is weighed.

Mercury is precipitated as sulphide (HgS), collected in a Gooch, dried at 100° C., and weighed.

Carbonates. As carbonic acid is widely distributed both as a constituent of the atmosphere and as a component of minerals, its estimation is a matter of considerable importance. Besides the methods already given, there are others depending on the decomposition of carbonates and the measurement of the gas evolved either by weight or by volume. The determination by weight is carried out by placing a weighed amount of the substance in a flask [A, 30] provided with a rubber cork pierced with two holes. Through one hole passes a pipette, B, closed with a piece of rubber tubing and a pinch cock. This pipette is filled with acid before the experiment. Through the other hole passes an outlet tube connected with two or more U-tubes, C C, filled with an absorbent for carbon dioxide such as soda lime. These tubes are weighed before starting the experiment. By opening the pinch cock, the acid from the pipette (this must be a non-volatile acid such as sulphuric) is allowed to enter the flask in small quantities at a time, so that the carbon dioxide is given off in a slow stream, and is absorbed by the soda lime. The second U-tube should remain cool, showing that practically all the gas is absorbed in the first one. When the action is complete, the carbon dioxide remaining in the flask is drawn into the U-tubes by the aspirator D. The air drawn through the flask should be freed from carbon dioxide by passing it through the soda lime tube, E, and a wash bottle, F, containing strong sulphuric acid to retain moisture, should be interposed between A and C. The U-tubes, C C, are reweighed, and the increase in weight represents carbon dioxide.



30. APPARATUS FOR ESTIMATING CARBONIC ACID

27. FLASK FOR FILTERING UNDER PRESSURE

If the flask A be removed so that the soda lime tube be open to the atmosphere, and a definite volume of air be sucked through the tubes by running out and measuring the water from D, we have an apparatus for estimating the amount of carbon dioxide gas in the atmosphere.

Measuring Moisture. Moisture has frequently to be measured, as substances which have been exposed to the air are never dry. The simplest method is to place a weighed quantity of the substance in an open dish, watch or clock glass, also previously weighed. Then heat in an oven [25] at 100° C., or a little higher, till the substance ceases to lose weight. The loss of weight will give the moisture or water contained in the substance.

This method is simple and accurate, provided,

29. CARIUS TUBE

first, that the substance contains no other volatile matter, which would be driven off and lost with the water; and, secondly, that it does not take up oxygen (oxidise) during the heating. Most mineral substances, but few organic ones, comply strictly with these conditions. Some bodies (such as iodine and naphthalene) are far too volatile to admit of treatment in this manner, while others, such as rosin, are only slightly volatile, so that the results are good enough for most purposes, although not strictly accurate. Oils oxidise and increase in weight, as also do substances such as wood pulp, but the action is slow, and seldom leads to serious error. Sometimes the moisture in mineral substances is held very firmly (water of constitution), and a much higher temperature than 100° C. is required to drive it off. The same principle can be made use of as already described,

but the watchglass must be replaced by a crucible, and the temperature, if necessary, raised to a red heat. Unfortunately, the substance frequently suffers other chemical changes at these high temperatures, so that in many cases the water cannot be estimated by difference. In such cases the substance is heated in a hard-glass tube, and the moisture drawn over weighed U-tubes containing calcium chloride, the water being directly estimated, as in the case of carbon dioxide absorbed in soda lime.

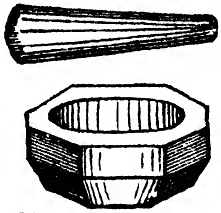
Silicious Materials. The analyst is frequently called upon to examine substances such as cement, clay, fireclay, and firebrick, silicious limestones and dolomites, sand, iron ores, slags, and numerous other substances containing silica, and we shall now consider the best methods in such cases.

Some substances, such as iron ores, limestone, lime, magnesite, dolomites, and cement are decomposed on repeated treatment with strong hydrochloric acid to which a few drops of nitric acid have been added, leaving a residue consisting of silica. A portion of this tends to remain in solution, owing to the persistency of the colloidal state, and is rendered insoluble only by

33. GLASS BLOWPIPE

evaporating down the mixture in a porcelain dish and heating the dry residue for half an hour at about 150° C. The "baked" mass is then treated with a small quantity of strong hydrochloric acid, stirred up with a glass rod, and the insoluble silica filtered off and washed with hot water. The residue may be ignited straight away and weighed as described for barium sulphate. The solution contains iron, aluminium, calcium, magnesium, etc., as chlorides, which may be estimated by methods already described. Of course, the iron and alumina must be first precipitated, and the filtrate carefully preserved, as this will contain calcium and magnesium. The calcium is precipitated as oxalate, and the magnesium estimated in the filtrate.

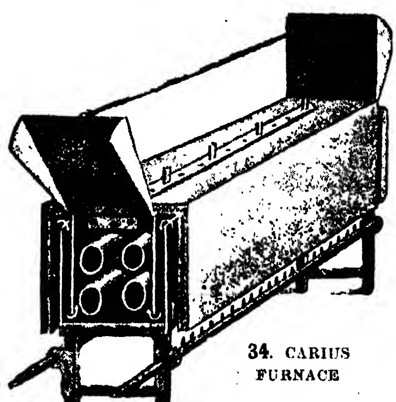
Analysis by Fusion with Alkali. In the case of many silicious substances the decomposition with acids is not sufficiently complete for analytical purposes. This applies to some of the substances mentioned in the preceding paragraph —cement, for instance—although for many purposes the acid treatment gives good enough results, and is, besides, a rapid method. It cannot, however, be used where an exact analysis is required. In either case, the substance to be analysed must be very finely powdered, not always an easy matter. Some substances when they come to hand are already in a finely divided state, as clay and cement; but a portion from which the sample for analysis is to be taken should always be reground in an agate mortar [31] to reduce larger particles which



31. AGATE MORTAR

32. STEEL MORTAR

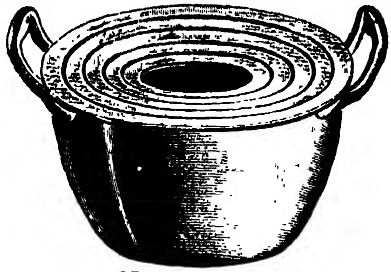
are always present. Iron ores are often very hard, and must first be crushed in a steel mortar [32], and then powdered in the agate mortar. Weigh out accurately about one gramme of the material into a capacious platinum crucible [20], and add about eight grammes of the mixture of equal parts of pure dry carbonates of sodium and potassium— "fusion mixture"—which has a lower melting point than either carbonate by itself. Mix thoroughly with a glass rod, cover with the lid, and heat on a clay triangle, first with a small flame, and then gradually increasing its size until the gas is full on, finally heating for a quarter of an hour over a blowpipe flame. The mouth blowpipe will not do; you will want a gas blowpipe [33] fitted with foot blowers [37]. The contents of the crucible should be at a bright red heat and in a state of gentle fusion. Take the crucible firmly in a pair of tongs, and while still red hot plunge it to about half its height into a basin of cold water. This cools the "melt" rapidly, so that on solidifying it usually cracks away from the sides, and is easily removed. Place the crucible on its side in a deep porcelain dish, cover with water, and gently warm on a water bath [35] till the contents come away, when the crucible is removed, and rinsed with a jet of water so as to retain everything in the dish. Cover the dish with a clock-glass and run



34. CARIUS FURNACE

in hydrochloric acid very carefully down the lip of the dish. The addition of acid is continued, keeping the dish covered with the clock-glass all the while until effervescence ceases. In this

manner, particles of liquid spray are caught on the under surface of the clock-glass and drip back into the dish. The clock-glass should, of course, be placed convex side downwards. Remove it, and wash any drippings back into the dish, and continue heating on the water bath till the contents are dry, then place in the air oven and heat to 150° C. for half an hour, to render the silica insoluble, and continue the analysis exactly as before.

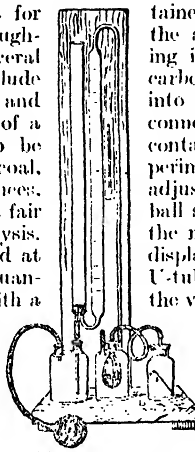


35. WATER BATH

Sampling. We have assumed that the portion of material selected for analysis is a representative sample of the whole. To ensure this, special precautions have to be taken, as most materials for analysis are by no means uniform throughout. Take, for instance, a delivery of several truckloads of coal. It will probably include material from different parts of the seam, and even if we analyse different portions of a single lump, it will not be found to be uniform throughout. In the case of coal, ores, clay, and numerous other substances, it is at least as important to procure a fair sample as to make an accurate analysis. Supposing the trucks are being unloaded at the works, the chemist removes small quantities, say a pound or two at a time, with a shovel or other suitable instrument, every now and again at some convenient point—say, where the material is being taken by an elevator to storing bins. These samples are thrown out on to an impervious floor and thorougly mixed and divided into four quarters or heaps. Two of the diagonally opposite heaps are removed, and the remaining two remixed, and again divided into four, and the process repeated. At a certain stage large lumps must be broken up, and the division repeated, until we are left with only a few pounds of lumps and powder, not larger, say, than walnuts. These are taken to the laboratory, crushed further in a mortar, and dividing operations repeated, with further grinding at suitable stages, until we are left with only a few grammes of the finely powdered material for analysis. If the process has been properly conducted, the sample, amounting to only a few grammes, will be fairly representative of several tons of the material which we started to examine.

The Calcimeter. In the cement industry and some others, rapid estimations of carbonates have to be frequently made, and for this purpose some form of calcimeter is generally used. In cement works it is necessary to make regular tests of the slurry [see page 1580] to ascertain the proportion of chalk it contains.

A small quantity of the slurry is dried, weighed, and introduced into the bottle shown on the right-hand side of the illustration [36]. This bottle is provided with a short tube, which rests against the side and holds rather more than sufficient acid to decompose the chalk contained in the slurry. On inclining the bottle, the acid flows out of the tube, and, coming into contact with the slurry, liberates carbon dioxide gas. This gas finds its way into the middle vessel, which stands in connection with a long graduated U-tube containing water. Before starting the experiment the levels of water in this tube are adjusted by means of the bottle and rubber ball seen on the left. The air driven out of the middle flask by the carbon dioxide gas displaces water in the graduated limb of the U-tube, and on adjusting the levels again the volume of carbon dioxide may be directly read off. A correction has to be made for the amount of gas absorbed by the acid in the bottle. Of course, this method is suitable only where rapid estimations are required, as the results are probably not correct to more than half of one per cent.



36. CALCIMETER

It is hoped that this short account of some of the more important analytical operations will give the reader an insight into the principles on which the science is based. He will, however, find a number of analytical processes described in the subsequent sections of Applied Chemistry, Kjedahl's nitrogen estimation under Glues and Adhesives, the analysis of nitrates and phosphates under Manures, and food and water analysis under the various food sections. The subject of volumetric analysis has been omitted as it could not be adequately dealt with in the space at our disposal. For further study we recommend the text-book of Clowes & Coleman, or the standard work on volumetric analysis by Sutton. Most of the illustrations in this article are from apparatus supplied by Messrs. Baird & Tatlock

PHOTOGRAPHERS

For those who have an artistic taste, combined with a knowledge of the art of photography, professional photography offers good prospects. It is usual to decry photography as a business on account of the enormous number of amateur photographers which, it is imagined, spoils the field for the professional. Curiously enough, the number of persons who seriously practise photography as amateurs is comparatively small. The average amateur who possesses a camera does not turn out presentable work His friends gaze at his attempts and say, "Very well for an amateur," which is only another way of saying that the professional is not seriously rivalled by the amateur. If anything, the public learn, from seeing the productions of an amateur, that photography is not the simple art it appears to be at first sight. It is also a fact that amateur photographers invariably patronise the professional when they require presentable photographs of themselves or their relatives.

Apprenticeship. A boy with the proper aspirations should be apprenticed to a good country business when he has reached the age of sixteen. In some cases a premium of £20 to £30 is asked; in others no premium is paid; and, again, small salaries are not unusual. A boy learns just as much at places where he receives a salary as where a premium is paid. The young beginner is taught printing, toning, developing, and mixing up solutions for a year or so, and is then introduced to the studio, where he helps in the operating, until he is competent to operate himself. Retouching is the last department taught. During these three years the young man should attend evening classes at the local science and art school. In London the excellent courses in photography at such institutions as the Polytechnic cannot be too highly recommended. The country lad should not, however, be discouraged by the lack of classes on photography in his town, but should occupy his evenings at the art classes, and go through a course of elementary chemistry, light, and heat in a science school.

Remuneration. The salaries paid in the business of a photographer are from 30s. to 45s. a week, the amount depending on the experience of the assistant, and on his ability as an operator. Many women are engaged in certain departments of the photographer's business, and they are quite successful as reception-room attendants, retouchers, printers, and mounters. The salaries paid to women range from 15s. to 30s a week, according to experience.

The Professional Photographers' Association has devised a "registration certificate" scheme for assistants. There has not yet been time to judge whether the scheme will be successful, but it may be added that it does not involve examination—merely a consideration of experience in the various departments of the business.

Starting in Business. To begin business is the aim of most assistants, but this step should not be taken until experience has been obtained in three different studios. Whether the photographer decides to buy an existing business or to start a fresh one is a question which circumstances must decide. As a rule, it costs the same in the long run, because, although the established business has a certain amount of goodwill attached to it, there is sometimes an undesirable reputation which neutralises the advantages. A photographer who starts a new business can soon make a reputation if he delivers his work promptly. The writer remembers a case in which the photographer built up a lasting reputation by delivering the finished photographs within three days of the sitting. It is a fact, however, that a beginner has often to make his name chiefly by work outside his studio. He will need to cater for work by taking local views, but should make a point of always being in his studio at certain times of the day, or he will never be able to build up a home business. As soon as the business is large enough to support an experienced assistant, most of the difficulties outlined above disappear.

Capital Required. It is hardly possible to state an exact sum as necessary for one starting the business of a photographer. Many have started on £20 or £50, but to start in a fairly comprehensive manner needs from £200 to £300. A studio, for instance, may cost £50 to £100, and the camera from £10 to £30. In the following estimate, a medium class of business has been taken as a basis of calculation:

Portable studio	£60
Furniture and carpets	20
Backgrounds and accessories	20
Camera, lens, and stand	25
Dark-room fittings	10
Apparatus (printing frames, retouching desk, washer, trimmer, rolling press, etc.)	10
Mounts and stationery	10
Plates, paper, and chemicals	10
Miscellaneous (including advertising)	15
Working capital	20
	£200

Premises. The above estimate provides for a portable studio, but it may be that waiting-rooms and dark-room will also have to be provided. Usually these last-named are the ground-floor

rooms of a house, and lead to the garden, where the studio is situated. Rents are higher in town, but a business is built up sooner than in the suburbs. Many town business premises are handicapped by having no shop window, the show-cases in a doorway being a poor substitute. If possible, have a shop window at disposal. The outside should be painted in a quiet colour—cream or plum colour are favourites—while for the inside of the window brown is to be recommended, as it shows up carbon and platinotype portraits best. The floor of the shop or reception room should be linoleum (self-colour), and the walls look nice if papered olive green, with white paint. The rule should be to avoid a pronounced colour. The furniture must be in good taste if a good-class business is to be cultivated; an oak gate-leg table and antique chairs help to give an air of culture, which educated people appreciate. Conventional furniture is not to be despised, and as customers have to wait some time, care should be taken to have comfortable chairs. Adjoining the studio a dressing-room should be provided.

The Studio. The studio is the most important consideration. It must be disposed so that the light is received from the north, or preferably from a north-easterly direction. The length of the studio should be not less than 24 ft. and the width 12 ft., although it is better, if space permit, to make it 35 ft. long by 18 ft. wide. The pitch of the roof is usually 35 to 45 degrees, the height to ridge being about 14 ft.

As regards the studio camera equipment, an average specification would be a 12 × 10 set, to cost, complete, £25. The camera is fitted with a dark slide to take one 12 × 10, one 10 × 8, one 8½ × 6½, two boudoirs, two promenades, two cabinets, and two carte-de-visite pictures. A good portrait lens and massive stand is also included. Many photographers start studio work with an ordinary outdoor outfit, with rapid rectilinear lens, and purchase proper studio apparatus as means permit. The other contents of the studio will be three backgrounds—a reversible neutral-coloured background, and one outdoor and one indoor scene—a head-rest, rugs, palms and grasses, and a few pictures for the walls.

The heating of the studio is best managed by means of a "syphon" gas-stove or by hot-water radiators, and it is essential that the studio be comfortably warm in winter, or successful results cannot be expected. The method of fitting up a dark-room is explained in the article on Photographic Dealers, which follows.

Mounts. The tints of mounts are numerous, but two kinds of mounts are well defined—Bristol and enamelled board. It costs about 5s. per thousand to have the photographer's name stamped on back and front of mounts, the price depending upon whether gold or colour is used. The table in next column gives approximate prices of the various mounts in use by photographers.

These should be supplemented by a selection of circles and ovals, slip-in mounts, and mounts with greetings embossed upon them.

VARIETIES OF PHOTOGRAPH MOUNTS.

Name.	Size.	Approximate Price.
Midget	2¼ by 1 5/16	3s. 6d. 1,000
Victoria Midget	2¾ „ 1½	4s. 6d. 1,000

„ ..	8½ „ 6½	
—	10 „ 8	6s. 3d. to 12s. 100
—	12 „ 10	9s. to 25s. 100

Tissue paper covers for photographs, protector bags, and postal wrappers will be needed as well as memorandum forms and bill-heads.

A registration system for negatives must be inaugurated, a ruled book being provided in which the name and address of each sitter is entered with date and other particulars. The stock of negatives ought to be stored in a dry place and be put in order so that there will be no difficulty in finding a particular negative.

Selling Prices. Vary according to the class of trade. The following are average prices: *midgets*, 4s. 6d. to 6s. dozen silver prints, 7s. 6d. platino; *carte-de-visite*, 7s. to 8s. 6d. dozen silver prints, 10s. 6d. to 12s. platino; *cabinet*, 15s. to 24s. dozen; *boudoir*, 18s. to 20s. dozen to 35s. dozen; *panels*, 10s. 6d. to 15s. each; *wedding groups*, whole plate, one to two guineas, including three to six copies.

Copyright. In the case of ordinary photographs the copyright belongs to the person who pays for the sitting unless it is expressly reserved by the photographer. A book of forms should be provided for the latter purpose if the extent of the business allows it. The wording of the form is usually something like this:

"In consideration of your allowing me a reduction from your usual terms for taking photographs of me or on my behalf this day, I hereby agree that the copyright in such photographs shall be reserved to you, and that I will not deal in any way with the photographs to prejudice your interest in the copyright."

The reduction should be stated, and the agreement stamped with a sixpenny stamp, dated, filled in with the names of the parties, and witnessed.

Copyright in artistic property can be registered at Stationers' Hall, Ludgate Hill, London, E.C., the fee being 1s. Registration is necessary before a legal action can be taken against anyone infringing a copyright photograph. The Photographic Copyright Union, 23, Soho Square, London, W., and the Professional Photographers' Association, 51, Baker Street, London, W., are

useful societies for professionals; the subscription in each case is small. The Copyright Union recommends the adoption of a minimum reproduction fee of 10s. 6d. to a guinea according to the size. This is for newspaper work. For advertisement purposes the charges are higher; for postcards 10s. 6d. per 1,000 is a usual charge.

Class of Work. Photographer's work is very varied. It includes copying old photographs, enlarging pictures by bromide, carbon, or platinum processes, architectural work, photographic enamels, flashlight groups of dinners, lantern slides, transparencies, and photographs for the Press. In the old days, unmounted and mounted views had a large sale, but this has all disappeared before the ubiquitous picture postcard. Picture postcards are either direct photographs or collotypes. Collotype postcards cost 16s. 6d. per 1,000 if six subjects are taken, while for a set of 50 subjects the charge is 9s. 6d. per 1,000 if 10,000 are taken. Bromide postcards cost from 7s. to 12s. per 100, according to quantity and number of subjects. In the case of photographs for the Press, half-plate prints full of detail are preferred. A country photographer should arrange with an agent in London who sells photographs on commission to the various newspapers. The work needs to be done quickly. For dinner and ball-room groups a good flashlight apparatus is needed. Some photographers make a speciality of machinery photographs, and now that photographs are so much used for illustrating catalogues, this branch should by no means be neglected. For this class of work an air-brush, costing about seven guineas, is almost a necessity, as large spaces have often to be stopped out or retouched before the picture is fit for reproduction. Enlargements, miniatures, and fancy printing on opal, etc., are at first best left to trade printers, but the first-mentioned branch can easily be undertaken by the photographer, and it pays well if a special line be made of framed enlargements.

A side line neglected by professional photographers is the supply of plates, papers, and apparatus to amateurs. The article on Photographic Dealers should be consulted for details of this trade.

Frames and Framing. A valuable adjunct to the photographer's business is the sale of photograph frames. It is no use going in for this department unless the photographer has a really fine selection of frames and in all sizes—round, square, landscape and midgets. There are several styles which allow the frames to be used either upright or lengthways—for views or portraits. Midgets with round or oblong openings cost 3s. 6d. per dozen and sell at 6d. each. Carte-de-visites with round or oblong openings cost 5s. per dozen, and sell at 9d. each. Cabinets with round or oblong openings average 7s. 6d. per dozen, and sell at 1s. each. The panel cabinet size-frame either round or oblong costs 15s. per dozen, and sells at 2s., while the boudoir frame costs 17s. per dozen and sells at 2s. 6d. Picture framing [see Picture Framers] should also be a department of a photographer's business.

Advertising. Advertising is much neglected by photographers. If more price lists were distributed more people would be led to have their pictures taken. Make a special offer of a certain style of photograph or enlargement, but in so doing do not make a mistake of cutting prices; rather, make the quality and style better than charge a cheap-jack price. When sending home proofs enclose a price list of various styles in which the photographs can be printed, even though the customer has paid for the sitting. In many cases a few additional prints are ordered because some variation in style is fancied. The proofs sent should be from retouched negatives, and are best on printing-out paper. They should be stamped "to be returned," and, in case of neglect, should be charged for in the number ordered.

Profits. The photographer should obtain good profits, as his business is not on a par with one where goods are simply handed over the counter. Each customer has to be studied so as to get the best results in a photograph, and considerable artistic ability is required to retouch a negative and finish a photograph. These must be paid for as they involve an expenditure of time. The writer, endeavouring to work out the cost of carte-de-visites and cabinets on printing-out paper arrived at the figures 3s. and 5s; on platinum, the cost would be 4s. and 6s. 6d. As a matter of fact, it is not possible to arrive at the exact cost as it varies according to the extent of the business, but it may be taken that the gross profit is 50 per cent. on the turnover. A source of much loss with many photographers is the waste of material that goes on. Spoilt plates and paper, and wasted solutions, especially if the last-named contain the precious metals, account for a respectable leakage in profits. The leakage can be stopped by proper supervision and systematic working.

PHOTOGRAPHIC DEALERS

Photography is essentially a summer pursuit, and a business which has only a few months of activity is not a desirable one. Steps have been taken to educate the public to winter photography and magic-lantern work; but it is only the enthusiast who can dabble in ice-cold water and pretend that he likes it. Lantern work tends also to make the hobby expensive.

Qualifications. The photographic dealer should have a taste for scientific pursuits and, above all, should practise photography himself.

There is no apprenticeship in the business; the embryo dealer starts as a junior assistant, and works his way up. Wages are not on a liberal scale; 30s. to 45s. a week are fair averages for junior and senior assistants of experience, and it is not astonishing that any young man of enterprise and small capital soon looks about for a neighbourhood where he can set up in business for himself.

The best neighbourhood is obviously the busy residential suburbs of great towns or seaside resorts. Near public schools a photographic dealer can generally make a living as successive

generations of schoolboys take up the fascinating and educative art. It is true that it is often taken up for only a few months, but even this means a considerable expenditure in outfits. The boy's parents probably start the youth with a camera, as a birthday or season gift, unmindful of the fact that the camera is the least expensive part—comparatively speaking—of an energetic photographer's outfit.

The Dark-room. In connection with a photographic dealer's business, provision should be made for a dark-room for the use of amateurs. The room should be lighted by sliding shutters on the window and the source of light for the ruby lamp should be gas or electric light. Means must be adopted for obtaining white light at will, as some printing processes require a white light for a few seconds at a time. A by-pass is a useful addition to the gas burner, but with electric light a separate lamp for white light is readily fitted alongside the ruby lamp. The walls should be painted a dull lead colour, the same treatment being applied to the ceiling. Water should be laid on, and beneath the tap should be a porcelain or lead-lined sink. The tap to the water-pipe should be fitted with a reducing nozzle, and a rose cap is an advantage. The developing space should be on one side of the sink, and arranged so that splashes of developer and water drain away to the sink. Shelves underneath the sink and the developing bench should be fitted up for the dishes, while on the walls shelves are placed for the developing solutions and measures. Another table should be provided for the dark slides while filling them or while the plates they have contained are being developed. This table should be arranged at the opposite side of the room from the sink, so that it is not likely to get splashed. It is an advantage to have it away from the light, as plates should not be exposed even to red light unnecessarily. The room should be well ventilated. Any carpenter will understand when it is explained to him that he must make the ventilators light traps. The inside of the door also must be trapped round the edges, but this may be rendered unnecessary by the provision of a curtain on the outside. The door should lock on the inside so as to prevent the possibility of disturbance at critical periods of plate changing or developing. A refinement in dark-room doors is to have two doors separated by a lobby so that a person can enter the room without admitting light. In large photographic businesses several dark-rooms are provided. To casual customers a small charge—minimum, 6d.—is made for the use of the dark-room for plate changing, but if the customer be also a purchaser of goods at the shop it is unwise to press the charge. When the room is used for developing plates a charge of 1s. is made, this amount covering the use of the room for an hour.

Capital Required. The amount of capital required for starting the business of a photographic dealer depends upon whether it is to be subsidiary to another business, or to be mainly photographic requisites. When started in connection with a drug business, a ten-pound note would suffice to stock the most frequently required apparatus and plates, the chemicals being already articles of stock. Great care must be taken not to lay in a stock of plates and papers that will last beyond the season, as these goods do not keep well. It is better to replace the stock of perishable goods entirely each season, selling off the remains of last season's goods at sale prices to clear. When a new business is being started, the amount of capital will depend, in a measure, on the neighbourhood, but for the purpose of this article £100 is taken as a medium figure. It will be noted that no special brands of goods are mentioned, this being a matter which depends upon the wholesale house with whom the order is placed. It is also understood that the beginner desires scope for his energies in selecting the goods his experience suggests, and most suited for the requirements of the neighbourhood. There are new papers and plates being introduced every year, and fashion in cameras changes from season to season. This is especially the case with hand cameras, where last season's goods are looked upon as old-fashioned. This is a reason for caution in buying.

Estimate for a £100 Stock. The following is an approximate estimate of the manner £100 would be laid out in stock for a photographic dealer. The list was originally printed in the "Photographic Dealer's Annual."

	£	s.	d.
Two ¼-plate stand camera sets	2	2	0
One ½-plate stand camera set	3	10	0
One ½-plate high-class camera set, with 3 dark slides	6	0	0
Three daylight spool cameras, 1, 2, and 5 guineas	8	8	0
One flat film hand camera	3	0	0
Two magazine ¼-plate hand cameras	2	2	0
Two each camera cases, ¼-plate and ½-plate	0	9	0
One each camera case, solid leather, ¼-plate and ½-plate	1	6	6
Three camera levels	0	3	0
Three carriers, ½-plate to ¼-plate	0	2	6
One exposure meter	0	7	0
Three focussing cloths	0	4	6
Three each focussing screens, ¼-plate and ½-plate	0	1	9
Two focussing glasses	0	3	0
Two each R R lenses, ¼-plate and ½-plate	3	10	0
One anastigmat lens, ½-plate	8	0	0
One W A lens, ¼-plate	1	15	0
Two each roller blind shutters, T. and I., ¼-plate and ½-plate	3	18	0
Two each S S. shutters, ¼-plate and ½-plate	1	14	0
Two cheap drop shutters	0	3	0
Two tripod stands and tops, 3-fold	0	16	0
Two tripod stands, 2-fold	0	8	0
Two tripod stands, aluminium telescopic	1	1	0
One brilliant view finder	0	3	6
Two hand camera view finders	0	2	6
12 albums, assorted, for C.D.V., ¼-plate; cab., and ½-plate	0	15	0
Three camelhair brushes, 2 in.	0	2	0
Six 1s. handbooks on photography	0	6	0
Three each, cutting shapes, C.D.V., ¼-plate, cab., and ½-plate	0	6	3
Three boxes dark-room pins	0	1	6
Six bottles 6d. mountant	0	3	0
12 each deep porcelain developing dishes, ¼-plate and ½-plate	0	17	0
Six ditto, 10 in. by 8 in.	0	8	6
Three ditto, 12 in. by 10 in.	0	6	9
12 each composite celluloid dishes, ¼-plate and ½-plate	0	13	0
Three metal racks and tanks	0	4	6
Three each folding racks, ¼-plate and ½-plate	0	5	3
90 doz. ¼-plates, assorted brands	4	10	0
54 doz. ½-plate ditto	6	1	6
12 doz. 5 in. by 4 in. ditto	0	10	0
9 doz whole-plate ditto	1	18	3
12 doz lantern plates	0	12	0
Three yards ruby and orange fabric	0	3	0
Six 1s. ruby lamps	0	6	0

	£	s.	d.
Three 4s 6d. ruby lamps..	0	13	6
Six ruby lamps, assorted, for candle, gas, and oil	1	0	0
Three hock bottle lamps..	0	3	0
Assortment G.B.E. mounts for C.D.V., ¼-plate, cabinet, and ½-plate	1	10	0
Assortment slip-in mounts for ¼-plate and ½-plate	1	0	0
Assortment paste-down mounts for ¼-plate, ½-plate, whole plate, 10 in. by 8 in., 12 in. by 10 in. prints	1	10	0
Assortment fancy mounts..	0	15	0
36 packets ¼-plate gelatino-chloride paper, assorted brands	1	16	0
45 packets cabinet ditto	2	5	0
18 packets ½-plate ditto	0	18	0
12 packets whole-plate ditto	0	11	6
12 packets ¼-plate bromide paper	0	6	0
12 packets ½-plate ditto	0	13	0
Six packets whole-plate ditto	0	11	6
Three packets each, 10 in. by 8 in., and 12 in. by 10 in., bromide paper	1	0	0
One packet 15 in. by 12 in. ditto	0	6	6
Six ¼-plate wood negative boxes for 50 ..			
Four ½-plate ditto..			
Two japanned negative boxes, ¼-plate and ½-plate, for 12			
Two plate and print washers	0	9	0
12 each ¼-plate and ½-plate printing frames ..	0	16	0
Six each, 5 in. by 4 in., ditto	0	4	0
Three whole-plate ditto	0	5	3
Six print trimmers	0	3	0
One blade print trimmer	0	7	6
Three zigzag print trimmers	0	3	0
One retouching desk	0	8	6
Three retouching sets	0	3	0
Three sets hand scales, glass pans	0	6	0
Three sets pillar scales, ditto	0	16	6
Six roller squeegees, 4 in.	0	6	0
Three ditto, 6 in.			
Three each ¼-plate and ½-plate glass vignettes			
Assortment of plain and stoppered bottles ..			
Three dropping bottles		1	0
Three packets each, ¼-plate and ½-plate, backing paper		3	
Six ferrotype plates	0	2	

	£	s.	d.
Three packets masks and discs	0	6	
Six assorted lens caps	0	3	
Two each ¼-plate and ½-plate cloud negatives	0	2	
Two rose sprays	0	3	
Three each 2 dr, 2 oz., and 20 oz. measures ..	0	10	
One developing sink	5	5	
Small sundries	2	10	
	£100	0	0

The discount on this estimate would amount to between £25 and £30, which should be spent in the purchase of chemicals from the list which follows.

Photographic Chemicals. The list below shows the approximate cost and retail price of the chief chemicals used in photography, and also their uses. The prices do not, as a rule, include the bottles in which the chemicals are sold. Wholesale photographic warehouses supply most of the chemicals bottled in small quantities (1 ounce, 2 ounces, and 4 ounces), which is a convenience to dealers, but it is cheaper to purchase in bulk and to re-bottle into smaller containers if required. There are chemicals used in photography other than those given in the list, but all chemicals have been included which have a regular sale among amateurs and photographers. The chemicals should be kept in large bottles distinctly labelled, so that no mistakes can be made. The names printed in italics in the following list are alternate designations.

Put-up Goods. The photographic dealer will require to keep ready-made developers and

NAMES, COST AND USES OF THE CHIEF PHOTOGRAPHIC CHEMICALS

Name of chemical.	Wholesale price.	Reta price.	Uses.
Acetone	1s. 6d. lb.	3d. oz.	Instead of alkali in developer.
Adurol	1s. 8d. oz.	2s. 6d. oz.	Developer.
Aluminium powder	7s. 3d. lb.	1s. oz.	For flashlight.
Alum, powder	1s. for 7 lb.	4d lb.	Hardener for plates and paper.
Amidol	1s. 8d. oz.	2s 6d. oz.	Developer.
Ammonia, 880°	6d. lb.	2d. oz.	As alkali in developer.
Ammonium bromide	3s. lb.	6d. oz.	As restrainer in developer.
Ammonium sulphocyanide	2s. lb.	3d. oz	Constituent of toning bath.
Benzol	1s. 6d. pint	2d. oz.	Solvent for wax.
Borax	5d. lb.	1d. oz.	In toning bath.
Calcium chloride	10d lb.	3d. oz.	Siccative for platinum paper.
Cotton wool	1s. 4d. lb.	2d oz.	For filtering.
Eikonogen	12s. lb.	1s. 2d. oz.	Developer.
Formaldehyde	1s. 6d. lb.	3d. oz.	Hardening gelatine films.
French chalk	6d. lb.	1d. oz.	Cleaning glass plates.
Gelatine	3s. lb.	3d. oz.	As mountant.
Glycin	1s. 8d. oz.	2s. 6d. oz.	Developer.

* Can be sold only by chemists † Vendor must hold a licence

other solutions for his customers. These can be bought from a wholesale dealer, but if made by the retailer yield better profits. In making up developers distilled water should be used, as this makes clearer solutions. Good corks must be used, and, before putting them into the bottles, they should be dipped into melted paraffin wax to keep them from contact with the solutions. The bottles should be preferably of some distinctive shape, and if of amber colour the contents are not likely to be mistaken for medicine. Many photographic solutions are poisonous, but it is well to avoid giving the impression to customers. A stock of printed labels should be bought, upon which are given the directions and the name of the dealer. These cost about 5s. for 250, and are cheaper still in lots of 1,000.

It is fashionable to have developer in the form of tablets, and they are a great convenience when travelling. Most of the wholesale houses supply these, and will put the dealer's name on the packet when a fair quantity is bought. Branded kinds are made by Powell, called "Developoids," and Burroughs Wellcome & Co. call theirs "Tabloids." To use these tablets, they are crushed to powder in a little water, and the necessary quantity of water added.

Side Lines. It is becoming increasingly popular for amateurs to hand over their exposed plates, or films, to the photographic dealer for development and subsequent printing. Some amateurs do their own development, and hand the negatives over for printing. The profits are from 20 to 25 per cent on this class of work.

Repairs to cameras and apparatus should be undertaken, and arrangements made with a manufacturer for promptness in carrying out this work. Often a customer needs some adaptation. It is quite usual to have to fit filmholders to cameras originally made only for plates.

The hire of cameras is another branch of the dealer's business. A few good cameras accumulate through being shop-soiled, or possibly by exchange with a customer requiring a new instrument. The cameras should be in perfect order, and if the customer is unknown, a deposit up to the value of the apparatus should be insisted upon. The charge for apparatus is 5 per cent. of the value of the camera per week, with a minimum of 5s. The charge for the hire of a camera for a single day should depend on the class of apparatus; but a minimum should always be fixed, as the convenience of hiring is one for which a customer should expect to pay.

Lantern slides are let out on hire at many large photographic dealers, the charge for the hire of a set of slides being from 1s. to 2s. per night, the customer paying carriage.

Picture postcards are sold at present by many shopkeepers besides the photographers; but a photographic dealer specialising in high-class local views can be sure of the best class of trade.

Picture framing is suitable for this business, as photographic enlargements are generally incomplete without a frame [see Picture Framers].

Advertising. The photographic business lends itself in a peculiar manner to advertising. The makers of plates and papers supply specimen photographs taken on the articles of their manufacture, and very beautiful some of these prints are. It is, however, preferable that the displayed pictures should be of local interest, and if the photographic dealer be a practical man—and he should be—he will have no difficulty in making suitable prints for display in window and shop. The public will always stop and look at a picture, and they are much more interested if it is of a familiar scene, or of a curious out-of-the-way subject. A label, "Taken with our two-guinea camera," should be affixed to suitable specimens. An additional attraction is to be found in having an enlargement of unusual size in the shop. Such a specimen could be designed to show the degree of enlargement that photographs taken with a certain lens will bear, or it may be a specimen of the work that can be done from customers' own negatives. In dressing the window care must be taken to use only dummy packets of plates and paper, which can be obtained from the manufacturer. The window must be shaded from the sun, as the coloured leather of camera bellows bleaches if exposed to bright light for long.

A stereoscope on the counter, with a plentiful supply of stereographs, is good for amusing customers who are kept waiting, and a selection of the newest books and journals on photography should be placed within reach of the amateurs who frequent the shop. Several publications contain lists of photographic dealers and darkrooms, and, as names are inserted free of charge, there is no reason why the dealer should be backward in supplying the information. "Photogram" supplies an outside sign for dealers' use, which is useful in places where tourists are found. If there be a local photographic society, the secretary should be asked for a list of members, and the dealer should be unceasing in sending each member price lists and catalogues of novelties. Very nicely produced catalogues, which the dealer can adapt for his own use, are supplied by the wholesale houses, and bills and folders are sold by those who specialise in photographic printing.

Profits. The profits are good, but this should be qualified by the statement that much soiled stock is likely to accumulate if business is not brisk. The sale of such stock is, perforce, done at reduced rates, and, consequently, is profitless in some senses. The question of branded goods is one which troubles the photographic dealer. It is necessary in the case of plates and papers; but the extension of branded goods to the details of the business should be discouraged as much as possible, as branded goods may be cut in price, and injure the profits considerably. Price protection is in vogue in many photographic articles, and the profits are thus maintained. On apparatus and accessories 33⅓ per cent. profit is allowed, varying with the kind of goods, but some proprietary articles allow a profit of only 10 to 15 per cent.

DRAWINGS OF ENGINE DETAILS

Cylinders. Pistons. Crossheads. Connecting Rods. Crankshafts. Flywheels. Eccentrics. Valves. Pumps

continued from page 4329

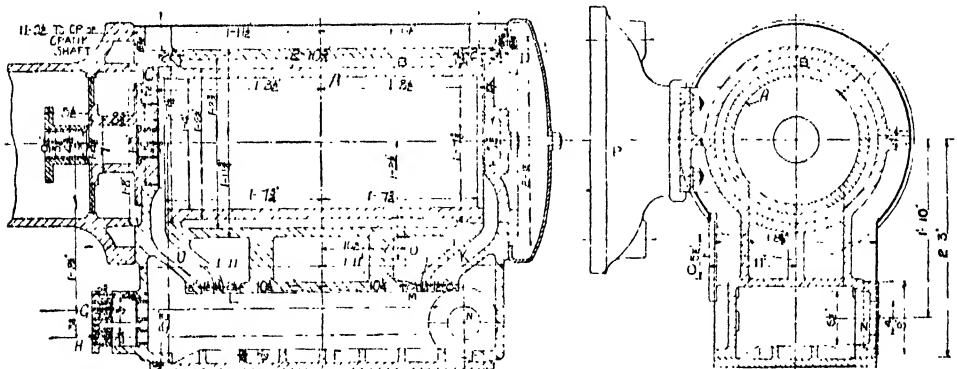
By JOSEPH W. HORNER

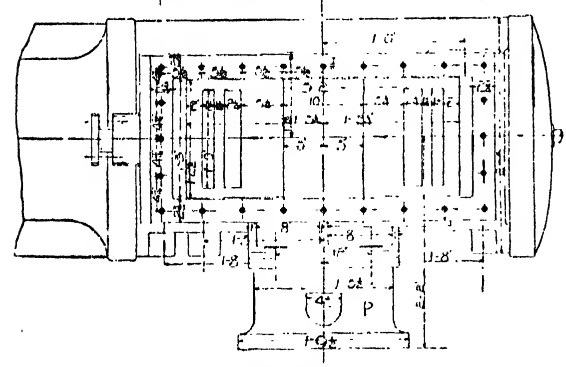
Cylinders. One of the principal *detail drawings* of an engine is that which represents the cylinder or cylinders. Fig. 152 shows a drawing of the high-pressure cylinder of a compound engine; the bore is 16 in. and the stroke of the piston is 36 in. The liner, A, is cast of harder metal than the cylinder body, and is forced into place by hydraulic pressure; the space, B, between the liner and the body is frequently used as a steam jacket—that is, live steam is admitted to the space in order to keep the temperature of the liner as uniform as possible. Small engines are not usually so made, but the cylinder body is simply bored out for the passage of the piston. The thickness of cylinder walls and liners is largely determined by practice; it is seldom less than $\frac{5}{8}$ in. for cylinders up to 10 in. bore; above 10 in. the following formula may be used:

$$T = \frac{D \times P}{3{,}000}$$

where T = thickness required, D = diameter of cylinder, and P = steam pressure in pounds per square inch. It would not do to simply calculate the thickness necessary to withstand the bursting effort of the steam pressure; there must be sufficient metal to ensure rigidity and to stand reboring after wear has taken place.

The cylinder ends and covers, C and D, are slightly thicker than the cylinder walls; the size and pitch of the studs or bolts which secure the cover affect its thickness to some extent. A good rule is to make the cover and the flange of the cylinder $1\frac{1}{4}$ times as thick as the cylinder itself, then the studs may be pitched $4\frac{1}{2}$ diameters apart for steam pressure up to 100 lb. per square inch, and $3\frac{1}{2}$ diameters apart up to 160 lb.





152. ENGINE CYLINDER

The diameter of the cover-studs is determined by calculating the load upon the cylinder cover, and apportioning sufficient area in the studs to meet the load; a safe stress is 3,000 lb. per square inch of stud area. Care must be used in taking the area at the bottom of the thread [see Table on page 3005]. Studs smaller than $\frac{5}{8}$ in. diameter are not to be recommended for covers, as they are liable to damage in tightening up with an ordinary spanner. The covers of small cylinders are made with a single sheet of metal; for medium cylinders this sheet is strengthened with ribs, while for large cylinders the covers are made hollow with internal ribs.

The front cover, C, is cast with the cylinder, and has a stuffing-box, or gland, fitted for the piston-rod to work through.

The Valve-chest. The valve-chest forms part of the cylinder casting, is of sufficient size to accommodate the valves, and is provided with a cover, F, and stuffing-boxes, G and H; the box G is for the main-valve spindle, and the

box H for the expansion-valve spindle. Steam-ports, U and K, are arranged from each end of the cylinder to the valve-chest; the ports L and M are for the exhaust steam. The area of the steam-ports should be such that the steam does not flow at a greater velocity than 6,000 ft. per minute, while the area of the exhaust port should allow a velocity of 4,800 ft. per minute; the calculation is then:

$$\text{Steam-port area} = \frac{\text{area of piston} \times \text{piston speed}}{6{,}000};$$

$$\text{exhaust port area} = \frac{\text{area of piston} \times \text{piston speed}}{4{,}800}.$$

The length of the port—that is, the dimension measured at right angles to the length of the cylinder—is usually three-quarters of the cylinder diameter, and this being settled, the width of the port is easily calculated from the area. The wider the port the greater the travel of the valve, and it is sometimes necessary to make the port as long as the cylinder diameter in order to restrict the travel of the valve.

Steam is admitted to the valve-chest by the opening N, and exhaust steam leaves by the opening O, both of these apertures having facings to which pipe-flanges connect.

The front end of the cylinder is supported by the end of the main frame casting; a foot casting, P, takes the weight of the cylinder to foundation. Bosses are cast on for attaching a drain-cock at the end of the cylinder, a drain-cock for the jacket, and an indic[illegible] cock at e[illegible].

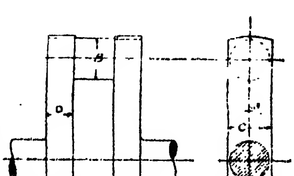
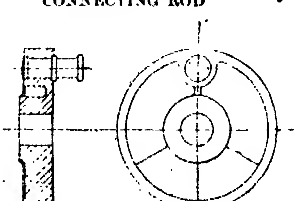
160. SMALL END OF CONNECTING ROD



161. FORGED DOUBLE CRANK



162. CRANK DISC

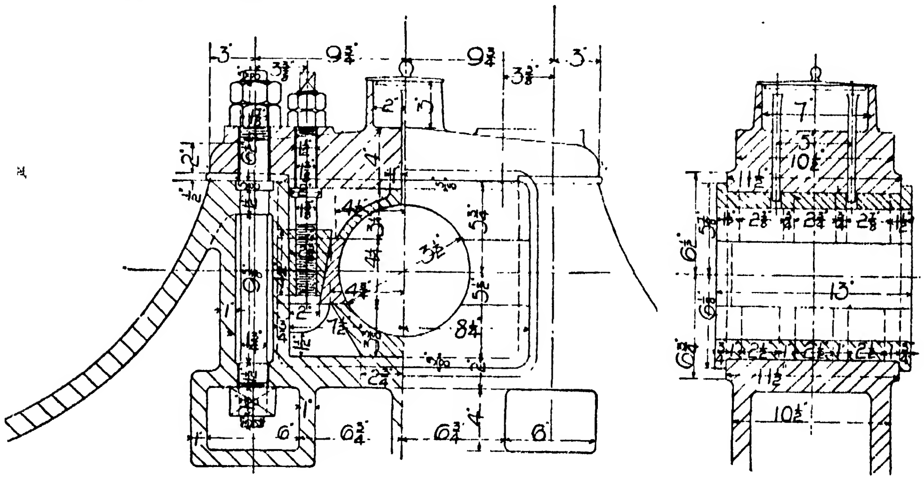
The whole cylinder is lagged and finished off neatly with sheet steel, a dished casting being fitted over the back cover.

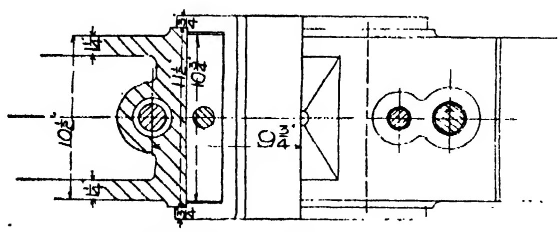
Clearance. The length of a cylinder is always slightly greater than the stroke plus the thickness of the piston—that is, there is a small space allowed at each end of the stroke. This space is termed *clearance*, and is necessary in order to prevent the piston coming into contact with the cylinder covers; it should be kept as small as possible, and may range from $\frac{5}{16}$ in. in small engines to $\frac{1}{2}$ in. in large ones. This space must be taken into account when calculating the amount of steam used in an engine; the same remark applies to the capacity of the steam-ports, as these have also to be filled and emptied at each stroke. The total clearance space in an ordinary engine is usually from 3 per cent. to 6 per cent. of the actual volume swept by the piston in its stroke.

Piston. A piston is not quite such a simple article as would appear at first sight, and, as a matter of fact, there are scores of different types in existence. The simplest form is shown in 153, and consists of a cast-iron body having three rings let into recesses; these rings are made slightly larger than the piston body, and are then cut through diagonally in one place; they are sprung into position on the piston and squeezed into the cylinder. The effort of the compressed rings is to expand constantly, and the resulting pressure on the walls of the cylinder makes

the piston steam-tight. These are known as Ramsbottom rings, and are made of steel, but cast iron wears better. When made of the latter metal they should not be less than $\frac{3}{8}$ in. wide. Another form is shown in 154, which presents a larger wearing surface than 153. There are two rings, both of which are cut through diagonally; a large spiral spring forces them outward to make them steam-tight against the cylinder. Such rings cannot be sprung into place, so the piston is made in two parts. The body, A, is a hollowed casting, as shown in 154, and a loose ring, B, termed a *junk ring*, is secured to the piston body and serves to keep the rings in place. The depth of a piston may be from a quarter to half of the diameter of the piston.

frame 135, page 4203. The end of the piston-rod is swelled up to receive a half brass, and to accommodate the cap-bolts of the other half brass; provision is also made for bolting on the cast-iron slipper which runs between the guide-bars. The cap and rod are of mild steel, and the slipper is easily renewed when worn. Fig. 156 illustrates a heavier type of crosshead made with double slippers, to bear on double guide-bars; reversing engines should have double guides. Looking at the diagram [157], and considering the engine to be running in the direction of the arrow A, it is evident that both the piston-rod and connecting rod are in a state of compression during the outward stroke; there is consequently a downward force acting on the crosshead, which





163. MAIN BEARING

is supported by the guide-bar. Now consider the return stroke, as shown in dotted lines. Here the piston-rod and connecting rod are in a state of tension, and consequently there is again a downward force on the crosshead. In fact, so long as an engine runs in one direction, the pressure on the guide-bar is always in the same sense. If the engine be reversed, then the direction of the force on the crosshead is reversed, and means must be provided to support it. The example given [156] is in general the same as 155, but the slippers are larger, and are secured to the forging by studs and square keys as shown.

Adjustment for wear is made by means of wedges let through the keys; these wedges are moved by the nuts on their screwed ends; the main bolts have lock nuts similar to those in 37 on page 3007. Crossheads are also made to work in circular bored guides, the slippers being turned to suit.

The diameter of the piston-rod may be calculated by the use of the formula:

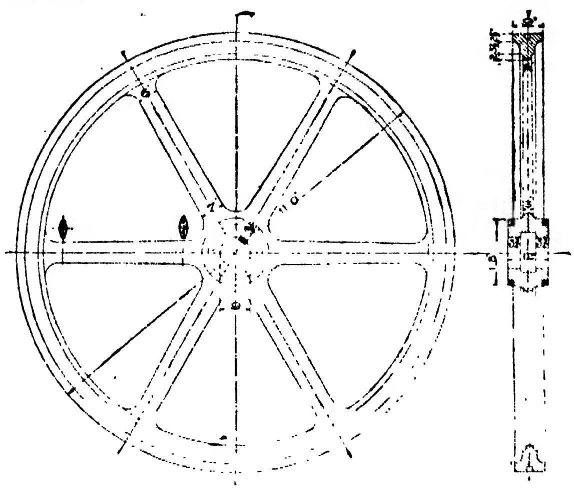
$$d = \cdot 013\sqrt{DLP},$$

where d = diameter of rod,
D = diameter of cylinder,
L = length of rod in inches,
P = steam pressure in pounds per sq. in.

The attachment of the piston to the rod is usually made with a taper end and nut, as shown in 153, but the taper is not absolutely necessary, for a parallel neck could be used and a shoulder or collar provided at the front end. A good taper is $1\frac{1}{4}$ in. of diameter to 12 in. of length.

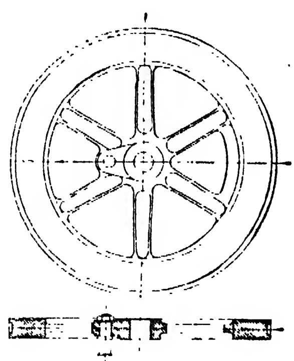
Crossheads. Crossheads are made in great variety; 155 shows a single slipper crosshead, such as might be applied to the engine frame 135, page 4203.

Connecting Rods. Fig. 158 shows a connecting rod of marine type suitable for working with the crosshead illustrated in 155. The end

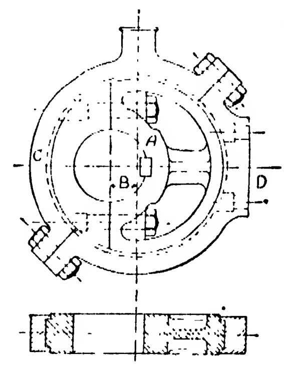


164. ENGINE FLYWHEEL

is forked to embrace the crosshead, and the pin is kept from turning by means of a small stop-pin, as shown; the rod is circular, and is forged with a head-piece to take the gunmetal wearing-blocks. These blocks are divided at the centre, and are held together with two bolts passing through them. An outer steel cap takes the bending movement due to the pull on the rod. The nuts on the bolts are similar to 37, page 3007, but the steel cap receives the locking screw in place of a separate collar; in small engine work it is usual to use ordinary double nuts. Connecting rods, like piston-rods, are subjected to alternate tensile and compressive loads. As they are weakest in compression, they are designed as struts or columns, but allowance must be made for the inertia of the rod itself, and this factor—especially in high-speed engines—makes the calculation quite a complicated one. The following empirical rule due to Seaton agrees closely with modern practice:



165. PUMP FLYWHEEL



166. ECCENTRIC

Diameter of connecting rod in middle $= \dfrac{\sqrt{LK}}{4}$

where L = length of connecting rod in inches

and K = ·03 × $\sqrt{\text{load on piston in pounds}}$.

The length of a connecting rod is usually two and a half to three times the stroke of the piston. Figs. 159 and 160 show two other types of connecting-rod ends, both of which have solid ends and adjustable brasses. The former is adjustable by cottar, and has a Babbitt lining; the flanges of the brasses are left off on the top and bottom on one side so that the brasses may be put in place sideways. The example 160 is used for the crosshead end of the rod, in which case it enters a socket in the crosshead; it is adjustable by means of a wedge-block and nuts, as shown. The crankshaft end of a connecting rod is termed the *large end*, and the crosshead end is termed the *small end*.

Crankshafts. The Board of Trade rules for marine crankshafts are as follows:

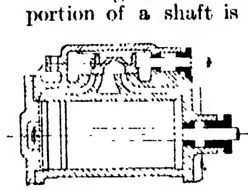
Let S = diameter of shaft in inches.
P = absolute boiler pressure.
C = length of crank in inches.
D = diameter of low-pressure cylinder.
d = diameter of high-pressure cylinder.
f = a factor depending upon angle of crank.

For compound condensing engines with cranks not overhung,

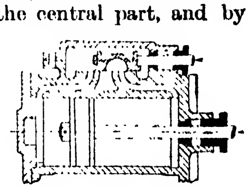
$$S = \sqrt[3]{\frac{C \times P \times D^2}{f\left(2 + \frac{D^2}{d^2}\right)}}$$

The values for f may be taken from the table on the next page.

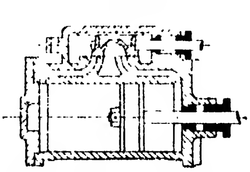
Ordinary crankshafts with overhung cranks may be calculated for combined bending and twisting in a similar manner to the example given in 49 on page 3135. Hollow shafts are made in order to save weight of material; the least effective portion of a shaft is the central part, and by



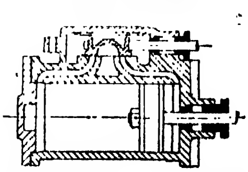
167. VALVE ADMITTING STEAM



168. VALVE FULL OPEN FOR STEAM



169. VALVE CLOSED FOR STEAM



170. VALVE CLOSED FOR EXHAUST

removing it the weight of the shaft is diminished in a greater proportion than the strength.

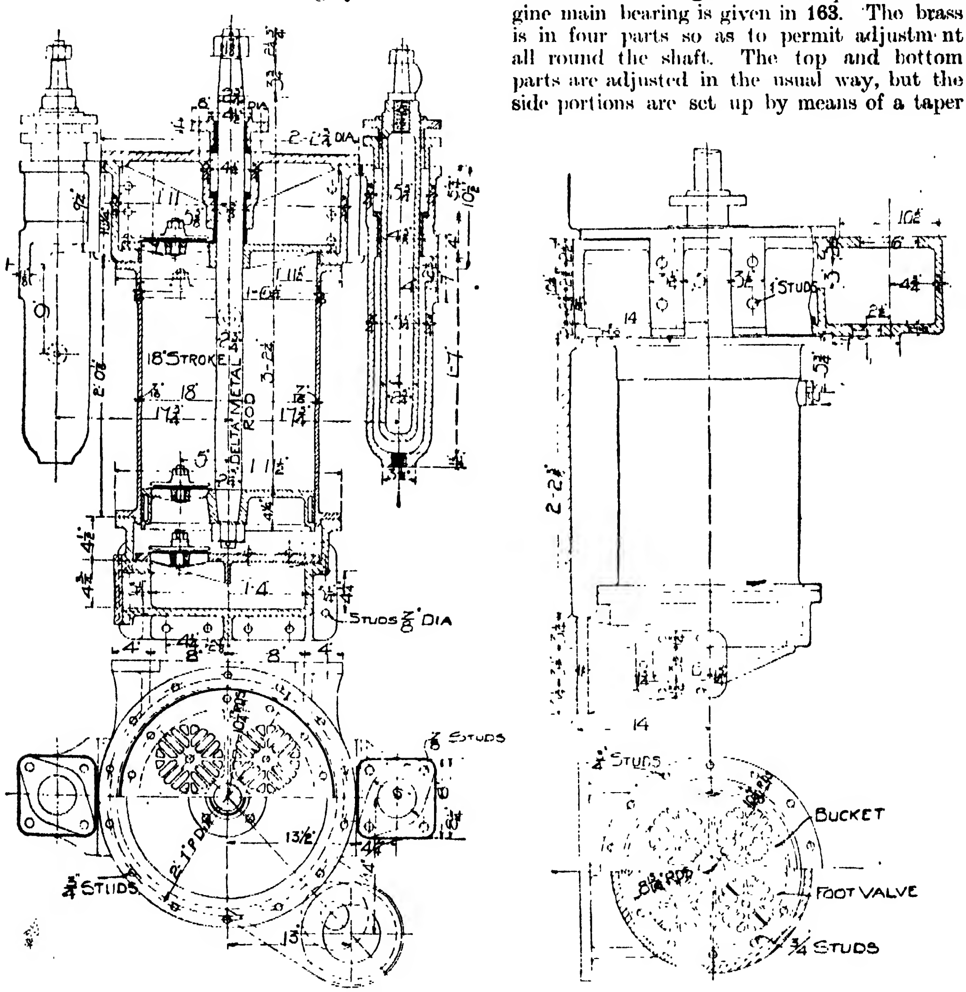
Angle between cranks	90°	110°	120°	140°	160°	180°
Value for f ..	1047	904	855	788	751	740

The modulus of a hollow circular section is found by subtracting the moment of inertia of the inner diameter from the moment of inertia of the outer diameter and dividing by the radius of the outer diameter. A table of moments of inertia is given on page 3134.

Cranks may be forged with the crankshaft, or they may be separate pieces keyed on the shaft. A forged crank is shown in **161**: it is generally machined all over, and the ends turned in the lathe about the centre, A. The diameter of the pin, B, is usually the same diameter as the shaft; the width, C, is one and a quarter times the shaft diameter, and the thickness, D, is three-quarter times the shaft diameter. The cranks and pin may be separate pieces; in which case the cranks are swelled out to fit over the shaft and over the pin; the thickness of metal allowed in the swelled parts should not be less than ·4 of the shaft diameter.

Cast-iron crank discs are made as **162**, the crank-pin is fitted in tightly, and the end riveted over; the metal is thickened up at the side opposite the pin for the purpose of balancing the connecting-rod head.

Main Bearings. An example of an engine main bearing is given in **163**. The brass is in four parts so as to permit adjustment all round the shaft. The top and bottom parts are adjusted in the usual way, but the side portions are set up by means of a taper block and screws, as shown; the drawing explains itself.



171. AIR AND BILGE PUMPS

Flywheels. The theory of flywheels is discussed on page 2018 in Mechanical Engineering. Fig. **164** shows an ordinary flywheel; the rim is solid and is arranged with pockets round the periphery; these pockets are used for starting the wheel from rest when the engine is on dead points. The appliance which effects the starting is termed a *barring gear*, and may range from a simple lever to a separate small engine. The arms of the

wheel are oval, and they taper from the boss to the rim. The boss has wrought-iron rings shrunk on to give it increased strength.

A smaller flywheel is shown in **165**; the arms are rectangular in section, and cranks are cast with the boss; such a wheel would be used on a small pumping engine. The inside of the rim opposite the crank-pin is thickened up to balance the pump-rod head.

Eccentrics. Eccentrics are used to give reciprocating motion to the valve-rods on an engine; a common example is shown in **166**. The inner part, or sheave, A, is keyed to the shaft; the centre of the sheave does not coincide with the centre of the shaft; the distance apart, B, of the centres represents half a stroke of the strap C, and the eccentric rod is bolted up to the end, D. Both strap and sheave are in halves for convenience of renewal, but the sheave is not always in halves; the straps must be made so on account of getting over the register, which keeps it sideways.

Valves. A simple D valve is shown in various positions of stroke in **167** to **170**; the stroke of the valve is due to the eccentric. In **167** the valve is just open to steam, the piston is at the beginning of its stroke, and the connecting rod and crank are in a horizontal line—that is, on dead centres. The exhaust port is nearly full open. In **168** the valve is full open to both exhaust and steam, the piston is travelling along the cylinder, and the crank is at 45 deg.

In **169** the valve is reversed by the eccentric, and has closed the steam-port, the piston is moving forward under the influence of the expanding steam, and the exhaust is partially closed; the crank is well over 90 deg. In **170** the exhaust is closed, and the valve is moving to open steam for the reversal of the piston stroke. There are many types of valves in use, but their duties are all identical—namely, to regulate the flow of steam and exhaust to and from the cylinder economically.

Pumps. An air-pump together with two bilge-pumps are shown in **171**. The air-pump is of brass, though not necessarily so, and the thickness of its walls is kept down to a minimum, as the metal is expensive. The piston is termed a *bucket*, and is fitted with non-return valves for lifting water; the top and bottom of the pump are fitted with separate plates carrying similar valves. The bilge-pumps are of heavier metal, as they have to pump against a head; they are used for pumping the bilge-water from steamships. The plunger displaces a volume of water equal to its bulk at each stroke. Both bilge-pumps and the air-pump are driven from a single crosshead, operated by the air-pump levers. The bilge-pump valves are simple in construction, and are fitted in the piping connected to the pumps.

In an engine fitted with a jet condenser, the air-pump has to remove the condensed steam, the water used for condensing the steam, and the air which enters with the water. In a surface condensing engine the air-pump removes the condensed steam and any air which may enter the engine; the condensing water in such cases is dealt with by separate pumps, termed *circulating* pumps.

Size of Air-pump. The size of the air-pump for a condensing engine may be determined by the following rule:

$$\text{Volume of air-pump} = \frac{\text{Indicated H.P.}}{\text{revs. per min.}} \times C$$

where C = 700 for single-acting and jet condenser,

C = 300 for single-acting and surface condenser,

C = 470 for double-acting horizontal pump and jet condenser.

Another rule is to make the capacity of the air-pump one-twelfth of the capacity of the low-pressure cylinder. There are so many contingencies to be allowed for in the working of an air-pump that pure theory cannot be relied upon in the design. The action of the pump is not perfect inasmuch as it does not remove at each stroke an amount of water, etc., equal to its capacity. Ordinary pumps are defective enough in this respect, but air-pumps, and particularly vertical ones, are very inefficient. The speed of the pump affects its efficiency to a great extent; the best results are obtained at a bucket-speed not exceeding 200 ft. per minute; many examples are, however, to be found running at as high a speed as 450 ft. per minute at a lower efficiency.

The limit of speed is that at which the water can follow the bucket and so provide a full barrel for the next stroke, and this in turn depends upon the vacuum maintained. The pressure of the atmosphere is 14·7 lb. per square inch, and a good vacuum is 2 lb. per square inch; it is not possible to maintain a perfect vacuum in practice. The theoretical velocity of water under a pressure of 2 lb. per square inch is 1,025 ft. per minute, but it would not do to speed the pump bucket accordingly. Allowance must be made for friction, for the inertia of the water, and for the presence of air and gases in the water; this can only be determined by practice, and the speed range of 200 ft. to 450 ft. per minute as given above is deduced therefrom.

Fouls. It will be noticed upon examination of the sectional elevation of **171** that one bucket valve is shown dotted at the upper end of the stroke, while the bucket itself is shown at the lower end of the stroke; there is an object in doing this, and one which must be ever present with the designer of moving machinery.

Wherever one part of a machine moves relatively to another part it must be drawn in its extreme, and sometimes intermediate, positions in order to avoid fouls. All the various movements must be carefully plotted on paper beforehand in such a way as to ensure the complete and smooth working of the whole machine. It sometimes happens during manufacture that through an oversight in the drawing office a machine cannot complete a cycle of movements without a foul of some nature.

DRAWING FOR ENGINEERS *concluded; followed by* DRAWING FOR SHEET-METAL WORKERS

THE EDITOR & HIS PAPER

The Editor of a Great Newspaper. Functions and Ideals of Editing. The Editor's Duties to His Readers. Office Journalism

Continued from page 4316

By ARTHUR MEE

TO be the editor of a great newspaper is an achievement of which any man may well be proud. To help to shape the opinion of a nation or to entertain it in its leisure hours is a function which, if it is honourably fulfilled, rightly brings a man esteem and fame. There is not a journalist with the essence of journalism in his soul who would not rather be an editor in deed than a prince in name.

The Ideal Editor. It is a compelling theme, the business of the man whose pen Napoleon feared more than 30,000 bayonets. Nothing could be much more interesting, if we had space, than to consider it in its relation to life and affairs. Nothing could be more interesting, and nothing could be more comprehensive. For the editor is a many-sided man, who touches the world at all the points we can conceive. His duties and responsibilities reach out through countless avenues. He owes to every man in his public relations the consideration which one gentleman owes to another; it is one of the first maxims of his life to do nothing as a journalist that he would not do as a gentleman. He has something of the duty of the preacher to lead people towards the right and warn them from the wrong. He must have some of the foresight and something of the delicate craft of statesmanship. He must have the ingenuity of the advocate with the impartiality of the judge, and he must weigh great problems in all their bearings as if he were a jury. He must be able to exercise the grave care of a doctor who hides the truth from his patient for his patient's good; he must know exactly what to say and when to say it. He must have the soul of the artist for interpreting and revealing the meaning of things; he must be moved by the spirit rather than by the letter. He must have the imagination of the poet with the veracity of the scientist. He must have the astuteness and caution of the diplomatist when a crisis is looming, the calmness of the philosopher and the dignity of a king when the crisis has come. He must be a patriot in the highest sense of patriotism, with a love for his own country the more profound because he loves the human race. He must have, all this is to say, far more than an average share of the qualities of the ideal man.

The Ideal Paper. Somewhere, far away from Fleet Street, is such an editor; somewhere, farther from Fleet Street still, is his ideal paper.

The ideal paper is the story of men and women. That, after all, is the beginning and the end of papers. It is the business of a paper to compel a great public to read it, and the ideal paper comes with such compelling force as it can find in the simple, human story of the world.

It finds its interest in no narrower field; it draws its drama from no narrower stage than the world in which all the men and women are actors. It tells us, week by week, the wonderful story of the world we live in—such a story as bewilders the writer of fiction, stranger in its truth than dreams, more startling in its reality than all imaginings, more beautiful in its unfolding than all the poet's thought. It tells the story of men and women, the story of a man and a maid. "It cometh unto us with a tale which holdeth children from play, and old men from the chimney corner."

The Editor's Raw Material. So entrancing, could it be brought before us, is the history of our own times. There died not long ago, unnoticed in our papers, an old woman in a country poor-house, lifting the veil in her last moment from the tragic mystery of a Royal Court. There was carried from a lowly house, not many years ago, the dead body of the president of a great republic which has never known the truth of his strange end. There passed away by fire a year or two ago a beautiful woman, a sister of two queens, who would have been a queen herself had not a king broken his word; there lives still a woman whom the same king loved, who might have left a village inn for a German throne, but who, instead, came in a boat upon a lake one day to see her young king drown. Almost in the shadow of our own King's castle lives a widow who sat upon the throne of France. Not an hour's journey from her there lay, the other day, broken in fortune and at the door of death, a widow whose winsomeness split parties in the House of Commons and dashed a nation's hope. The greatest of all human stories is written by the hand of Fate.

The Scope of the Paper. That, as far as it can be stated in a word, is the keynote of the ideal paper. It is human. It is true. It is interesting because it is life. It takes account, not of names, but of things. It is planned on no arbitrary lines, but is fashioned by affairs as they occur. It picks up the threads of romance wherever they may be found. It knows neither time nor place; it gathers its story from the ends of the earth and from all ages. It is universal in its scope. It appeals to the man who has read everything and to the man who has read nothing. It is conducted on the principle that nothing interesting is ever old, and that everything human is interesting.

It believes that men and women are interested in themselves and in the race. It realises that the most wonderful thing in the world is the

world itself; that the things we know least about are the things of which we wish to know most. It finds romance in the sky and the bottom of the sea. It does what in a paper lies to make men and women know themselves. It tells the story of all the great discoveries and inventions that are changing the face of the earth.

We live in an age of miracles. "I never handle the telephone without realising that I am handling a mystery," Sir William Crookes has told us, and he puts well the truth that, so far and so fast has the world moved, that the greatest mysteries in the universe are almost commonplace. We lay our sixpence on the post-office counter and think nothing of the electric wires which will convey our message from Edinburgh to St. Ives before we are at the bottom of the street. We open our papers in the morning as carelessly as if it were not a miracle which has brought to our breakfast-table the history of the last twenty-four hours from every part of the earth. We strike a match without thinking that the light that comes is nothing less than a bit of sunlight imprisoned in the earth for thousands of years. We switch on the electric light without fear and trembling, playing like children with the appalling power of which science knows almost nothing. We pluck a rose without a thought of the unseen and silent forces which have wrought so beautiful a thing.

A Human Picture of the World. The romance of the world can never be written, can hardly be conceived. But such threads as can be caught the ideal paper takes, weaving them into the picture of our day. It has all the faults of a paper made in haste and read at leisure, all the evidences that a penny, after all, cannot buy everything. But it is an enthusiastic endeavour to make up the best magazine of helpful and interesting journalism that can be secured for its price. It makes its appeal to all—from the smallest child who would hear a story, to the man who would know what new thought has been spoken, what new height in science has been reached, what is happening in any part of the world that will leave its mark on history. Nor does it ignore the problems of life. Every issue of it discusses some social subject of interest to the individual and the home. It strives to bring the best thoughts to bear on the best topics of the day; to pick out the truth as well as the romance from the affairs of the world; to keep itself abreast of all that happens that an intelligent man or woman should know, to be, from beginning to end, interesting and helpful and true.

The ideal paper is a human picture of the world, beating with the lives and the hearts of men.

It is the paper of a dream, the dream of every editor who is awake. How near sometimes we get to it, how far from it sometimes we are, is a good or ill-fortune dependent on many things within and without the editor's control. It is not intended in this course, necessarily brief and suggestive, and in no sense exhaustive, to go into all the questions that come to the mind when we meditate upon editors and papers. Those who have read so far will have formed some conception of what we hold journalism to be; those who have reached this stage in actual journalism will need no advice here as to how to advance still further. All that we need attempt is a brief consideration of one or two practical matters concerning the editor and his staff.

Good Copy and Bad. The editor must not succumb to the temptation, so strong in these days, to think more of the machinery of his paper than of its readers. The story of how he obtained a piece of news may be interesting, and in some cases it may be quite legitimate to tell it; but the chief matter is the news itself, and not the getting of it. It is, of course, important sometimes to know the source from which news comes, but the talk about these things has come to be more of a desire to advertise the paper's machinery than to satisfy the public as to the authority of the news, and in so far as this is its object, all display is to be condemned. Waste of space is one of the unpardonable sins. One of the most remarkable popular delusions is that editors are gasping for something to put in their papers. The difficulty at the last moment is always, "What can we leave out?"

That question must be decided by the editor, who knows his readers. He will probably decide to leave out the thing that interests the least number, although this may not always be so. He will, at any rate, leave out the non-essentials first. His whole purpose in leaving out news will be to sacrifice as little of the general interest of his paper as possible. Only long experience of editing can help him here, but he should have no difficulty in deciding what copy is good, and what copy is bad. An editor confesses his own weakness when he publishes long accounts of trivial things, or allows anybody who has nothing better to do to occupy his space by writing silly letters. The standard of letter-writing in papers is much too low, and it is simply bad journalism which enables a man to become notorious by writing letters about gravestones when he has nothing to say about them that matters to anybody.

The Chief Figure in the Editor's World. The editor is safe from these temptations if he remembers that the most important person in all the world to him is the reader of his paper—not the advertiser, not the proprietor, not the man with a log to roll or an axe to grind, but the man who buys his paper to read it.

One of the worst enemies of journalism is the proprietor or commercial manager of a paper, usually calling himself the managing-editor, who, knowing nothing about a paper save that it prints advertisements, dictates to the editor how he shall edit. The last person in such a man's mind is the reader of the paper. One of the best of these managing-editors that we have known once refused to order the report of a speech by Mr. John Morley, owing to a dispute between his paper and a certain press agency. It was nothing to him that he was withholding from his readers something it was his duty to give them, something the great majority of them expected to see when they opened the paper; it was everything

to him that he should spite the face of the press agency—even by cutting off his own nose.

The Morality of Editing. Somebody will write a book some day, perhaps, on the morality of editing, and it will contain many examples of this kind. It will also publish a copy of an announcement in a provincial morning paper that "in attending meetings, etc., preference will be given to those fixtures advertised in our business columns." It will print such letters as that written by the manager of a well-known evening paper in reply to a publisher who had sent him books for years, and had had no reviews. The publisher wrote to ask if the paper wished him to continue sending the books, and the manager replied that his newspaper believed in the old-fashioned principle of *quid pro quo*, and as the publishers did not advertise in it they got no reviews." These are the things which distress the journalist who conceives it his duty to be a faithful recorder of news, and to keep his readers well informed about literature; but they are done, let us remember, not by journalists, but by men to whom a newspaper is a thing for advertising pills.

The good editor knows every man on his staff. He knows where to turn when, late at night, he wants a leading article quickly, a special introduction to some important event, or a sketch of somebody's career. He knows the man on whom he can rely for initiative, for descriptive power, for getting hold of people, for evolving theories, and following them up. And if the good editor knows his man, the good journalist knows his editor. He knows his editor's point of view, understands his purpose, and responds to it.

The Men an Editor Likes. The news editor of a newspaper with a reputation for enterprise throughout the world has written for the SELF-EDUCATOR his conception of the kind of men an editor likes to have about him. He says:

"The sub-editor needs a good education, and especially a sound knowledge of spelling; a catholic and quick judgment as regards the value of news, and a clear conception as to the most interesting form in which the news is to be printed in his paper. He should be well informed generally—an ordinary school or college education is adequate, coupled with a close study of newspapers, whereby he assimilates the events of the day He should have a keen recollection of occurrences in the past, immediate and more remote, an unfailing memory for names, a sound judgment as to 'possibilities' in the reports which reach him. Shorthand is useful, but not vital

"The older sub-editing is, for the most part, the abbreviation, the punctuation, and the checking of reports sent to the office, either telegraphed or written; the newer sub-editing—for instance, of the ultra-modern papers—requires extensive rewriting and constructive reproduction. All this can be acquired by practice. Patience, however, is necessary, method essential, and discretion vital. Only by the possession of these qualities by its sub-editorial staff can a paper attain a high standard.

"While a sub-editor should have a general knowledge of newspaper work and an all-round education, he should at least know one modern language, preferably French, and should specialise on one subject—for instance, medicine. Finally, he should never be above verifying a reference or checking a quotation. And in his spare time, if he has any, let him make himself familiar with events outside his office. The best sub-editor is always a 'man of the world.' He knows the public pulse and the public taste, and can better estimate thereby the specific value to be attached to specific news.

"No one unless possessed of strong physique should become a sub-editor. The work is sedentary, and the strain on the nervous system severe. There are always openings for good men. But it is essentially routine newspaper work, which only needs ordinary intelligence, rightly trained; and few persons of special genius ever devote themselves to it for long, for it offers no opportunities for ambition, and exercises a numbing influence on its votaries."

Office Journalism. We can now leave office journalism. We have considered all too briefly the work of a newspaper journalist, from the moment he makes up his mind to become a journalist to the time he becomes an editor; and we have now to consider that wider field in which journalism ceases to be a profession and is open to all the world. It is not necessary to discuss the thousand and one duties of an editor, which the journalist must learn for himself. We have said nothing of the salaries paid in a newspaper office, because it is impossible to give any figures which would not be misleading in some cases. The apprentice who enters the reporters' room may begin with a few shillings a week, and rise until at the end of his apprenticeship he receives, perhaps, 16s. or £1 per week. In an ordinary town he may then receive a salary of £2 or £3 a week as either reporter or sub-editor; or in a large town, such as Manchester or Birmingham, a salary of £5 or £6 a week. The custom is growing of paying reporters according to the work they do instead of a fixed salary, and this custom, often adopted in London, is preferred by some reporters. In this way a reporter may earn as much as £10 or £15 in a week if he is fortunate. In any case, if he is a good, reliable man he can always be sure of a living income in London. Necessary expenses are always allowed. A sub-editor's salary is, of course, fixed, and may be anything in London from £4 to £10 a week.

Whether as reporter, sub-editor, leader writer, musical or dramatic critic, special correspondent, or in any other capacity, the journalist will find opportunities for distinction inside the newspaper office. Office journalism has its drawbacks. It involves long hours, and leaves a man little freedom of movement. But it has abundant compensations, and he may look forward, if he is strong and willing and enthusiastic, with the certainty that he will have plenty of opportunity of putting into his work the best that is in him.

TOP-MAKING

The Machines and Processes in Factory Practice. Clicking, Machining, Skiving, Buttonholing and Finishing

By W. S. MURPHY

Cutting Tops. Machinery is not much used in the cutting-rooms of factories producing first-class boots. The matter has often been debated on this side of the Atlantic, because on the other side cutting machines are largely used. American methods, however, differ largely from ours. For our own trade the subject may be considered in this way. Leather is not like a web of cloth, the uniform quality of which can be depended on. A web of cloth is the same breadth and thickness throughout, and one web is exactly like another. On the other hand, no two hides of leather are similar in every respect, and qualities vary indefinitely, even in the same class of stuff. In cutting up leather, the selective eye cannot be dispensed with.

Cutting by Machinery. If a man is prepared to risk defects and incur a large percentage of waste, he may go in for cutting by machinery. Under special circumstances, perhaps, the loss in waste is balanced by the saving in wages, for machines in this department do effect enormous savings in labour. Working with cheap leather, for a coarse trade, the manufacturer may find cutting by machinery a paying business; but with leather costing about 3s. per lb. all over, and buyers scanning every fibre for damage, hand-cutting is the safest and the best.

The Clicker. The *clicker*, as we name the top-cutter, has a bench space all to himself, and a special class of boot to cut. In a factory producing for an all-round trade, clickers are ranged in classes or sections, one section cutting for the "nursery" department, another for the girls', another for the women's, for the boys', for the men's, and for the fancy departments. Some large factories have over a hundred clickers working, divided into sections varying in number from seven to 20, according to the class of trade or system of management. When it is remembered that the tops of a pair of half-goloshed Balmoral boots contain 36 pieces, including linings, the possibilities of division and subdivision are obvious.

Clicking a Skilled Craft. Clicking in the factory differs little from top-cutting for the hand-made boot. The clicker is a handicraftsman who is required to show special skill within very narrow limits. He should be able to tell at a glance the different classes, kinds, and patterns of leather. His duty is to detect defects in fibre or pattern, and plan to cut out of the hide in the most economical manner possible. The clicker who wastes leather is certain to be among the unemployed more frequently than may be pleasant. We have already shown a picture of the kinds and patterns of leathers most commonly used for the boot trade in this country, illustrating the distinguishing qualities of each [see Plate facing page 3217].

The Clicker at Work. Now, let us get to work. Knives [29, page 3875] are the clickers' tools, and he must keep them in good condition. The slightest roughness on the blade may mean a ragged edge on the leather just at that point where it has been cut neat. A properly organised factory gives out work cards, with the details of the particular job specified. Suppose that our work card contains the order for a dozen of half-goloshed Balmoral boots of first-class quality. The quarters are to be the best calf-kid, the golosh and vamps French calf, and the facings and toecaps patent or enamel leather. Having selected the pieces, we next go to the pattern file, and take off the set of patterns proper to the size of boot. Before beginning to cut, plan out the stuff; a little forethought may save the leather of a pair of tops. When assured that the most has been made of the material, take the patterns and carefully cut cleanly and swiftly. Mind the corners. If the points have been well cut, every piece will come away as cleanly as if it had been struck by a die. Ragged ends give you more work, or somebody else has to lose time in rectifying the defect.

Linings. The linings and other accessories are similarly gathered. For light boots of the best quality fine leathers are sometimes used; but good drill serves the purpose quite well.

Small Machines. We have said that machinery is not wholly debarred from the clicking-room. Tongues, toecaps, and the other small additions are generally cut by machines worked by boys. Neat little things those machines are. Here is one, looking very like a sewing machine, and it is used for cutting out and perforating toecaps, cutting and scolloping button-flaps, and such purposes [47]. Another little machine, equally interesting and efficient, is the tongue and backstrap cutter. The knives can be adjusted to any angle, and scraps of leather passed through come out well-shaped tongues. The backstraps, of course, are of good leather; but the pieces may be useless otherwise, and the machine makes them into fine straps in the twinkling of an eye. As there is nothing to learn in these machines, elaborate study of them is needless. Any lad brought in from the street can be taught to work them in a very short time.

We gather together our stuff, and bundle it up, each part separately, and hand along to the inspecting department. Thence the tops pass into the machine-room, and begin the journey towards the destined end.

The conditions under which clickers work are usually very good and healthy, light and

ventilation being provided by employers from purely economic motives. The work is pleasant, but not very well paid

Patterns and Measurements. Wherever material is elaborately cut out, there must be patterns. The pattern everywhere saves time, trouble, and material. Upon the pattern-maker rests the efficiency of the whole boot factory. He it is who gives the clicker the shapes to which he must cut all the parts of the boot-top.

Thousands of Shapes. A shape is a piece of stiff paper cut to a given form and size [see 30, page 4015]. For every part of every size and class of boot there is a pattern. In this way the pattern-maker seems to have plenty of work before him; but that is not all. New shapes are being devised every week, and a factory producing for a high-class shop trade has a thousand or two special measures coming in every week. No decent-sized factory can get along with less than ten thousand different patterns, and these duplicated as required by the number of clickers employed on each class of work.

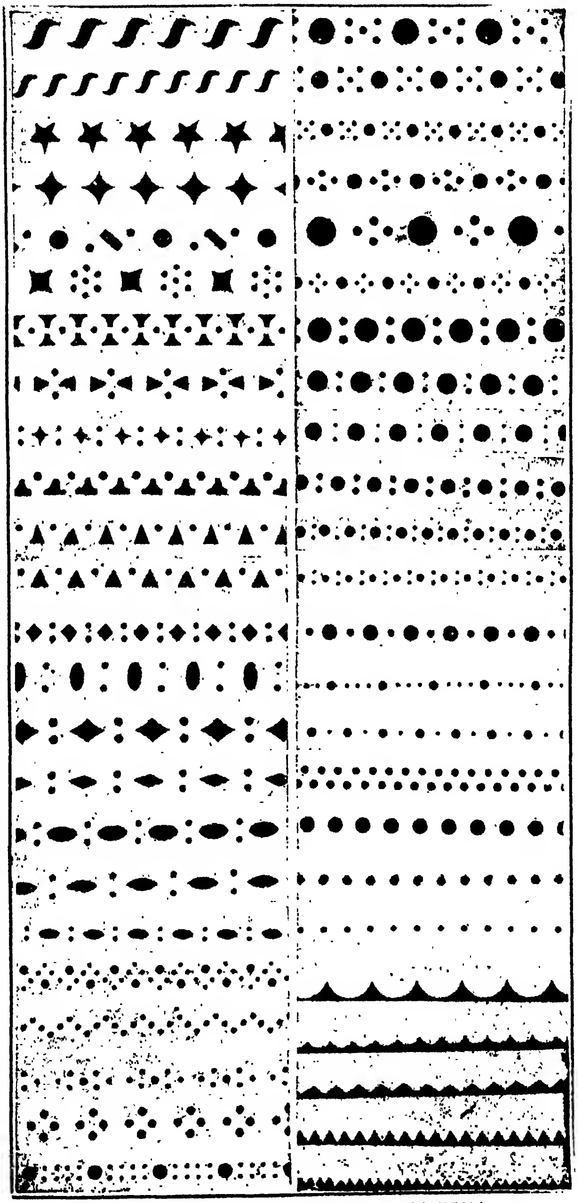
When a new measure comes in or a new style of boot is drawn out, the pattern-maker has to calculate how much of the total area of surface represented by these measurements must be apportioned to each part of the boot. These proportions are determined by the design of the boot.

The Fit of Factory Boots. Measurements in the boot factory have been a source of great trouble, the variations in the proportions of feet making fit by a common standard almost a matter of impossibility. In the course of experience, however, a fair approximation has been arrived at, and now the ready-made boot has a chance of being a good fit. Factory managers assert that the ready-made boot fits the average foot just as well as the average hand-made boot, and does not so often misfit, the margin of error in the former being reduced to a minimum by the scientific grading of sizes.

Measurements. The tables [see page 4435] of measurements and notes have been compiled from the experience of one of the largest, if not the largest, boot factories on this side of the Atlantic. Based on a long and wide experience, we think they are reliable and, in some ways, unique.

Machining the Boot-tops. This department of the boot factory has been taken possession of almost wholly by the fair sex. Nor can the productive capacity of the industry be said to have suffered on that account. It has been calculated, from everyday experience, that, in a well-equipped factory, the girls employed in top-making turn out, on the average, forty pairs of tops per head every week. Machines driven at enormous speed perform the work. For every little detail there is a machine or group of machines. Yet skill and keen attention are demanded from the women workers.

Skill Required. The machines are not automatic. A fairly good idea of the ability required may be gathered from the domestic sewing machine. It is a curious fact, and worth noting,



47. STYLES OF LEATHER PERFORATIONS
(B. U. Shoe Machine Co., Leicester

that all our boot-top machinery has been modelled on the principle of the sewing machine. The numerous and dainty details of boot-top making lend themselves to that particular method of treatment. At the present time the trade is probably unique in this respect. Instead of taking the tools and forming them into an automatic group scarcely recognisable, as he has done in other industries, the inventor simply took the tools of the boot-top maker and put them into machinery, so that they might be mechanically driven at more than human speed.

Variety of Machines. This fact has lent itself to another development which may be confusing to the student of the trade. Because the needle, the awl, the punch, the knife, and the hammer are the common property of the human race, it is open to anyone to gear them on to driving inventions, with the result that there are many different machines for every conceivable detail of boot making, and for some parts the number runs into high figures. After having mastered one machine in a factory, the worker may find herself confronted by a form of machine utterly unfamiliar. This need cause no dismay. The difference is more apparent than real, and in a few hours, or at most days, the new machine will have become as familiar and easily worked as the old.

Skiving. When making boots by hand, we saw how carefully the pieces to be joined were thinned off, so as to make the point of contact as unobtrusive as possible. In the factory, skiving is even more imperatively required, because neatness is one of the special merits of machine production. The skiving blade [see 31, page 4017], which is all that we need attend to, is a flat piece of sharp steel set horizontally on a spindle working above an automatic feed. Lay in the vamp, and immediately the edged disc begins to shave away the leather. Almost while you look the work is done. The circular blade runs at the rate of 1,000 revolutions a minute. One thing is noteworthy in this skiver. No matter how fine the workmanship of the hand worker, some little difference is apt to come in between one skiving and another on the boot-top; but this machine automatically gives the same breadth of skive at all times. Every part of the upper is skived alike. This part of the work done, the stuff is passed on to the sewers.

Sewing. The up-to-date factory has nothing but the new, swift model of sewing machine. Occasionally, however, the worker may be called upon to use the older kinds. Those old-fashioned machines were built under a mistaken idea; it was supposed that heavy machines only could do heavy work. Clumsy things they are, with arms like those of hydraulic riveters, and a grip strong enough to hold down the plate of an Atlantic liner. When working one of these machines, the tension of the thick thread should be specially attended to, because the stitch may be loose if it be left slack, and the whole mechanism may be made to jump if the tension be too tight. For strong boots, made in imitation of hand-mades, those old machines are still useful. For the modern machines mostly used, direction is hardly needed. The worker lays in the work and the machine does the rest. This machine, on which a pile of plain uppers are being sewn, has one needle, and makes a single row of stitching forward, and doubles the row by bringing back the seam. Another group of machines do double rows at once with two needles working at the same time, locking the two threads within the cords from two shuttles.

Difference in Ability. No one ought to imagine that machining boot-tops is easy work. The mechanical appliances are wonderfully perfect, but the human factor can never be eliminated. Side by side, working the same kind of machine, driven by the same motive power, the output of workers differs widely. Of two girls, both equally conscientious, the abler will take 20 per cent. more work out of a machine than her less expert neighbour. Where simple processes are constantly repeated, little delays amount to large losses in the aggregate. Delays arise from inattention to the setting of the seam, careless management of the spools and threads, and too frequent changes of work. The last cause of delay is a matter of management, but the others, and many too small for special mention, lie in the power of the worker.

Seam Finishing. When the bootmaker has sewn a seam, he taps it down level with his hammer. Machine-sewn seams are also rough and obtrusive, and inventive genius has given us quite a number of seam finishers. One form is directly imitative of the hand hammer, with a hammer head set on the end of an arm driven by power; another is a wheel under a spring block, which presses the seams with a rubbing motion; and others combine the two principles, with varying degrees of success. All the models are simple and easy to work, and three or four kinds may be used, the one being regarded as specially good for one purpose, and the others for work of differing classes. Most generally applicable, and most favoured, is the mechanical hammer. Vibrating at the rate of 1,200 beats a minute, the hammer does the work rapidly and prettily. Lay the seam neatly on the block, and let the hammer play upon it while drawing it round. We need hardly say that the operator's intelligence is called upon to some extent in working this machine. Stitches tightly drawn, or hard threads, may be pulled asunder if provision is not made for vibration; but the differences can be readily adjusted by the exercise of a little common-sense.

Seam Rubbers. For light tops, ladies' kid and fancy boots, the seam rubbers are probably the safest. These contrivances are certainly very finely adjusted, and work prettily. One of the best seam-rubber machines has a solid wheel running under a fixed disc, dependent on springs adjustable to any pressure, and therefore fitted to meet the variations in the thickness of the leathers. All the working parts are in sight, and can be operated upon by a young worker.

Bagging. Another small auxiliary of the sewer is the bagging machine. When the linings have been joined to the tops the joints are round and slack. Flaps of button boots are simply

TABLES OF MEASUREMENTS FOR ALL SIZES OF BOOTS

4-FITTING, MEN'S.

Length of Last in Sizes.	Length of Last in Inches.	Joints Measurements.	Instep.	Heel.	Ankle.
5	10	$8\frac{1}{2}$	$8\frac{7}{8}$	$12\frac{5}{8}$	$8\frac{1}{8}$
6	$10\frac{4}{12}$	$8\frac{3}{4}$	$9\frac{1}{8}$	$12\frac{7}{8}$	$8\frac{3}{8}$
7	$10\frac{8}{12}$	9	$9\frac{3}{8}$	$13\frac{1}{8}$	$8\frac{5}{8}$
8	11	$9\frac{1}{4}$	$9\frac{5}{8}$	$13\frac{3}{8}$	$8\frac{7}{8}$
9	$11\frac{4}{12}$	$9\frac{1}{2}$	$9\frac{7}{8}$	$13\frac{5}{8}$	$9\frac{1}{8}$
10	$11\frac{8}{12}$	$9\frac{3}{4}$	$10\frac{1}{8}$	$13\frac{7}{8}$	$9\frac{3}{8}$
11	12	10	$10\frac{3}{8}$	$14\frac{1}{8}$	$9\frac{5}{8}$

NOTES. The sizes range from 5 up to 11. We give length of foot in sizes and the length of foot in inches. We then follow on giving joints measurements, instep and heel and ankle measurements.

(A) A size equals $\frac{4}{12}$ in. in length.

(B) A fitting equals $\frac{1}{4}$ in. small and large.

(C) Girth measure from size to size equals $\frac{1}{4}$ in.

(D) Width of bottom of last from size to size and fitting to fitting, $\frac{1}{12}$ in.

(E) Extension of last over the length of foot: Square toes, 2 size equals $\frac{8}{12}$ in.; medium toes, $2\frac{1}{2}$ size equals $\frac{10}{12}$ in.; spike toes, 3 size equals $\frac{12}{12}$ in.

4-FITTING, LADIES'.

Length of Last in Sizes.	Length of Last in Inches.	Joints Measurements.	Instep.	Heel.	Ankle.	Leg, 6 in. high.
2	9	$7\frac{3}{4}$	8	$11\frac{3}{4}$	$7\frac{1}{2}$	$8\frac{1}{2}$
3	$9\frac{4}{12}$	8	$8\frac{1}{4}$	12	$7\frac{3}{4}$	$8\frac{3}{4}$
4	$9\frac{8}{12}$	$8\frac{1}{4}$	$8\frac{1}{2}$	$12\frac{1}{4}$	8	9
5	10	$8\frac{1}{2}$	$8\frac{3}{4}$	$12\frac{1}{2}$	$8\frac{1}{4}$	$9\frac{1}{4}$
6	$10\frac{4}{12}$	$8\frac{3}{4}$	9	$12\frac{3}{4}$	$8\frac{1}{2}$	$9\frac{1}{2}$
7	$10\frac{8}{12}$	9	$9\frac{1}{4}$	13	$8\frac{3}{4}$	$9\frac{3}{4}$

Remarks as No. 1.

Same notes apply as on No. 1—A to D.

(E) Extension of last over the length of foot: Square toe, $1\frac{1}{2}$ size equals $\frac{6}{12}$ in.; medium toe, 2 size equals $\frac{8}{12}$ in.; spike toe, $2\frac{1}{2}$ size equals $\frac{10}{12}$ in.

4-FITTING, BOYS'.

Length of Last in Sizes.	Length of Last in Inches.	Joints Measurements.	Instep.	Heel.	Ankle.
7	$6\frac{4}{12}$	6	$6\frac{3}{16}$	$9\frac{7}{16}$	$5\frac{7}{16}$
8	$6\frac{8}{12}$	$6\frac{3}{16}$	$6\frac{6}{16}$	$9\frac{10}{16}$	$5\frac{10}{16}$
9	7	$6\frac{6}{16}$	$6\frac{9}{16}$	$9\frac{13}{16}$	$5\frac{13}{16}$
10	$7\frac{4}{12}$	$6\frac{9}{16}$	$6\frac{12}{16}$	10	6
11	$7\frac{8}{12}$	$6\frac{3}{4}$	7	$10\frac{3}{8}$	$6\frac{1}{8}$
12	8	7	$7\frac{1}{4}$	$10\frac{5}{8}$	$6\frac{3}{8}$
13	$8\frac{4}{12}$	$7\frac{1}{4}$	$7\frac{1}{2}$	$10\frac{7}{8}$	$6\frac{5}{8}$
1	$8\frac{8}{12}$	$7\frac{1}{2}$	$7\frac{3}{4}$	$11\frac{1}{8}$	$6\frac{7}{8}$
2	9	$7\frac{3}{4}$	8	$11\frac{5}{8}$	7
3	$9\frac{4}{12}$	8	$8\frac{1}{4}$	$11\frac{7}{8}$	$7\frac{1}{4}$
4	$9\frac{8}{12}$	$8\frac{1}{4}$	$8\frac{1}{2}$	$12\frac{1}{8}$	$7\frac{3}{4}$
5	10	$8\frac{1}{2}$	$8\frac{3}{4}$	$12\frac{3}{8}$	8

(A) A size equals $\frac{4}{12}$ in. in length.

(B) Girth measurement from size to size, $\frac{3}{16}$ in. for 7 to 10; girth measurement from size to size, $\frac{4}{16}$ in. for 11 to 1; girth measurement from size to size, $\frac{4}{16}$ in. for 2 to 5.

(C) Width of bottom of last from size to size, $\frac{1}{16}$ in. for 7 to 10; width of bottom of last from size to size, $\frac{1}{12}$ in. for 11 to 1; width of bottom of last from size to size, $\frac{1}{12}$ in. for 2 to 5.

(D) Extension of last over the length of foot: Square toes, $1\frac{1}{2}$ size equals $\frac{6}{12}$ in.; medium toes, 2 size equals $\frac{8}{12}$ in.; spike toes, $2\frac{1}{2}$ size equals $\frac{10}{12}$ in.

4-FITTING, GIRLS'.

Length of Last in Sizes.	Length of Last in Inches.	Joints Measurements.		Heel		Leg.

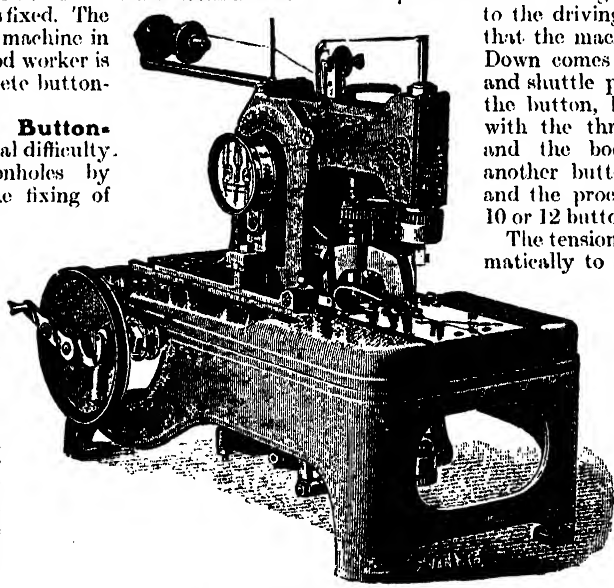
bags sewn on the inside and turned out. To make the flaps solid and flat, the seams must be pressed somehow. Here we have a machine equal to the need. It is double-jawed. On the under jaw is a long finger of electroplated metal, and a solid round disc sits in the upper jaw. Place the flap on the top of the finger, and bring the upper jaw down. The finger vibrates on the seam inside, and the disc rolls on the outside, the pair between them reducing the bag to an apparently solid piece of leather with a fine edge.

Buttonholing. Button boots are produced in large quantities, of all sizes, by the factories. In fact, the popularity of that class of boot is almost wholly due to the cheapening effect of machinery. Anyone who looks at a buttonhole can readily realise how laborious and costly the making of buttonholes in leather must be. Our problem was to find a machine which could make buttonholes in a satisfactory way. For a long time the machines offered to us, in good faith no doubt, proved miserable failures, producing botched work. At last, however, the problem was solved, and now we have machines which both cut and sew buttonholes in very fine style. The machine with which we are most familiar is the "Reece" [48]. A die knife cuts out the hole. From spools set on the head of the machine the two threads come down into the oscillating needles which work round the hole. When the end of the hole is reached, the machine automatically stops sewing, and fixes in the ends of the threads. On the head of the machine the tension regulator is fixed. The production of this machine in the hands of a good worker is about 6,000 complete buttonholes a day.

Finishing Buttonholes. One special difficulty in making buttonholes by machinery was the fixing of the ends after the buttonholes were sewn. As everyone knows, the sewing machine always leaves open threads at the end of a seam, and these must be tied or cut away. The method adopted was to run a bar of sewing along the flap at the bottoms of the buttonholes. This, however, added a pattern to the flap which was not desired. As we have said, the newest forms of machine have overcome the trouble, but, as a rule, at some expense of neatness. An ingenious man conceived and invented a machine that could take a stitch in one ply on a flap while leaving the other one untouched. With this contrivance the bar to fix the ends of buttonholes can be made on the underside of the flap and out of sight.



48. HIGH-SPEED REECE BUTTONHOLE MACHINE

(B. U. Shoe Machine Co., Leicester)

Sewing on Buttons. Men not very old in the trade can remember well the many vigorous attempts made to devise a mechanical fastening for buttons. Rivets, flat discs, long wires like miniature hairpins, and many other devices were tried but the public unmistakably showed a constant preference for the hand-sewn button. No wonder, for the flap of a buttoned boot with one of those sets of fasteners on felt like the sole of a heavily-hobbed boot. But our machinists were not to be beaten. Small as the matter may seem, there is a large amount of money in it. The happy idea of using the form of the sewing machine for the button fastener was struck, and then the problem was solved, not all at once, but by successive attempts, each one improving on the last. What improvements may yet be made we do not undertake to predict, but the present form of machine serves our purpose fairly well. The plan of this machine is an arm and stand extending at right angles from the operator [49]. On the top of the arm is a hopper from which a channel leads down in front of the needle. Resting on the stand is the gripper, which keeps the work in place and guides it automatically from button to button.

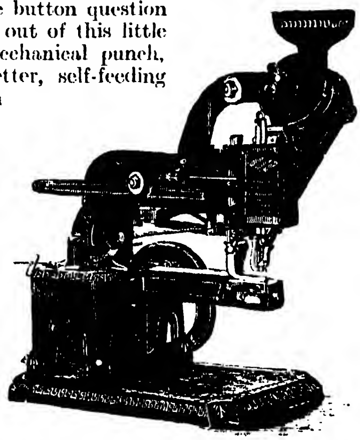
A Perfect Machine. The inventor has done his work well. So far as the worker is concerned, the machine is simple. We put a few gross of buttons into the hopper, and clamp the work upon the stand. Bring the driving belt on to the driving wheel, and watch that the machine does its work. Down comes a button; needle and shuttle play over the eye of the button, linking it firmly in with the thread; they retreat and the boot-top moves on; another button comes in place, and the process is repeated till 10 or 12 buttons have been fixed. The tension adjusts itself automatically to any grade of work, from French kid to heavy grain leather, and each button is secured independently. With the button-sewing machine a thousand boot-tops can easily be disposed of in a day. We have heard objection made to the single thread, and the criticism has some reason in it. We will gladly learn another and better machine, if the invention comes along.

Punching and Eyeletting. The staple of our trade is the lacing boot. Fashions come and go; but for the past fifty years the lacer has been the stand-by. In the average

boot there are 16 holes; in boots of the better class six of these holes are filled with eyelet hooks and ten with eyelets. For a man working by himself, making three pairs a week, this does not mean very much; he can punch them in a short time, and think little about it. But when you have charge of a large factory sending out from twenty to thirty thousand pairs a week, two-thirds of them lacing boots, then the punching and eyeletting becomes a very serious item. It means the employment of twenty men for that small matter only, and smart men, too. But the genius that solved the button question was quite equal to helping us out of this little trouble. First we had the mechanical punch, then its companion the eyeletter, self-feeding and capable of being driven by power; next came a combination of the two, and lastly the automatic punching and eyeletting machine. All four kinds are still on the market, made by various firms. Factories of small dimensions, or factories chiefly engaged in producing ladies' and childrens' boots, can very well get along with the smaller machines, because eyeletting is never a large business with them.

Small Machines. The small punches and eyeletters are simply die-stamping machines with, in the one case, a punch, and in the other an eyelet holder instead of the die. With these machines two operators can produce between them from 3,000 to 4,000 finished eyelets in an hour, though the speed on the working day may be a little less.

Factory Eyeletting. The automatic eyeletter is the contrivance with which the work of the factory is done. Here, again, the sewing-machine idea is seen in operation, with additions. A small box tray on the top holds the eyelets, and from it a channel runs to the nose of the punch. As the punch comes down and retreats, the eyelet setter follows its action as quickly as lightning, and the eyelet is done. By an automatic motion, the top is moved the space, ½ or ¼ in., between the holes, and the next hole is made and eyeletted. The operator's duty is to put the top in position, lift it away when finished, and guide the work, while keeping his foot on the foot lever for emergencies. By mastering this machine, the worker can punch and eyelet 10,000 holes per hour.



49. STANDARD BUTTON-FASTENING MACHINE

Eyelet-hooks. Rather more difficult is the hook-setting machine, and it works more slowly, though on the same principle as that just described. We have seen several kinds of these at work, and they perform very well, considering the difficulty to be overcome. A hook is an eyelet with a fixed hook lying over it; the drive home differs, therefore, from that of an open eyelet; but the difference has been negotiated by a change in the punches.

Linings. We have left linings out for the moment. It depends on the kind of boot when the linings are brought in. Say that it is a batch of ladies' boots we are doing. Sometimes these are lined with fine morocco, but the kind most commonly in demand are lined with good cotton drill, edged with chamois, morocco, or other fine leather.

The linings are cut with the uppers, and sent into the machine-room at the same time; but they are put together in a different way on a separate set of machines. On the folders, neat little fingers working under a machine arm turn over and press down the edges of facings and heads of the linings. Next the parts are joined together on ordinary sewing machines, fronts and backs being lightly seamed into unity. Now the upper or top, without the vamp or front, comes round and meets the lining. They are put edge to edge, the insides coinciding, and sewn round. When finished and turned right-side out, the top and lining are joined, and not the vestige of a seam appears.

An economy is effected in this way, for you can attach the vamp to the lining at the same time as you are attaching the vamp to the rest of the upper. If it be desired to put several rows of stitching on the vamp, the upper lining can be turned back after being joined.

The edgings of the linings are beaded and bagged in the same way as the button flap, before described.

When the top is completed, it is prepared for the lasting, and sent in batches to the bottoming department.

THE BANK'S BOOKKEEPING

Contingent Liabilities and Assets. The Balance-sheet and its Items. General Ledger Accounts. Bills

By R. LAING

Bullion Reserve and Note Issue. The care of the bullion reserve and note issue will also be given to certain special officials. The work attendant on the first will not be of great amount (the needs of the bank at varying seasons becoming well known in course of time), the main object of the officials concerned being to curtail as much as possible the expense of the transfer of coin from one office to another.

The note issue claims more attention. Great care must be taken in the first place to prevent forgery, the principal checks against and means of discovery of which are the watermark, colour printing, designs on the back of the note, secret marks, and the use of, say, alternate numbers only. The number of notes printed is agreed with that of the blank sheets delivered, and, as an additional check against fraud, they may be signed before issue by some official below the lithographed signature, although such a practice is not universal. The custom with regard to re-issue also varies. The notes of the Bank of England are never re-issued, but those of the Scotch banks are paid out again and again. The records of the issue and destruction (usually by fire) of the notes are kept by this department. The destruction or loss of a bank-note by the holder is equivalent to the cancelling, without payment, of a liability of the bank, and the profits accruing in this connection to banks issuing small notes are—there is reason to believe—of considerable amount. The amount of a partially, or wholly, destroyed note may, however, be paid upon a declaration being made, and a satisfactory indemnity given.

The work of the head office, and more especially that undertaken by the managers and chief officials, includes, of course, the arrangement of general business, decisions on questions of policy, and, generally, the oversight of all large transactions, in conjunction with the board of directors. If the bank be a joint-stock company, the usual secretarial duties will be carried on at the head office, and the necessary returns to Government made up there.

Agency Business. The head office will further look after the accounts between the bank and the various correspondents, the ledger accounts being posted from the advices or returns received from the branches. If, in the course of business, it is found that the community in any locality where the bank has a branch have large and frequent transactions with any other district, or with some foreign country, arrangements will be made with another bank situated there, to their mutual advantage, both direct and indirect. Such arrangements are usually detailed in a correspondents' book, any additions or alterations being intimated by circular. The arrangements come to by the contracting banks may be expressed in a multitude of ways, while the consideration will be determined by their relative needs. For example, a London bank acting as correspondent to a small country or foreign bank confers on it a much greater benefit than it receives, a fact that will influence the terms of their contract. The consideration may take either the form of a stipulation to keep a certain balance, or of a commission on the whole, or on certain of the transactions. An account with a foreign bank requires to be kept in two currencies, one in sterling to balance with the bank books, and the other in foreign currency to agree with the accounts of the foreign bank.

If the trade of any small town does not warrant the establishment of a separate office, a branch may be opened (doing business during the whole or a part of the week) under the charge of some subordinate official of a neighbouring office, the manager of which is responsible to the head office for the transactions of both branches.

The Balance-sheet. The balance-sheet is invariably drawn out in a form similar to that adopted for all commercial undertakings. For the sake of clearness, an abbreviated example is given below. The special entries requisite for its completion are dealt with in the course on Bookkeeping.

The first two items on the liabilities side represent the capital and the reserve fund of undivided profits, forming the total due to the shareholders. As this amount forms the last charge on the bank's assets, it is subject, in the event of liquidation or other winding-up to a reduction equal to the sum by which that actually realised by the assets falls short of the amount at which they appear in the balance-sheet. Such a reduction may be nullified, or even transformed into an addition, by the existence of the hidden reserve afterwards dealt with.

Reserve and Contingency Fund. The investing and the depositing public look to a steady increase of the reserve fund, while,

Dr.			Cr.
Capital	£1,000,000	Cash on hand and with bankers ..	£2,500,000
Reserve fund ..	700,000	Money at call and short notice ..	1,550,000
Deposits	13,000,000	Investments ..	1,500,000
Drafts and transfers	30,000	Bills and Loans ..	9,630,000
Notes issued ..	450,000	Premises	200,000
Acceptances and endorsements ..	120,000	Acceptances and endorsements ..	120,000
Profit and loss ..	200,000		
Bills rediscounted, £750,000, of which £500,000 has since matured, and run off.	£15,500,000		£15,500,000

on the other hand, a reduction in the amount would have a most disastrous effect on their confidence. In consequence, no sum is ever taken from such a fund, save in most exceptional circumstances, and to enable this course to be carried out, a *second* (or *hidden*) *reserve* is maintained, to which sums which would otherwise pass through the public reserve are placed, and withdrawn as occasion demands.

This second fund, in making up the balance-sheet, may either be included in the current accounts or written off the assets.

The deposits are usually included in one total. Drafts and transfers follow, and represent the aggregate amount of these which have not yet been settled by the bank, either by cash payment or by a credit in account, while the sum shown against note issue is the actual amount in the hands of the public.

The item "acceptances and endorsements" is only a contingent liability, and is balanced by an entry for a similar amount on the assets side. The bank has given the security of its name to this extent, but in the event of making any payment it will look to its clients for a refund. The business represented by the two entries has been already referred to.

The treatment of profit and loss account is similar to that generally adopted. The amounts which are placed to the credit of this account will represent interest on loans, discount and commission of any nature, returns on investments, rents, bad debts recovered, etc., while the amounts withdrawn will include interest on deposits, rediscount (if any), commissions, stationery, rent, taxes, salaries, expenses of note issue (if any), bad debts, depreciation, etc., and, in addition, any sums transferred to reserve or dividend accounts.

The amount of rediscounts is shown as a contingent liability, if the bank is in the habit of rediscounting.

Assets. Assets are divided, in varying degrees of detail, into different classes according to the ease with which they can be converted into cash or its equivalent, any item easily convertible into cash being termed a liquid asset. Cash on hand (coin, bullion, and notes of other banks) may or may not be coupled with the balances deposited with other institutions. Money at call or short notice with brokers follows, and the proportion shown in the balance-sheet between the liquid assets and the liabilities to the public is subjected to the closest scrutiny.

Cheques and similar documents in course of post may be included in the cash total or incorporated in the amount shown against loans. The figure at which the customary investments in first-class stocks is entered is the one at which they stand in the bank books. This will be found to be very much below the current market value, the securities, when bought, being written down to a figure to which it is thought they will in the ordinary course never fall. Before the recent enormous fall in Consols it was very customary to value them at 90, but the unexpected course of events has rendered a lower figure necessary. It is usual to give in the balance-sheet a somewhat detailed statement of the securities held. Bills discounted and loans may be either given in one sum or in detail.

Bank Bookkeeping. In this section it is assumed that the reader is either possessed of some practical acquaintance with the above, or has a knowledge of the system used in mercantile business. If the contrary be the case, some study of ordinary bookkeeping will be necessary, after which the special points of that applicable to banks will present no difficulty. One essential difference is the absence of stock and manufacturing accounts, and the attendant periodical stocktaking. The material property possessed by any bank is, compared with the total amount of its resources, comparatively small, seldom undergoes any change, and is held at a figure much below its real value.

Each entry in bank bookkeeping is a cash book or journal one, nothing corresponding to the mercantile day and invoice books being in use. A debit entry in a bank ledger has the effect either of: increasing a debt due to the bank, decreasing a debt due by the bank, increasing the amount of an account representing a material or similar asset, or ultimately forming a charge on profits; while a credit entry has the effect of either: decreasing a debt due to the bank, increasing a debt due by the bank, diminishing the amount of an account representing a material or similar asset, or ultimately forming an addition to profits.

We consequently find in all bank offices two books—which may be termed the general cash book (or journal) and the general ledger—through which all transactions pass, either briefly or in detail, the subsidiary books being divided into these classes:

1. Cash books.
2. Cross entry books.
3. Registers (with or without running numbers).
4. Ledgers.
5. Books partly registers and partly ledgers.
6. Books kept in diary form.
7. Books recording balances and other particulars.

General Ledger. The table given on the next page represents the balances shown in an imaginary general ledger, kept at a head office (the shillings and pence being omitted).

The Bank's Account. In the example given the bank is supposed to have three branches, a separate account being kept by the head office for the transactions referring to each of them. At each of the branches consequently three accounts will also be kept under this heading. This method is best adapted to a foreign or colonial bank with few and widely spread branches, as it enables each particular branch to ascertain at any time the position of its account with any other office, and allows of the inter-branch accounts being checked by the offices concerned.

In the case of a large home bank there is no necessity to know the balance of the transactions between any two branches, and the entries will, in consequence, be passed through

one account. The weekly returns from the branches of this account will, in such a case, be audited by the head office, and may be divided into sections, bearing either the names of the corresponding branches or of the various classes of business. The first method admits of an error once passed being perhaps more easily discovered, but the second allows of a summary of the different classes of outstanding entries being more readily made up. The amalgamation into one account in the example given would, of course, result in the substitution of the following for the first three balances:

Dr.	
£99,226	Bank's Account.

It will be apparent that the balances in the head office general ledger do not include the whole business of the bank, the £129,812 shown against Deposit Receipts being the total outstanding of those issued by the head office only. The business current at the other branches is represented only by the balance or balances at the Bank's Account.

In addition to the Bank's Account, the accounts which are common to the general ledger at all branches include current accounts (the balance of which represents the total of the accounts in credit less the amount of overdrafts, or vice versâ), loans, deposit accounts and deposit receipts, the balances shown corresponding with the current outstandings.

Discounted Bills. It is the practice to place the full amount of a bill, when discounted, to the debit of some bill account, crediting the discount at the same time to an interest account. Sums received in payment are credited to the bill account, and should the draft not be duly met at maturity the amount will be transferred to *Bills Past Due Account*, the balance of which agrees with the total of unpaid past due discounted bills in the hands of the bank. A doubtful overdraft is not treated in this manner, but is allowed to remain in the relative ledger, although an amount has actually been set aside against it. A distinction is made between bills payable locally and those domiciled elsewhere, the *Local Bills Discounted Account* agreeing with the amount of this class of paper in hand.

Two distinct methods of dealing with the bills not payable locally are in vogue. The transfer of the amount of the bill from the books of the discounting office to those of the office to which it is forwarded (for presentation for payment on due date) may be made either at the time of discount or at maturity, the draft disappearing as an asset from the books of the discounting branch when such an entry is made. The bill will, if the amount be debited at the time of discount, appear during its currency as an asset at the *Receiving branch*, and an account similar to that for Local Bills Discounted will be kept by it for *Discounted Bills Received from other Offices*. If the second method is adopted, the discounting branch will keep a *Bills Discounted and Remitted Account*, which will correspond with the amount of bills discounted (other than local), which have neither been advised as paid or returned unpaid. *Nominal* accounts may be kept by the remitting branch, in the first instance, and by the receiving office, in the second.

Nominal Accounts. When it is considered desirable to know the amount at any time of any particular class of business, which does not at the time constitute an actual liability or asset at the office in question, two accounts will be opened in the general ledger, the one to give the total outstanding and the other to balance the amount shown in the former. Two instances are given in the specimen general ledger balance—the first relating to bills received by the head office for collection which have not been discounted. On such a bill being received an entry is passed increasing the balances of the two accounts to the same extent, and on any bill being paid or returned the balances are reduced by an equal sum. The same procedure applies to the *Acceptances Account*, which shows the total contingent liability of the bank and contingent liability of its clients in this connection. As no book-keeping check exists on such accounts special care requires to be exercised with regard to them.

The Stamp Account. The *Stamp Account* shows the value of stamped forms as yet unsold to the bank's clients. The cheque forms, etc., are not stamped immediately after being printed, but only when required to replenish the stock in hand, and, in consequence, the balance of this account will never be of very great amount.

Letters of credit and circular notes represent the amount of such documents issued. The balance of a *Circular Notes Account* kept at a branch appears on the opposite side of the ledger, the head office, in forwarding a supply to the branch, treating the latter as if it were a customer, and debiting the branch with the full value. An account is accordingly opened by the branch and kept on similar lines to its local Bill Account. On any note being issued its amount is deducted from the branch account, the account kept at the head office being reduced on payment being made by it to the ultimate holder of the note. The foregoing accounts may be added to, or divided, to suit the convenience of any particular office or system.

Profit and Loss Accounts. Profit and Loss Accounts are represented in the example given by interest, commission and charges, but these may be subdivided to show the amounts relating to each particular class of business, a result that may also be obtained by ruling the portion of the ledger used in the manner indicated on this page (the interest account being dealt with).

The columns shown (increased to cover all classes of transactions) are summed and balanced periodically, and give the information required.

The remaining accounts (with the exception of cash) come under the heading of *Accounts Peculiar to the Head Office.* The Cash Account simply represents the cash on hand, including the bank's own notes in the cashier's tills. Capital, Reserve Fund, and Contingency Fund require no explanation. Notes Issued represents the total handed to the cashiers or sent to the branches which have not returned for destruction, the amount including all notes held at any office. *Dividend Account*, the balance of which is transferred after a certain time to the *Unclaimed Dividend Account*, shows the total of the current dividend warrants outstanding.

To Profit and Loss Account the balances of the profit and loss accounts at all the offices are transferred at each balance, while it is reduced by the sums put to dividend, reserve, contingency, premises, investment, pension, or other accounts. If any amount is laid aside to provide the working of a pension scheme it is placed to a special account kept at the head office. *Suspense Account* is dealt with under balance work. The other accounts have already been referred to, and subsidiary books are dealt with subsequently.

With a view to convenience, some accounts other than in the name of clients may be kept in the Current Account Ledgers instead of in the general ledgers. "Unclaimed Balances"—the account to which all sums left unclaimed for a certain time are transferred—is invariably one of these, while accounts for the temporary disposal of money which cannot be finally dealt with on receipt may be treated similarly—*e.g.*, an amount transferred from another office to await instructions may be placed in such an account.

Cash Books. The General Cash Book may either be written up from the subsidiary books, from vouchers, or partly from one and partly from the other, all cross entries between departments (which in a large office will be numerous) being, of course, eliminated. It may either be written up concurrently with the subsidiary books or on the following day, the entries being collected and arranged in the order most convenient, while the book may be closed off, either daily or weekly.

In large offices, the cashiers may be divided into two classes—receiving and paying. The cash books of the first simply record the sums paid in during the day, the total being agreed at the close of business with that of the relative waste book.

The latter is a very wide book, in which the particulars are entered in a manner similar to that shown on this page.

* Number of Note. † Documents drawn on the bank in question.			40	10	130	10	20	210

The columns may be increased and divided, as may be deemed necessary, while the number of particulars given depend on individual practice. The paying cashiers record all sums paid away (mainly cheques drawn on current accounts), the numbers of Bank of England notes paid out being detailed.

Each cashier may deal with the ledger accounts only under a certain letter or letters, while Deposit Receipts, Country, Bill and other business will in all probability be dealt with separately.

The cash book of an official at a small office, however, contains the entries comprising the whole range of business, and in such a case the advantage of a columnar cash book is evident. By means of this any body of entries whose number is large (*e.g.*, those relating to current accounts) may be entered in a special column—the total of which is carried to the outer column at the end of the day—making the discovery of errors a much easier matter.

Cross Entry Books. A large number of books of varying form will be kept by the different departments to record the entries passed by them, the bill entries going perhaps into one, the correspondence remittances into another, and so on, although arrangements may be made to enable certain officials, through an elaborate use of vouchers, to deal with all such entries. All given to another branch or bank to cash the cheques of any client to a certain extent should be entered in the ledger, and a similar course adopted with regard to cheques on which an endorsement guaranteeing payment has been placed by the banker, so that, if necessary, the account may be kept at a figure sufficient to cover these outstanding liabilities. A very numerous body of entries (say, dividend warrants) may be detailed in a subsidiary book, and only the total inserted in the ledger.

Checking. The checking of the entries should be done by independent officers, while fraud is further guarded against by an occasional interchange of ledgers. It is usual to extract weekly the balances shown, and to agree the result with the general ledger account, the return of overdrafts being made up from this balance.

cash and cross entry books may only be used on alternate days, to facilitate, if necessary, the work of checking. The example shown above will show that a bank ledger differs somewhat from the ordinary mercantile form.

In the foregoing example we start the New Year with a balance of £100, £200 being received, and three cheques amounting to £350 being paid, leaving the account overdrawn £50. The balance must be shown at the close of each day, and, if it is an overdraft, must always be preceded by the sign *Dr.* In some banks it is not customary to repeat the sign *Cr.* against every balance when the account is *invariably* in credit. The numbers given are those on the paid cheques, although the names of the parties in whose favour the cheques are made out are in some cases entered.

For convenience in reference, the ledger accounts are arranged alphabetically, while the heading of each account should set forth the security held, the overdraft limits authorised, the names of persons authorised to operate, and so on, the ledger keeper being responsible to see that all cheques paid are in accordance with these particulars. In entering any sum received he should be careful to distinguish between cash and cheques, to obviate the possibility of a cheque, the fate of which has not been received but which is afterwards returned unpaid, being paid against as cash. The particulars of any authority

In an office employing several current account ledgers, two books, ruled in the manner shown below, will be used to record, under the heading of each ledger, the debits and credits referring to it. These books, which are agreed with the current account entries in the cash and cross entry books, allow of each ledger being balanced separately.

Each entry in the deposit receipt register is initialled by the official who signs the relative receipt, a similar practice being adopted with regard to drafts and transfers. The columns in the register for these will provide for date, number, on whose account, in whose favour, paying branch, amount, commission, initials.

Name.	Fo.	A—D	E—K	L—R	S—Z

Bill Registers. The bill registers (which will be divided into various sections) give all particulars regarding bills received from customers, either for discount or for collection, and any documents attached thereto—date of entry, running number, names on bill, date of bill, currency, place of payment, amount, rate and amount of discount, details of documents, etc. In the bills for collection section, the discount columns will be replaced by one in which the date on which payment is received or advised is marked. Bills received to be forwarded to some point, for acceptance and return, may be placed in a separate section.

The entries relating to bills received from other offices do not require to be so elaborate, but the due dates of these and of local bills require to be

very carefully entered in a book kept in diary form (under the date on which they mature), to prevent the presentation for payment being omitted.

Diary. The diary forms, in addition, a convenient method of noting the expiration of a loan, or any other business which will require attention on a certain date. The form given below is one covering several classes of business.

Discount Ledger. The discount ledger is kept to show the total discounts current at any time, the amounts of the bills being debited when discounted and credited when matured, a special account being opened for any client discounting largely, and all miscellaneous items being collected under "sundries." A statement may be made up weekly to balance with this ledger, showing the amount discounted at each rate.

In addition, books in which are recorded the particulars of periodical balances, cheque books sold, cheques and other documents received, with clients' signatures and letter registers, postage books, indexes, files for letters of credit and other authorities, and a multitude of small memo. books in which outstanding matters, particulars of securities, etc., are entered, will be required.

The securities lodged for safe custody are entered under the heading of each client's name, the fullest particulars being given both of the bonds, etc., and of any coupons attached. On delivery being made of any particular document, the receipt on which it appears may be returned, endorsed, and a new receipt for the remaining bonds issued, or the old receipt may be allowed to stand, the entry in question being deleted and a receipt taken from the customer. If the documents are numerous and operations frequent, it is desirable that the client should employ a locked box to which persons bearing authority are allowed access.

The bookkeeping returns from the branches may be divided into two sections—those which refer to local business (deposit receipts, current accounts, etc.), and entries to the bank's account. Every entry in the last requires to be detailed (for head office checking purposes), but the other transactions need only be given in brief form, no useful purpose being served by, say, a long statement of current account transactions.

Balance Work. With a bank possessing a large number of branches scattered all over the country it is clearly impossible for the auditors

Banks dispensing with waste books will, in addition, use registers giving particulars of cheques remitted.

Pass Books. The pass books are, in a way, distinct from all the other books of the bank, being the only part of the system which is directly subject to the scrutiny of the public. They are, moreover, regarded as the customers' books, the entries being placed on the reverse side to that on which they appear in the bank's ledger, the pass book being similar in form to the bank account kept in the customer's ledger.

The pass books should be written up from the vouchers, and not merely copied from the ledgers, all books in hand being regularly made up each morning to include the transactions of the previous day; and when any book is handed to the customer concerned, a mark to this effect should be placed against the relative balance in the ledger. The practice in Scotland is somewhat different. There the paid cheques are not delivered till the customer has certified the amount to be correct. In England, however, the paid cheques are, on the day following, sorted under the names of the various clients, being either sent with any statements rendered, or placed in a pouch provided in the pass-book cover and delivered when the book is sent for.

to examine all the books personally. In consequence, the signed returns from the other offices are accepted as correct (the periodical inspection from head office supplying the necessary check). The ordinary weekly returns are made up to the night of the balance, and from these the head office is at once able to make up a balance-sheet similar to the usual weekly one.

The balances of the profit and loss accounts at the branches having been transferred to the head office (after closing the books for the half-year), through the bank's account, the only modifications which the balance-sheet subsequently undergoes are on account of the suspense or adjusting entries for interest *due but not applied, etc.* For such entries no further particulars are actually required by the head office, beyond the total amount due at each branch of interest on deposits and loans of rebate on bills discounted outstanding at the time of the balance, etc. In practice, however, the individual amounts of principal and interest or rebate are given against each name. If the current account and deposit account interest is applied on the date of the balance, no adjusting entries will be required on their account.

Deposit Receipts and Ledger Accounts. Some little time before the balance, the decimals and interest calculations in the ledgers are carefully checked to date, and on the evening *previous* to the end of the year or half-year the total amount due on each account is found and entered in the return previously prepared. On the succeeding night after the ledger balance has been agreed, the principal sums are also entered. The interest due on individual deposit receipts is calculated, and the return of outstanding receipts made up before the date of the balance, those paid after insertion being subsequently deleted. The interest on receipts issued during the half-year is calculated on each separate amount (with the assistance of a table, giving the decimal for each day), while that on those which were outstanding at the date of last balance may be arrived at similarly, or by the addition of the amount due for the half-year to that accrued at the last balance, each calculation in the latter method being based on the same decimal. The correctness of the interest calculations may be proved by keeping an account showing the daily balance of deposit receipts, the interest due on which is reckoned in a manner similar to that on ledger accounts. This, added to the amount due at the previous balance, less what has been paid during the year, should equal the sum now due.

Bills Returns. The bills detailed in the Bills Returns may be either bills remitted or bills received, according to the method of keeping the general ledger account. In either case rebate for the time yet to run will be calculated at a rate (usually 5 per cent.) which will more than cover the rate at which discounted, a lower rate than that of discount inflating the current profits at the expense of those for the succeeding period. No interest is calculated on past due bills. These returns, together with any additional ones required by the head office for their own information, having been summed, checked, signed, and despatched, the ledger accounts having been closed and reopened in the usual manner, and the registers ruled off and new running numbers begun, the balance work at the branches may be considered to be finished, all further entries being passed by the head office.

Before passing on to the head office work, the important return in connection with bad and doubtful debts calls for remark. This return is made up at each branch and despatched to the chief office some little time (say, one month) before the actual balance. In it all past due bills are fully detailed, the security held and prospects of payment being dealt with at length, and the probable loss (if any) stated. Any loans or overdrafts considered in any way doubtful are dealt with in a similar manner, although the return may include every loan, whether doubtful or not. In addition, if any loss is thought likely to result on any bills held but not matured, the circumstances will be recorded in this return, which, on being received at the head office, is carefully gone into by some of the principal officers, and the amounts required to be set aside against probable losses determined.

Head Office Balance Work. The ordinary weekly audit is pushed forward as quickly as possible, and after it is finished the outstanding entries in the bank's account are dealt with, a special cross entry book or journal being utilised. The first class of such entries deals with the transfer of the balances of the profit and loss accounts at the branches, made by these offices on the last day of the half-year. These are carried to the profit and loss account. The book to which the outstanding drafts and transfers are weekly transferred is next taken in hand, and the items of this nature remaining unpaid agreed, these will be probably detailed in the book itself, the total being entered in the special journal, and appearing in the balance-sheet as a liability. Special entries carry the bills discounted and debited to the receiving branch on the last day of the half-year to a special account, the total of which is included in the amount shown against bills in the balance-sheet. A similar procedure is adopted with cheques and with any other entries unresponded to.

The amount of cheques in transit may either be included in the amount of ledger loans or combined with the cash items. The entries in this special journal, or cross entry book, clear out all sums outstanding in the weekly returns, anticipating the responding entries appearing in the returns subsequently received. In the case of a bank possessing only one office, these entries will be unnecessaiy ; but entries for unapplied interest, etc, require to be passed in every case.

The amount due by the bank as interest accrued but not paid, rebate, etc., forms a charge on profit and loss, while interest, etc., earned during the period just closed, but which has not been applied, requires to be credited as profit. Entries, based on the branch returns, will accordingly be passed.

Debiting Profit and Loss and	Crediting Suspense with	Interest due at date of balance by the bank on deposit accounts and deposit receipts, rebate on bills discounted.
Suspense	Profit and Loss	Interest due at the same date to the bank on loans, overdrafts, investments, rent.

As suspense account acts as a transfer account between the profits of one year and another, before any entries are made relating to the current balance the sum resulting from those passed at the preceding one is removed from suspense and carried to profit and loss. An amount of interest due to the bank, outstanding on the 30th June (the date of the balance) and paid the following day, will, if the next balance is on the 30th December, be included in the amounts of entries passed, as follows :

	Debited to	Credited to
June 30..	Suspense	Profit and Loss
July 1..	Current Accounts	Interest
Dec. 30..	Interest	Profit and Loss
	Profit and Loss	Suspense

The amount of suspense account will be included in the balance-sheet in the total of either current account deposits or loans.

Continued

FLOORS AND PARTITIONS

The Three Classes of Floors—Single, Double, and Framed. Floor Joists. Ceiling Joists. Trimming. Strutting. Binders. Girders. Various Forms of Partitions

CARPENTRY
continued from
page 4254

By WILLIAM J. HORNER

A FLOOR consists of a framework of joists covered usually by flooring boards, the work of laying down the latter being allotted to the joiner. Floors are no longer invariably constructed of wood alone. In floors of large area, steel girders are employed, and in warehouses, factories, and other large buildings even flooring boards are sometimes discarded in favour of concrete or other material. In such cases there is no carpentry work.

There are three types of framework on which flooring boards are laid, the span of the floor usually deciding which must be employed. In all cases the boards rest on a series of joists about 12 in. apart, running in the transverse direction to the boards. In the simplest type of floor, called a *single floor*, these joists bridging from wall to wall [**284**] are all that is necessary. In spans which exceed 20 ft., and often in much smaller ones, the joists themselves are supported at one or more intermediate points by a larger transverse timber called a *binder* [**285**]. This intermediate support makes it possible to use flooring joists of smaller dimensions than would otherwise be necessary. It is then called a *double floor*. In floors of very large area, further transverse members, known as *girders* [**286**], are employed to afford support to the binders. Such a floor is a *framed floor*. It is called framed because the girders and binders are generally framed together at the points where they cross, but in some cases, where the increased depth of the framework of the floor is not objectionable, the binders rest on top of the girders.

Single Floors. In single floors, where joists alone are used, they are usually made to bridge the narrowest way of the room or building. Their ends rest on wall plates, or templets, which in upper floors are usually built into the wall, and in ground floors are set on brick offsets. Very often offsets can be arranged for the joists of upper floors by reducing the walls in thickness above each floor. When built in, the templets are of stone or metal, in preference to wood, because the latter decays in such situations and is bad in case of fire. At least ¾ in. of air space is allowed round the ends of joists to prevent decay. Joists which do not have to span more than from about 8 ft. to 12 ft., should measure in section about 2 in. by 8 in., which is the average dimension, though 2 in. thick is a minimum, because a continuous line of nails has to be driven into them to hold the flooring boards, and less than 2 in. would be likely to split. Floor joists, like the common rafters of roofs, do not need to vary in strength with the area of surface covered, because it is found best to support them at intervals of about 8 ft. Long timbers are generally slightly curved in length, and should always be laid the rounding side up, to allow for sagging. Knots, if possible, should always be at the top, because they stand compression better than tension, and therefore are in the best place when in the upper portion of a beam.

In ordinary dwelling houses, single floors are usually sufficient as far as strength is concerned, but what is rigid enough for a floor is often not sufficiently so to prevent a ceiling below from cracking if the laths and plaster are attached directly to the under surfaces of the floor joists. Another objection to a single floor is that it transmits sound from one room to the other very readily.

Ceiling Joists. Without introducing binders to support the joists, these two defects may be reduced by attaching ceiling joists to the under surfaces of the floor joists [**288**], contact between them being made only at every fifth or sixth joist, to lessen the surface through which sound can pass. This is sometimes called a *double floor*, though it differs from the double floor in which binders are used. As ceiling joists have only the laths and plaster of the ceiling to support, they are of small dimensions compared with floor joists, being frequently not more than 1½ in. by 3 in., or 2 in. by 3 in. In floors where they have to span 8 ft. or 10 ft. from binder to binder, they may be 2 in. by 5 in. In single floors ceiling joists are nailed, and usually notched as well, to the under surface of the joists, running, of course, transversely to the latter. In double floors they are generally fitted between the binders [**291**] to avoid adding needless depth to the floor. In all cases they project slightly below the other members of the floor framework, so that when the laths are nailed to them there will be no other surfaces to prevent the plaster passing through and becoming keyed to the laths. When ceiling or floor joists are more than 2 in. thick, strips 1 in. square are often nailed to their under surface, to attach the laths to, thus affording a better key for the plaster.

Trimming. Examples of trimming are shown in **284**. Trimming is necessary in almost all floors, in order to keep the joists clear of fireplaces, stairways, and flues in walls. The trimming pieces which enclose the open space are stouter in section than the ordinary joists, an increase of an ⅛ in. generally being added to their width for every joist supported by them. The joints are usually tusk tenons, because that affords the best support with the minimum weakening of the timbers. Sometimes stirrups are used instead. When the trimming can be effected in line with the joists, as at A [**284**], it is,

of course, more satisfactory, and when the position of a fireplace or stairway is fixed this sometimes makes it advisable to run the joists the longest instead of the shortest way of the span, in order to simplify the trimming. On ground floors no trimming is required, because brickwork can be built out to support joists where necessary. The trimmed space before fireplaces is made flush with the floor boards by a hearthstone, the edges of which rest on the wood trimming and the body on a bed of concrete, which is laid on an arch within the trimmed space. This arch is sometimes of wood, but more often of brick, as in 290. Sometimes a flanged sheet of steel is employed. When the arch is large, its pressure against the wood trimming is considerable, and the latter is often better enabled to resist it by the insertion of long bolts, the nut ends of which go through the wood, while the other ends are hooked and built into the wall.

Strutting. Struts, or braces, between joists [289] enable them to assist each other in supporting a load and prevent them from twisting. They are placed in continuous lines at intervals of about 4 ft. In a span of 8 ft., for instance, there would be one line of struts across the centre. The herringbone method of strutting is the best and most commonly employed. The struts are in section about 2 in. sq., with their ends cut to the correct angle. They are held by a nail at each end, driven generally through a saw cut instead of a bored hole, as the former is more easily made, and obviates the risk of splitting. Solid struts are also sometimes employed. They are made slightly less in depth than the joists, and the whole series are sometimes tightened by a long bolt passing through the joists close to the strutting.

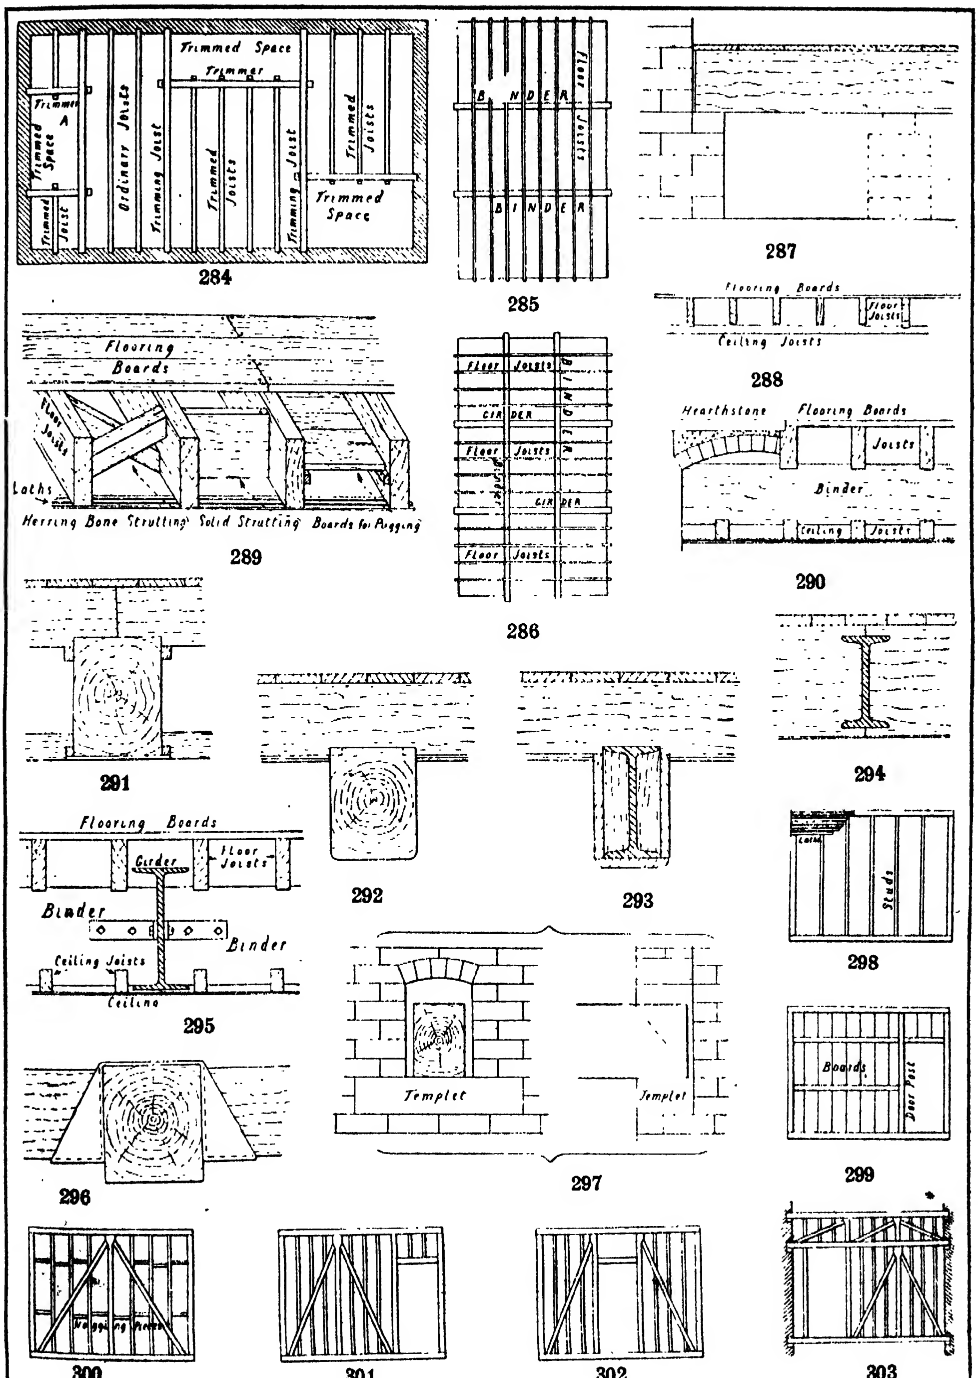
Pugging. This is often resorted to for preventing, as far as possible, the passage of sound and odour through a floor. The carpenter nails fillets and lays boards on them, as in 289, and on this is deposited rubble or other suitable material for absorbing sound. Another method is to tack felt on the tops of the joists. Sometimes felt is put on in continuous sheets dipping down between the joists so that it will support sawdust or other material in the same way as the boarding shown in 289. An objection to pugging is that the absence of ventilation tends to induce dry rot in the wood.

Double Floors. A double floor is made up of binders, floor joists, and, in most cases, ceiling joists. In these floors the binders usually lie the shortest way of the span, and they must rest on substantial parts of the building, never where there are window or door openings below. This, of course, is still more important in the girders of framed floors. Fig. 285 shows a double floor in which two binders are used, thus dividing the entire joist length into three spans. In many cases only one binder is necessary to support the middle of the joists. The floor joists are either cogged on top of the binders [292] or notched, and perhaps also supported on fillets, as in 291. The ceiling joists below are notched on, or fitted between, sometimes tenoned in with chase mortises, but a better method is that shown in 291, in which they are supported on fillets. Binders are very often of steel instead of wood. Sometimes they extend below the ceiling level, as in 292 and 293, and have their corners rounded or beaded if of wood, or are boxed in if of steel. The distance apart of binders may vary greatly according to circumstances, but an average distance is about 6 ft. or 8 ft. Sometimes, to avoid building all the joist ends into the wall, binders are used to support the ends of the joists, leaving a little clearance between wall and joist ends. Occasionally, when steel binders are employed and it is desired to keep the floor depth as shallow as possible, the joists may be framed between the binders as in 294, or in any other convenient manner, but, as a rule, joists rest on top of binders.

Framed Floors. The girders of framed floors [286] are now almost invariably of steel. When of timber they are generally flitched by bolting two halves together, with an iron plate between. In a few cases the binders rest on top of the girders, but, as a rule, they are framed together to avoid great depth of floor. When there is no ceiling the girders are sometimes placed below, or, even with a ceiling, they can be treated in the same way as the binder in 293. When framed together in the same plane the lower flange of the metal girder is utilised to support the binder ends [295], and further security is obtained by bolting brackets or angle irons to the sides. Either wood or metal members may be connected in this way. When the girder is of wood tusk tenon joints may be made, but they weaken the girder by the removal of some of its substance, and therefore it is more satisfactory to support the binder ends by light iron stirrups [296]. Generally, the distance between girders should not exceed 10 ft., but this depends on circumstances. Binders are never allowed to occur near the middle of girders, but are always divided equally on each side to strain them as little as possible.

The ends both of girders and binders rest in pockets in the walls [297], or on built up offsets; occasionally on projecting corbels, but this is not so satisfactory as either of the preceding. They are also often carried in cast-iron shoes or stirrups built into the wall. If the latter plan be substantially carried out, and the timbers be not heavy, it is better not to let them enter the wall at all but merely to rest in the stirrup, because in case of fire they cannot then damage the wall when they break and the ends tilt up. Another good means of accomplishing the same end is to bevel the ends of the timbers as indicated by a dotted line in 297. This does not appreciably diminish their strength, allows them to enter the wall, and also leaves plenty of air space. The main timbers in ground floors may be supported intermediately by brickwork [287], and those in upper floors by pillars or stanchions.

Flooring Boards. These are generally laid down by the joiner. The forms of edge joints between boards have already been shown in 132 to 139 [page 3845], but plain square butt joints are



TIMBER IN FLOORS AND PARTITIONS

284. Single floor **285.** Double floor with two binders **286.** Framed floor **287.** Brickwork for main timbers **288.** Ceiling joists **289.** Strutting and pugging **290.** Floor with brick arch for hearthstone **291.** Double floor **292.** Cogged floor joist **293.** Steel binder in floor **294.** Joists framed between binders **295.** Floor showing girder and binders **296.** Binder supported by iron stirrups **297.** Wall pockets for girders and binders **298.** Simple partition **299.** Partition with boards instead of laths **300-303.** Trussed partitions

frequently employed for flooring boards. They are generally nailed on to the joists with flooring brads. In some forms of joints these can be concealed. Occasionally, in high-class work screws are used, their heads being sunk about ½ in. and the holes afterwards plugged with wood, the grain of which runs the same way as the boards. End grain joints may be either square or splayed. In the latter case only the overlapping part need be nailed. These joints must, of course, always occur on joists. For the sake of uniformity the lengths are usually arranged so that alternate boards are joined on the same joist. An unbroken line of heading joints is never allowed to occur on one joist as it would be a needlessly weak arrangement. To minimise the opening of joints through shrinkage of boards in their width, they should be well seasoned and tightly cramped together in laying. Narrow boards shrink less than wide ones. In good floors two thicknesses of boards are sometimes laid, one at right angles to the other. In such cases the upper series of boards are usually of hard wood and less in thickness than the lower ones. Wood blocks are sometimes employed instead of boards, but they are laid on concrete.

The laying of floor boards should be delayed as long as possible to avoid getting them swollen by dampness in the building, and subsequently shrinking badly. When put down they should be as dry as possible. In cases where two layers of boards are put down transversely to each other, the under ones may be laid as soon as the joists are ready for them, and the others put on when the main work of the building is completed.

The Carpenter's Work. The dimensions of the timbers are decided by the span and by the weight the floor has to carry. This latter ranges from about 1¼ cwt. allowed for each square foot of floor surface in dwelling-houses to 3 cwt. in warehouses and factories. The stability of girders and binders, and the supports on which they rest, are of more importance than joists, which need not vary greatly in section in any floor. The carpenter is provided with timbers of the section required, and his work consists in cutting them to length, making the necessary joints, and securing them in place. This is generally done while the walls are in course of erection, because it ties the walls and also provides staging on which planks can be laid temporarily for convenience in building. As, with the exception of flooring boards, the wood is all concealed when the building is finished none of it is planed, and no regard need be paid to appearance. The work is usually of a simple character when the arrangement of timbers has been decided on, for the joints, both at ends and at intersections, are repeated, and are plain in character, with the exception of tusk tenons, which are now comparatively seldom employed.

Partitions. Partitions between rooms are very frequently of wood instead of brick or stone. The simplest form of partition is shown in **298**. It is called a *studded* partition, and is intended to rest on a floor or joist. It consists of a square frame, the outside members of which may measure 3 in. by 4½ in. or 4½ in. by 4½ in. in section, filled in with a series of studs measuring 2 in. by 4½ in. placed at intervals of 1 ft. or 2 ft. Laths are nailed across these and plaster laid on as for a ceiling. Another method is to use boards in place of the laths [**299**], two horizontal rails being shown in this case, the upper one corresponding with the top of the doorway. Sometimes the spaces between the studs are filled in with brickwork, and these are called *bricknogged* partitions. The partition is usually 4½ in. thick, to correspond with the bricks, but in some cases when the partition is very small, it is made 3 in. thick, and bricks may then be built in on edge. In many cases the weight of the partition cannot be allowed to rest on a floor, but must be carried directly by the walls.

Trussed Partitions. The framework then has to be trussed in a very similar fashion to that of roofs. Figs. **300** to **303** are examples of partitions which are said to be trussed, and which will bridge from wall to wall, with much more rigidity than the first two examples. Doorways at the side are usually necessary, and this complicates the trussing. Trussing, however, is not often now carried out so elaborately as formerly, the walls being often bridged by a steel girder which supports the partition, or the partition is arranged to come over one of the floor girders or binders, the dimensions of the latter being increased, if necessary, to carry the extra weight.

The vertical studs are often stiffened by transverse nogging pieces. These may be fitted between [**300**], generally out of line as shown, for convenience in nailing them in; or they may be in one piece notched in, either flush or slightly below the surface of the studs. In some cases short pieces are rebated between, instead of simply nailed. When laths and plaster have to be attached, the studs are generally a trifle wider than other parts of the framework of the partition, so that the latter will not interfere with the key of the plaster. As with ceilings, narrow strips are sometimes put on the surface of wider pieces so that when the laths are on the plaster will not have its hold interfered with by the wide surfaces immediately under the laths. The attachment of narrow strips for this purpose, both in ceilings and partitions, is called *brandering*, or *firring*. Studs are stub-tenoned, and principals tenoned through at top and bottom.

In large trussed partitions the joints and methods of connection very much resemble those of king and queen post roof trusses. Straps and bolts are used in the same way, and the methods of jointing are the same. The horizontal member at the base is called the *sill*, the one at the top the *head*, and intermediate ones *intertie*. The vertical members at the ends are *wall posts*, and those which form doors are *door posts*.

SOUL AND MATTER

The Physics of the Body. Animal Magnetism. Mesmerism and Hypnotism. Psychical Mysteries Can Never be Explained by Physics

Group 24
PHYSICS
31

Continued from page 4246

By Dr. C. W. SALEEBY

IT is good to have the opportunity of discussing, however briefly, a subject of very grave interest, which has unfortunately lent itself to all sorts of quackeries and abuses. It has long been positively known that the living body possesses a number of remarkable electrical properties. We have already seen, for instance, that electrical changes are produced in the retina of the eye by the influence of light. Muscular tissue, also, is the site, under certain conditions, of the production of an electric current. We may briefly remind ourselves of the celebrated observation made by Galvani, in 1786, of the motion in a frog's limbs hung from a metal railing. We now know that the muscles of that limb were alive. No current can be produced in dead muscle. The brief facts we have noted are only indications of the existence of a very interesting branch of science known as *animal electricity*.

Mesmer and Mesmerism. But the term *animal magnetism* has been applied to phenomena of a different kind. They were first and most notably exploited by the celebrated Anton Mesmer (1733–1815). It was his theory that the influence exerted by certain persons upon other persons, and notably upon some of their diseases, is really of magnetic origin. It was a reasonable inference from this theory of animal magnetism that similarly satisfactory results might be obtained from the use of ordinary magnets in the treatment of disease. It was not long, however, before Mesmer discovered that this theory did not hold; nevertheless the term animal magnetism survives to this day, and is still used or abused in many quarters. Only last year (1905), for instance, there was published, under the title "Personal Magnetism, Telepathy, and Hypnotism," a book which contains a good deal of truth, but which, unfortunately, tends to perpetuate a delusion. We may say positively that, in the sense in which the phrase has been used since it was first coined, there is no such thing as animal magnetism.

We must not be misunderstood. It is one thing to assert that there is no such thing as animal magnetism, another and an entirely different thing to deny the reality of the remarkable and extremely important phenomena which this stupid phrase has been called upon to explain. Mesmer was a clever man, but he had much quackery in him, and his successor, the Baron Reichenbach, was like unto him. This man believed that he had discovered an *imponderable*, or, as we should now say, a new form of energy, which he called *odyl*, produced by magnets, the human body, and other means.

Hypnotism. It was just about this time that, in 1841, James Braid, a Manchester surgeon, dismissed the physical explanation from the realm of the credible and raised the whole subject to a new plane. We owe to him the now recognised word *hypnotism*. The terms mesmerism and animal magnetism should be entirely dropped. They are wholly misleading, and indicate no truth at all. Amazing as the facts of hypnotism and suggestion are, and of the profoundest interest for the student of the mind, they have nothing whatever to do with what physicists have called magnetism, and the sooner the fact is generally recognised the better.

It has been thought by some that the recent and extraordinary extension in physical and chemical knowledge would reveal some basis of fact for the theories of those curious people who persist in desiring a materialistic explanation for these phenomena. This is not so, however. Neither the "chemistry of the ion" nor the "chemisty of the electron"—to quote useful phrases employed by Sir. Wm. Ramsay—has given the smallest indication of any physical basis for the facts of hypnotic suggestion; nor need the N-rays be adduced as providing a probable explanation. Whether these N-rays exist or not, at any rate they have nothing to do with hypnotism, which is concerned with the action of *mind upon mind*, and with that alone.

Human Radio-activity. The question arises, however, whether there has not been demonstrated such a thing as human radio-activity, and whether *this* does not furnish at last a reasonable physical explanation of the facts of suggestion or animal magnetism so-called - the term radio-activity merely being substituted for magnetism in the light of more advanced physical knowledge. In studying this question, the first point to consider is the existence of human radio-activity. As we have already seen, it is probable that radio-activity is a property possessed in varying degrees by all forms of matter, that which composes the living body being no exception. But, as we have also seen, there is only a very scanty group of rare elements which display radio-activity in anything like a high degree; indeed, the possession of this property by any elements other than radium, uranium, thorium, and a few more, is a matter of speculation and inference rather than actual demonstration. Now, though traces of these elements are possibly to be found everywhere, they are certainly not amongst the recognised constituents of the human body. For practical purposes, we may say that human radio-activity is a myth. If the living animal body displays any radio-activity at all, it is entirely negligible, being certainly

no greater than that of a host of impotent substances which have never been credited with the possession of "magnetism." That explanation must therefore be dismissed.

The Body is not Radio-active. The notion that the living human body is radio-active is due to a popular error as to the meaning of the term *radio active*. Readers of this and its companion course are aware that radio-activity is the outward and visible sign of an inward atomic evolution, and that this sign consists of the expulsion of electrons or charged units of negative electricity from the radio-active atom. It has been thought, however, and some of the medical papers have helped to propagate the error, that the term radio-activity means simply the production of rays. If this were so, the term would have no special meaning at all. Everything that transmitted light rays or heat rays would be radio-active in that sense. But the rays produced by radio-active bodies are not ethereal waves at all, but are actual particles or corpuscles.

The human body certainly does transmit ethereal waves, though there is no reason to suppose that these differ in quality or quantity in different persons according as whether they possess a high or low degree of *personal magnetism* so-called. The body reflects light that falls upon it. It also emits in large degree the waves of radiant heat. If we are to believe Professor Blondlot, the body also produces the particular kind of ethereal waves that are named after him, and if we are to believe his colleague, Professor Charpentier, these are produced in exceptional degree by active nervous tissue. None of these properties, however, has anything to do with radio-activity.

Non-physical Explanation of Psychical Things. Furthermore, all these properties may be absolutely excluded from the causation of the facts of suggestion. We may study the physics of the body as closely as we please, but we find nothing whatever that affords a physical or materialistic explanation of these facts. On the contrary, we are confirmed more than ever in our knowledge that they have nothing whatever to do with anything physical or material. They belong to a totally different order of existence, and no matter how subtle or refined or impalpable our conceptions of physical existence may become, we are not one whit nearer finding the psychical in the physical. The difference between the two is the most ultimate, fundamental and absolute of all differences in the universe; all other differences are superficial. Any kind of matter or energy can be transformed, we may believe, into any other kind, but soul can never be expressed in terms of matter.

The term *personal magnetism* is only one more illustration of the constant attempt to explain the psychical in terms of the physical. If the reader desires to realise how constant this attempt is, let him study the materialism which has always been, and still is, the curse of religion, and from which only the religious conceptions of the few in any age are free; then let him turn to language and, as in the case of the two meanings of the word *spirit*, he will realise that men have always tried to express the psychical in terms of the *rarefied physical*.

The Materialism of Human Thinking. Thus, in discussing the phenomena of suggestion and hypnotism, we must be entirely independent of any physical terms. We have to employ such words as suggestion and subconsciousness, but we will surely err whenever we introduce material language. The explanation of the whole illusion is immensely significant; it is to be found in the incurable materialism of nearly all human thinking. A purely psychical explanation will never satisfy anyone but the philosopher. The common people want something material, but, of course, they want it rarefied. They will be most indignant if it is suggested that the soul consists of matter—and rightly so. But if we suggest that the basis of the soul is electrical or ethereal, they are impressed, not realising that this explanation is just as materialistic as the other, and equally worthless. Thus, even at the present day, when some people who sternly reprobate materialism find solace in ridiculously materialistic explanations of psychical phenomena, we see the persistence of that habit of mind which the study of religions and the study of language which is almost incurably materialistic—proves to have prevailed amongst mankind throughout the whole of history.

Thirty years ago it was thought by some that physics, or, rather, the group of sciences which we include under that term, was approaching something like finality. There was doubtless much room for improvement in detail, but the great discoveries had been made. The last decade, however, has witnessed what is nothing less than a transformation of many aspects of physics and the addition to it of new sciences. Radio-activity is by no means the only subject which has sprung into new existence of late years. We must attempt to outline the main facts of some of these in the brief remainder of our course.

The Higher Psychics. It is to be hoped that we shall recognise how the "Great Mother of the Sciences," in giving birth to all these young children, has not lost her maternal control over them. On the contrary, every day shows more clearly, first, that each development in physics may be trusted to throw light upon subjects which, at first, may seem scarcely cognate, and, in the second place, that the empire of physics is steadily widening. Already we are on the verge of explaining all chemistry in physical language, as being none other than a matter of applied electricity, and the time is at hand when the whole of astronomy will be similarly included within the grasp of the great principles of physics. We cannot yet say that biology itself must be regarded as demonstrably no more than a higher physics, but the more closely we study living things and living matter, looking at them dynamically as well as statically, the more certain are we that this statement will one day be regarded as a platitude.

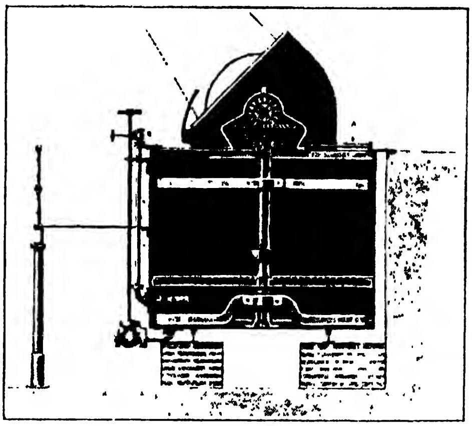
RĚFINING SUGAR

Melting, Filtering, Decolorising, and Boiling Down Processes. Crystallisation. Loaf, Cube and Granulated Sugar. Treacle. Golden Syrup. The Refinery

continued from page 4301

THE term *refined sugar* is used for those finer qualities which are made from raw sugar at central refineries, and in which animal charcoal has been used for decolorising. The term is often incorrectly applied to chemically treated beet sugars. Sugar refining is mainly a mechanical process, and consists briefly in dissolving the sugar in water, filtering through cloth to take out suspended matter, and then through animal charcoal to remove colour. The clear bright liquid is finally evaporated and boiled to crystallisation.

Preliminary Treatment. The raw sugar is usually submitted to a preliminary treatment before the first stage. The raw sugar is mixed with a small quantity of syrup, put into a centrifugal apparatus, and washed with steam until the syrup flowing from the centrifuge comes away of a light colour. Raw sugar may be said to consist of sugar crystals and molasses, and by washing out the latter the purity of the sugar is at once raised by this treatment. The method was first suggested by Weinrich, but much improved subsequently by Duncan and Newlands chiefly in the method of admitting steam and separating the grades of syrup. The process separates the raw sugar into partly refined crystals and washings containing a good proportion of the molasses.



21. MELTING OR BLOW-UP PAN
a. Charging opening *b*. Steam valve *c*. Steam injector for heating *d*. Discharge valve

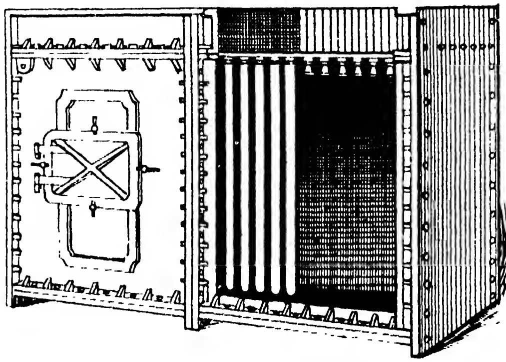
Melting. The partly refined sugar is dissolved in water, or as it is termed *melted*, the melting-pans, holding 3 tons to 10 tons, being known as *blow-ups*. The sugar is passed through a grating into the blow-up, which is provided with a false bottom, stirring gear, and heating arrangement either of copper coils or for live steam [21]. Here the sugar is melted at a temperature of 150° F. to 170° F. to a syrup of 28° Beaume, and is then filtered. In the case of low quality sugars defecants are used in the blow-ups, the oldest and best known being blood.

Filtration. Most refineries in Great Britain use the old Taylor bag or stocking filter [22] for clearing the liquor produced above, although the Danek filter is the favourite on the Continent. The filter presses described under Beet Sugar Manufacture are also used, but not to any great extent [page 4163]. The Taylor filter consists of a large iron chamber with tightly-fitting doors in the front. At the top is the tank or filter head, leading to a series of metal sockets to which long filter bags are attached. These bags are made of twilled cotton measuring 6 ft. long and 2 ft. to 3 ft. wide when opened out. The bags are put into sheaths of coarser material, and, the sheaths being smaller than the bags, a larger filtering surface is ensured. The bags are securely fastened on to the nozzles, and hang inside the chamber, which is fitted with steam heating appliances. A filter chamber contains 200 to 500 of the filter bags, and each bag can be separately controlled by plugging the hole leading to it from the filter head, this being necessary when one of the bags turns out to be defective. Some modern forms of Taylor filters have removable filter heads, so that the whole battery of filter bags can be removed at once and replaced by a fresh set.

The liquor from the blow-ups is run on to the filter head, and passes into the bags, the temperature being maintained by letting steam into the filter chamber. When the bags become blocked up with dirt the liquid ceases to pass, the supply of liquid is cut off, and the bags allowed to drain. The bags are then detached, and washed systematically in several tanks of warm water, the washings being reserved on account of the sugar they contain and run into the *sweet-water* tank.

Decoloration. From the Taylor filter the bright liquid is passed to large char cisterns. These are iron towers from 18 ft. to 50 ft. high, filled with animal charcoal or char. The bottom of the char cistern is a perforated plate covered with a blanket, and on this the char is packed to within a short distance of the top. The bright liquor, still warm, is allowed to flow in at the top, and, when full of liquid, the bottom cock is turned off and the whole left to "settle" for some hours. A char filter holding 20 tons of char has room, in addition, for about 10 tons of liquor. After a few hours, the cock at the bottom is opened, and the liquor, now free from colour, drains away. More liquor is slowly introduced, until the filtrate becomes tinted, when the stream of liquid is passed into a separate vessel for a lower grade product. This is continued until the colour shows that the char has ceased

to work, when the supply of liquor at the top is cut off, and what remains in the char cistern drained off; the char is then washed with hot water, and the washings run into the sweet-water tank as long as they show the presence of notable quantities of sugar. The char is in this way washed till the water runs clear, when it is allowed to drain, and the char taken out and revivified by burning. In some sugar houses, sulphurous acid is added to the yellow liquor and exerts a very effectual bleaching action, any excess of acid being expelled in the subsequent heating operations. Char-washing machines much used.



22. TAYLOR FILTER

Reburning Char. The revivification of the charcoal is effected in pipe kilns [23]. The pipe kiln consists of a series of cast-iron pipes into which the char is placed and heat applied to the outside of the pipes. The kilns are heated either by direct coke firing or by gas, the advantages of the latter method being that there is an economy of fuel, absence of ashes, and greater uniformity in heating. Beneath the kiln pipes are corresponding cooling pipes. The char is brought to the kilns wet, and is first dried and then, having been filled into the kiln pipes, is heated red hot. The char is next passed to the cooling pipes beneath by means of discharge valves, the contents of the cooling pipes being passed to a hopper, and from this taken to the char cistern for use again.

Animal Charcoal. Animal charcoal is prepared from bones by first degreasing them by heating with water or a solvent such as benzene, and then carbonising the bones in retorts. The carbonising takes six to eight hours and during the process bone oil and ammonia are given off and collected separately. The charred bones are then placed in air-tight bins to cool, and, after cooling, crushed and graded by sifting. Sugar refiners prefer a fine grain char for decolorising purposes. Why charcoal decolorises is not easily answered, but organic bodies in the char play an important part as colour absorbers. These organic bodies are gradually dissolved out by the sugar liquors, and although the char can be revivified a large number of times there comes a time when the organic bodies referred to are used up and the charcoal is useless.

23. CHAR REVIVIFYING KILN
(J. Buchanan & Son, Liverpool)

Alternative processes of revivification have been suggested by artificial cultures of bacteria.

Many substitutes for char have been proposed, several of them containing carbonaceous matter with absorbent earths. They fall far short of char.

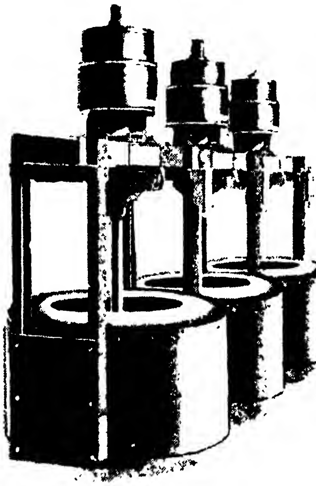
Boiling down is effected in the multiple effect apparatus and vacuum pans described in the article on beetroot sugar manufacture.

Crystallisation in Motion. In 1891 the Machinenfabrik Grevenbroich patented their method of crystallising in motion—a distinct advance on previous practice. The massecuite from the pan is run into the apparatus, which takes the form of a large cylinder, and is kept in very slow movement by a stirring arrangement. In most cases hot water is circulated in the outer vessel to control the cooling, and in some cases the vessel is airtight and worked under a partial vacuum, air pressure being utilised to empty the pan when finished. The process prevents the formation of small grain by inducing the crystallisable parts of the massecuite to grow on crystals already formed or introduced. In the latter case the crystals are brought up to the temperature of the massecuite before being added. The advantage of having large crystals over small ones is that the separation of molasses in the centrifugal machines is much facilitated.

The method is used in beet sugar manufacture as well as for residual products of the refinery.

Centrifugal Machines. When sugar is to be *machined* it is run from the vacuum pan into a heater fitted with stirring gear. From this it is placed into the baskets of centrifugal machines which, when revolved at a high speed, throw out the syrup. The sugar is more or less washed, discharged into bins, air dried, and packed in bags holding 2 cwt. for sale. The syrups and washings are collected separately; from the syrups another crop of crystals is obtained, while the washings, being

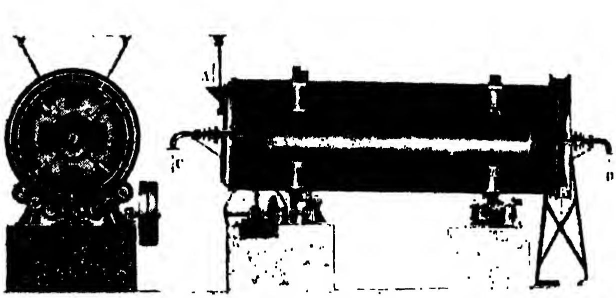
purer, are boiled up with the liquors used for producing first product sugar. The centrifugal machine [24] is an apparatus which by water, belt, or electrical driving is spun at a rate varying from 500 to 1,200 revolutions a minute. It is arranged for discharging the contents at the top or bottom and has washing or steaming appliances. Superheated steam is used in the Baker process. The basket into which the sugar is placed is made of perforated metal, the revolution of the basket causing the mass of crystals and molasses to be violently thrown against the inner wall; the molasses and a portion of the crystals pass through the perforations, but the greater part of the crystals are retained in the basket. Centrifugals are either driven or suspended, the latter type being used more. The size of the basket is 30 in. diameter, but a larger size of 48 in. diameter is in use which, although economising labour, takes more power to drive.



24. CENTRIFUGAL MACHINES (Watson, Laidlaw & Co., Glasgow)

Loaf Sugar. The oldest form of refined sugar is the sugar loaf. To make these the massecuite is formed with a small grain, run into a heater and raised to between 180° and 190° F. From this the mass is run into conical iron moulds, which have a small hole at the top or cone and a series of moulds is placed cone downwards in a supporting frame. The hole at the bottom is stopped up with a wooden spike. When the sugar has partly solidified the contents of the mould are mixed up with a "brushing off" hook with the object of making the texture throughout the loaf even. The moulds remain in the filling-house for 10 or 12 hours and by that time the contents have become solid. Next, the moulds are removed to a warm room, the plugs in the cones removed and "green" syrup drips from the mould for about 24 hours. A process known as liquoring then takes place. The top surface of the sugar is removed, mixed with syrup (*white liquor*, *cleare*, or *clairce*), and replaced. White liquor is then fed on to the top of the loaf and drains from the cone, taking with it any coloured impurities that remain in the sugar. The liquoring is repeated several times, blued water being used for the final liquoring until the runnings are quite clear and the loaves of uniform whiteness. Special appliances are in use for supplying measured quantities of clairce to the cones, and suction apparatus worked by compressed air is employed (by Steffen & Scheibler) to hasten the passage of the liquor through the sugar loaf. The loaves are eventually taken out of the moulds, dried in racks, and wrapped up in thick paper. The process takes about a fortnight. The blued water referred to above is prepared from pure ultramarine, the purpose of the slight addition of blue being to correct any remaining tint of yellow. Special centrifugal machines are made for purging sugar loaves in the centrifuge, and many machines have been devised for finishing off the loaves and also for cutting them into cubes.

Cube Sugar. The slowness of the method of making sugar loaves has led inventors to study the question of how to make cube sugar in a quicker manner. Many inventions to this end, which involve similar principles, have been patented. The massecuite is boiled to small grain and filled into divided moulds of such a size that a plate of sugar is produced. The moulds are either a kind of centrifugal basket or contrived to fit into the centrifugal basket. The massecuite is cooled in the mould, during which process the crystals are joined together by a secondary crystallisation. The cooled moulds are then put in the centrifugal and the syrup spun out. The plates are also washed with clairce, which is in turn spun out. The moulds are removed and taken apart, the plates of sugar being separated and dried in a special store in a current of hot air. When the plates of sugar are dry, they are cut up into cubes in machines invented for the purpose. The Adant cube sugar process is worked on the above lines.



25. GRANULATOR
a. Charging hopper *b.* Discharge valve *c.* Steam inlet pipe *d.* Water outlet pipe

Cube Sugar is Ousting Loaf Sugar. Another principle adopted in some machines, such as the Hersey cube machine, is to produce sticks or cubes of sugar by means of pressure

from soft, white sugar that has been dried and purged in the centrifuge. This process is much used in the United States. The method outlined above, in which the cubes are made from the massecuite direct, is preferable. The cube form is fast replacing the old form of loaf sugar.

Granulated Sugar. Granulated sugar is produced by the Hersey process, patented in 1873. The granulator [25] consists of an outer conveyer cylinder 23 ft. long, 6 ft. diameter, inside which is a smaller cylinder 23 ft. long, and 30 in. diameter, arranged to revolve about five times in a minute, and heated internally by steam. The granulator is inclined from the horizontal position, so that sugar introduced at one end travels mechanically to the lower end. A current of air is passed or driven through the drying chambers to absorb the moisture that arises from the sugar during its passage through the granulator. Sugar is first washed in a centrifuge, and then passed through the granulator, about 30 barrels of sugar being treated in an hour.

The effective drying of sugar is an important matter, since, if it be stored in a moist condition, much deterioration or "greying" results, owing to the action of bacteria developed on the sugar. A sugar store that has become infected with "greying" bacteria must be thoroughly disinfected, Tollens's formaldehyde lamp being useful for this.

Other Methods of Refining. Alcohol was suggested for refining sugar by Duncan and Newlands as long ago as 1878. The sugar was heated with alcohol when the sugar was dissolved; then, on cooling, the sugar was deposited in a pure state. Ten pounds of sugar required three gallons of alcohol. But the high cost of the alcohol and the expense due to loss are prohibitive.

In Langan's process the raw sugar is mixed with a saturated syrup so as to make a kind of artificial massecuite. The mass is drawn into a vacuum pan for the removal of small grain and any contained air. The mass is boiled to form a natural massecuite, then cooled in crystallisers to about 49° C., and subjected to a systematic washing and liquoring with saturated syrup to increase the purity. The sugar is then dissolved in the washing receptacle itself by means of a special appliance. The object of the Langan process is to prevent the waste of sugar ordinarily due to solution of the crystals in the centrifugal machines. By using saturated syrup this difficulty is overcome.

Fontenille and Desormeaux's Process. The Fontenille and Desormeaux process was patented in 1898, the claim being that by it raw sugar can be converted in less than four hours into refined sugar in pieces ready for delivery to the consumer. The method is worked in the following stages:

1. Melt the raw sugar at a temperature of from 70° to 75° C. and at a density of about 28 Beaume.
2. Add finely-powdered animal charcoal in the proportion of from 5 to 40 per cent. of the raw sugar, and mix at above temperature until the colour is discharged from the sugar.
3. Filter in press-filter, or separate the sugar in a centrifugal machine, the charcoal being recovered and washed.
4. Reheat the syrup to 75° C.
5. Pass the syrup through bag filters under pressure.
6. Concentrate, and boil to grain.
7. Pass the massecuite into moulds or crystallising apparatus, or submit to centrifugal action. If poured into moulds only one cleansing is required; if into a crystallising apparatus, the syrup is sucked away by vacuum, and one cleansing only is needed. When the centrifugal method is used the mass is cleansed in the centrifuge.
8. The mass from the crystallising apparatus, or centrifuge, is broken up and sifted, and then sent to the moulding machine after moistening with 2 or 3 per cent. of blue water.
9. The moulding machine forms the pieces of the size required for sale by pressing. The pieces are expelled mechanically.
10. The pieces are dried in a store at 60° C., either in air or vacuum.

Crosfield and Stein's Process. The Crosfield and Stein process depends on the treatment of the acid solution of sugar with peroxide of hydrogen.

The raw sugar is melted at about 160° F., and the acidity brought up to about 0·02 per cent. with phosphoric acid. The acid sugar liquor at about 27° Beaume, and at a temperature of 180° F., is treated with 0·01 to 1 per cent. of sulphate of alumina, and subsequently with 0·005 to 0·6 per cent. of tannic acid; then with 0·05 to 0·2 per cent. of phosphoric acid, this treatment partly destroying the colour. Where deemed necessary the liquor may be treated with sulphurous acid. The liquor is next filtered, and the filtrate is treated with 0·01 to 1 per cent. of peroxide of hydrogen, and phosphate of soda or ammonia in quantities of about 0·005 to 0·2 per cent.

The liquor is passed through a filter press, and the clear, bright solution boiled to crystals in a vacuum pan. The massecuite, which is very white and bright, is machined in centrifugal machines, and washed therein with concentrated syrup, or, if desired, sugar solution and peroxide of hydrogen.

Robin-Langlois' Process. By the Robin-Langlois method, patented in 1898, the fibres and dust in the sugar are removed by blowing air across a stream of sugar falling from a hopper on to a series of inclined boards. The sugar is then crushed and treated with steam in order to introduce a definite small proportion of moisture, and to brighten the facets of the small crystals. This operation is performed in the mixer for the sake of uniformity. Jets of steam or atomised water impinge against angle plates, whence they rebound on to the sugar, falling from the supply tube into the mixer in two streams.

The *mixer* is essentially an annular space between two concentric hot-water jackets, the rotating blades and sugar being contained in this space at a desired high temperature.

The discharge hole of the mixer stands above an annular trough in a revolving circular table, the circumference of the two machines intersecting to the necessary extent.

The circular table contains on its periphery a trough across which the moulds are arranged radially in juxtaposed boxes. These moulds are open at the top, and have perforated bottoms. They are locked, disengaged, and opened by special appliances which enable them to work continuously and to be emptied without injury to the bars of sugar. As the annular series of moulds revolve, they pass in turn under the discharge hole of the mixer, and are filled with sugar by inclined scrapers; they then pass on, and the sugar in each mould is compressed by a corrugated roller, fixed in relation to the table, but revolving on its own axis, so that its projections correspond consecutively with each mould. At a further stage of the revolution the moulds are automatically placed under vacuum and the syrup sucked out, and when dry they are unlocked, emptied, and readjusted continuously by the devices mentioned above.

La Fontaine's Process. In the La Fontaine method the patentee employs the reducing agents to the massecuite instead of the raw juice. Ten parts by volume of liquid sulphurous acid is diluted with 100 parts of water, and 4 litres of this liquid is added at intervals of five minutes to 100 kilos of massecuite previously diluted with molasses from a preceding operation. The mass is well mixed, allowed to rest for an hour, and then centrifugalised. When the greater part of the molasses has separated, 2 litres of the sulphurous acid solution is added by an atomiser jet to attack any colouring matter that may have escaped action and be still adhering to the crystals. By means of a perforated tube depending into the centrifugal machine, a mixture of dry steam and peroxide of hydrogen (6 vol. strength) is injected to remove any remaining sulphurous acid. After five minutes of this treatment the crystals become remarkably white and completely transparent, thus indicating their purity. Although this process does not properly come under the head of refining sugar, it is given here as indicating one of the newer methods of whitening sugar.

Ranson Process. In the Ranson process the syrup is made alkaline with barium hydrate or sodium carbonate, and hydrogen peroxide added in the proportion of from ½ litre to 5 litres per 100 kilos of sugar, according to the colour of the product. The decoloration is effected gradually. To every 100 kilos of sugar 100 grammes of powdered animal charcoal freed from phosphate is added to accelerate the liberation of oxgyen from the hydrogen peroxide by which the decoloration is effected. The excess of oxgyen is removed from the syrup by adding hydrosulphites of aluminium or barium or by producing hydrosulphurous acid in the syrup. The excess of sulphite in the syrup is converted into sulphate by adding hydrogen peroxide. The temperature is then raised to 78° C. and the syrup filtered and boiled to crystallisation.

Ultramarine. The substance ultramarine which has been referred to several times is a double silicate of sodium and aluminium, together with bisulphide of sodium. It is a beautiful blue colour, and is made by burning a mixture of sodium sulphate, china clay, and carbon in crucibles for from six to nine hours at a red heat. The dull green product thus obtained is mixed with sulphur and roasted until it assumes a bright blue colour. In the "direct" method soda is employed, and a very careful regulation of the heat of the crucibles is required for successful manufacture. Processes of washing, sifting, and drying have to be gone through before a marketable product is obtained. Ultramarine exists in Nature as lapis lazuli, and was not prepared artificially till 1828, when the above method was discovered independently by Guimet and Gmelin. Since then improvements in the manufacture have brought about reductions in the cost, and, consequently, new uses for the product have been opened out.

Treacle and Golden Syrup. When the syrups no longer yield sugar they are made into treacle, golden syrup, or invert sugar. Golden syrup is a purer kind of treacle. Of late years the quality has much improved, the appearance in many cases being artificially improved by the addition of glucose syrup. Glucose syrup is also used to prevent granulation, but in the opinion of some experts is not necessary if the sugar syrup be well inverted. The process of inverting sugar is explained in a separate lesson, either the acid process or Tompson's yeast method being used, although there are objections to Tompson's method on account of the introduction of organic matter. The golden syrup is passed through a char filter and when perfectly bright and clear is concentrated in the vacuum pan to the required viscosity.

Residual molasses of too low a quality for making golden syrup is sold to the distiller or used for cattle food.

The Refinery. The site of a refinery should be well chosen for the purchase of raw sugar, and the distribution of the finished sugar. If near a coalfield it would be an additional advantage. There should be a good supply of soft water and the cost of labour should be moderate. The blow-ups are placed on the top floor of the factory, beneath them being the Taylor filters, and lower still the char filters. The char kilns are usually in a separate building. The number of refineries has much diminished of recent years owing in a great measure to the baneful influence of sugar bounties. In 1875 there were 20 refineries in London, 9 in Liverpool, 3 in Bristol, 2 in Manchester, 1 each in Earlestown, Plymouth, and Newcastle-under-Lyme, 13 in Greenock, 1 in Leith, and 1 in Dublin; total, 52. At the present time there are approximately only 10 refineries in the United Kingdom.

SEWERAGE & SEWAGE DISPOSAL

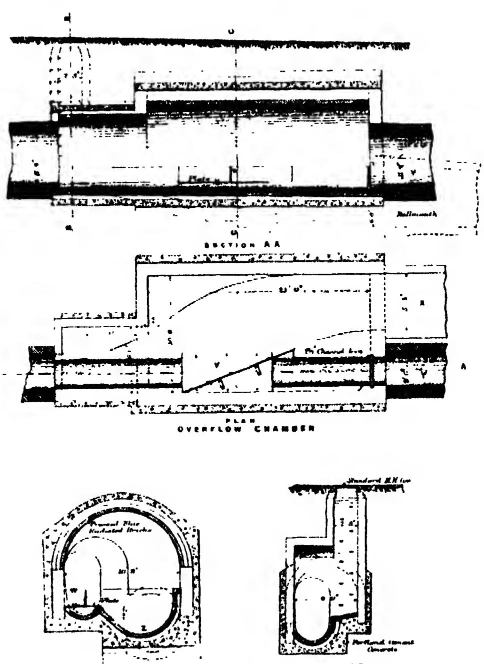
Sewerage Systems. Laying Out a Sewerage System. Sewers, Manholes, and Syphons. Pumping and Ventilating Sewers

By Professor HENRY ROBINSON

IN this course it is intended to describe briefly the principles which govern the design and execution of works relating to the sewerage of a town, and the disposal of the sewage therefrom. By the house drain the fluid refuse of a building is delivered into the public sewer, to be conveyed away for disposal as quickly as possible. In some cases several house drains discharge into a drain serving a row of houses at their backs (called a *combined drain*), and this connects with the main sewer.

Sewerage Systems. In determining the volume of sewage to be dealt with in a town, the first thing is to decide whether the whole, or only part, of the rainfall is to be admitted to the sewers. If all the rainwater is to pass into the sewers it is called the *combined system* of sewerage. If the rainwater is not admitted to the sewers, but is carried away by independent pipes, it is called the *separate* system. If the rainwater from roofs, yards, etc, is admitted—which it often is—the system is called the *partially separate*. The separation of the rainfall—or, at all events, of a considerable part of it—enables the sewers to be designed so as to be self-cleansing, and the sewage which is removed by them is brought to the point of discharge in a fresher state than is possible where the sewers are calculated to convey the larger volume, as they may become sewers of deposit in dry weather. That which is admitted should be limited, if possible, to the rain falling on roofs, streets, yards, courts, back areas, paved surfaces, etc., which may be termed *impermeable* areas. Partially permeable areas are lawns, gardens, fields, etc.

The first flow off town roads with much horse traffic (however good the scavenging may be) is very foul, and should be carried to the outfall. After this has passed away, the subsequent volume is comparatively clean water, and may be discharged by storm overflows.



1. STORM OVERFLOW CHAMBERS

Volume of Sewage. The volume of sewage to be provided for in a system necessarily depends on the rainfall, a part of which inevitably reaches the sewers. If the town has many manufactories, the fluid from which is admitted to the sewers, then provision must be made for a much greater volume. This has to be determined by an intelligent investigation on the part of the engineer, as no fixed quantity can be adopted for general application, as is shown by the fact that in forty towns in this country the volume varies from 25 gallons per head to 90 gallons per head. The factors which govern the questions are:

1. The amount of water used in private houses.
2. The amount of rainfall that is admitted to the sewers. This depends on the system, either separate or combined, which is adopted, and also upon the rainfall of the district.
3. The number of manufactories, and the volume that is discharged from them.

In calculating the amount of storm water that will enter a sewerage system the rate of rainfall has to be ascertained, especially the falls of short duration, which are more frequent and intense than those over longer periods. A study of the rain gauges in a town can determine this. An interesting paper was read at the Institution of Civil Engineers by Mr. Lloyd Davies in January, 1906, in which the results of a careful series of observations made in Birmingham over a long period are given. Only a brief reference can be made to it, and the following conclusions recorded:

(1) That the storm-water discharge from any defined district is directly proportional to the percentage of impermeable area comprised in it.

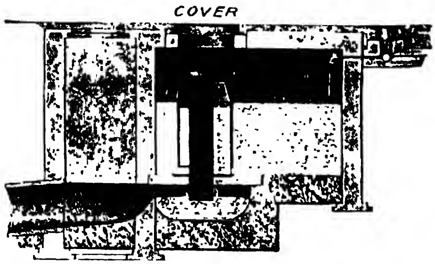
(2) That, subject to a time allowance being added for the entrance of the rain into the system, the discharge of storm water from underground channels is proportional to the aggregate rainfall during the time of concentration of the water through the

conduits, from the extreme boundaries of the district to the point of observation.

(3) That the maximum rate of flow is reached when the greatest cumulative rainfall applicable to the duration of the minimum time of concentration and to the district considered occurs.

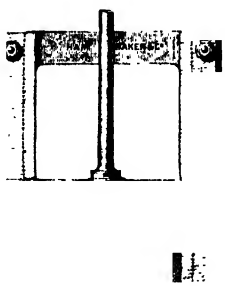
(4) That the total volume of storm water received is proportional to the maximum rate of flow.

Overflow Chambers. The design of storm overflow chambers [1] deserves a reference, and the following is a description of one adopted at Birmingham with success, and detailed observations are given in Mr. Lloyd Davies' paper.



2. THE FIELD AUTOMATIC FLUSHING CHAMBER

The overflow sill is situated at a level equal to that attained by six times the average dry-weather flow in the foul sewer. Across the foul sewer at the sill-level a cast-iron separating-plate, V, is fixed horizontally, and to this is riveted a vertical deflecting plate, W, with a hood. When the flow exceeds the volume giving the requisite dilution, the surplus storm-water is accurately separated and deflected into the relief culvert, X, the remainder passing freely under the plate, and down the foul sewer, Y. The length of the sill is arranged so that a large percentage of the overflow will fall into the tumbling bay, Z, before the plates are brought into action, and undue impact is thus avoided.

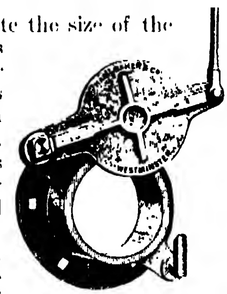


3. PENSTOCK

The reason for taking six times the average dry-weather flow is that at the present time the Local Government Board requires provision to be made for that amount at sewage disposal outfalls.

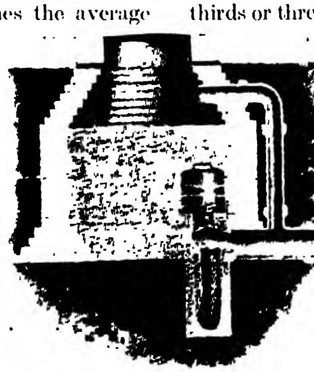
Treatment of Isolated Buildings. For isolated buildings and villages, where no sewerage system is admissible, the excremental refuse is got rid of by dry earth closets, pail, or midden system, and by cesspits. In the first-named the refuse has to be removed from the dwelling promptly, and disposed of on land in the neighbourhood, where it can be utilised for agricultural purposes. If cesspools receive the fluid refuse, they should be placed so that when filled, whatever overflows is conveyed to adjoining land of a suitable character to allow the fluid to sink quickly below the surface, and away from wells. In cesspools a septic or liquefying action takes place on the organic solids. A certain amount of solid matter, however, remains, involving the clearing out of the cesspool at stated times.

Laying Out a Sewerage System. Having ascertained what amount of sewage has to be provided for in the sewers, we now consider how to lay out a sewerage system. It is obvious that the total discharge from a town must vary during the twenty-four hours. It is usual to calculate that about one-half the flow will pass off in six hours, or about 8 per cent. per hour in the tributary sewers. The volume to be provided for in the main outfall sewer will be affected by the distances of the tributary sewers serving the various parts of a large town from the outfall sewer, and also by their gradients. The sewage from one part will reach the outfall sooner or later than from another.



4 DISC VALVE

It is usual to calculate the size of the sewer so that it runs about two-thirds or three-quarters full at its maximum flow, with a velocity of about 3 ft. per second, which, it has been decided, will carry away the usual solid matters, and prevent them depositing and putrefying. In large sewers, a velocity of $2\frac{1}{4}$ ft. per second should be obtained when they are running one-third full, $2\frac{3}{4}$ ft. per second when running one-half full, and 3 ft. per second when running two-thirds or three-quarters full. The velocity should never be less than 2 ft. per second.



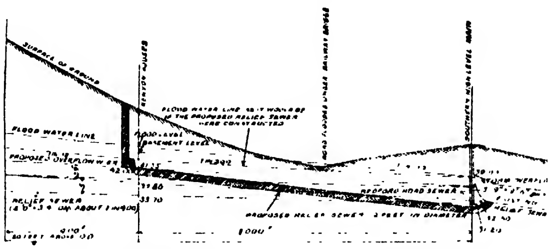
5. ADAMS FLUSHING TANK

Automatic Flushing. If the district be flat, so that the levels do not admit of the gradients giving the required velocities, automatic flushing tanks have to be adopted, or the sewage can be headed back by penstocks, placed so as to divide the sewers up into sections. The rush of fluid thus produced ensures the solid matters being carried forward. The illustration [2] shows an automatic flushing chamber with which the name of the late Rogers Field, the inventor, will always be associated.

Fig. 5 is an illustration of an Adams flushing tank fixed in a manhole.

When the manhole has to be entered for any purpose, it can be drained by removing a plug, which clears it of water.

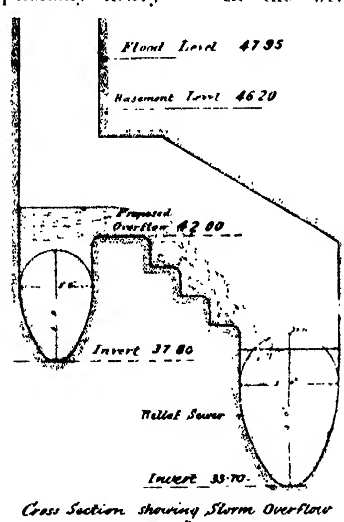
Penstock. A penstock consists of a sliding flat plate or shutter which fits into, and can move up and down in a grooved recess at the bottom of the manhole in the sewer. This sliding plate is attached to a rod, by which the penstock is put into operation. A man screws down the plate, and closes the lower part of the sewer, thus heading back the sewage, which rises behind the penstock until the sewer is filled to any height that the arrangement has provided. After a time the man returns and raises the penstock, causing the impounded sewage to pass with a rush down the sewer.



6. RELIEF SEWER AND STORM OVERFLOW

The form of penstock shown [3] is provided with a rod, and is moved up and down by means of a key which fits on to the top of the rod. For smaller sewers the same object can be attained by means of an ordinary disc valve, a form of which is shown in **4.**

Storm Overflows. In the event of sewers receiving the whole of the rainfall it is essential that provision should be made of storm overflows or relief sewers, to deal with times of floods due to exceptionally heavy rainfall acting for a short time, resulting in the sewers becoming gorged, and flooding the basements of houses. We can best emphasise this by giving particulars of a case in which the writer was engaged some years ago. A district on the south side of the metropolis had been gradually built over, but no adequate increase of the sewerage system had been made. Eventually, a heavy fall of rain occurred, which caused one of the sewers to become gorged, and houses were flooded, doing much damage. This sewer discharged into one of the metropolitan outfalls, which, being also gorged, could not receive the sewage. The writer had to investigate the matter, and a relief sewer, together with a storm overflow, were proposed. A study of the illustrations [**6** and **7**] will explain the state of affairs at the time of the flooding, and the remedies.



7. RELIEF SEWER AND STORM OVERFLOW

The diagram [**7**] shows how the gorging of the old sewer was to be remedied by providing a storm overflow when the sewage rose to a level of 42·00, when it passed away to the new relief sewer.

Size and Gradient. Having ascertained the volume of sewage to be dealt with, and the various levels of the ground and of the house drains having been recorded, we have to calculate the size and gradient of the sewer to carry away the sewage. The following formula has been adopted by the writer:

$$V = \frac{R^x}{C\sqrt[n]{S}}$$

where V = the mean velocity in feet per second, R = the "hydraulic radius" in feet—that is,

$$\frac{\text{area of water}}{\text{wetted perimeter}},$$

S = the cosecant of the angle of inclination of the hydraulic gradient $= \frac{\text{length}}{\text{head}}$,

C = a coefficient representing the roughness of the surface.

The index x, the root n, and the coefficient C depend on the nature of the surface of the channel.

For brick sewers in good condition, the value of $x = \cdot 61$, $n = 2$, and $C = \cdot 007746$. The formula for brick sewers therefore becomes

$$V = \frac{R^{\cdot 61}}{C\sqrt{S}}$$

where $C = \cdot 007746$

In the writer's book on "Sewerage and Sewage Disposal" a diagram is given, from which can be scaled the velocities, discharges, etc., of various sewers, without having to work them out by the formula.

An oval or egg-shaped sewer, instead of a circular one, has an advantage, owing to the greater velocity obtained in the contracted lower part of the oval, when the volume of sewage is at its minimum.

The internal dimensions of an oval or egg-shaped sewer are determined as follows:

If D = the internal depth of the sewer—that is, from the top of the arch to the surface of the invert,
R = the radius of the top of the sewer,
= the radius of the invert of the sewer,
= the radius of the sides—that is, the curve joining the top and bottom curves, then

$$D = x$$

$$R = \frac{D}{3}$$

$$\frac{D}{6}$$

In some cases r is taken at $\frac{1}{8}$ of D, where the sewer has to convey at times only a very small volume of sewage, as the contraction of the invert tends to prevent deposits by increasing the depth of sewage, and consequently improving the velocity. If the volume of sewage be subject to great fluctuation, so that at times it is very small, the egg-shaped or oval sewer is preferable to the circular form. Where the sewage generally half fills the sewer, the oval shape loses this advantage, and the circular shape is cheaper to make, while it is also stronger.

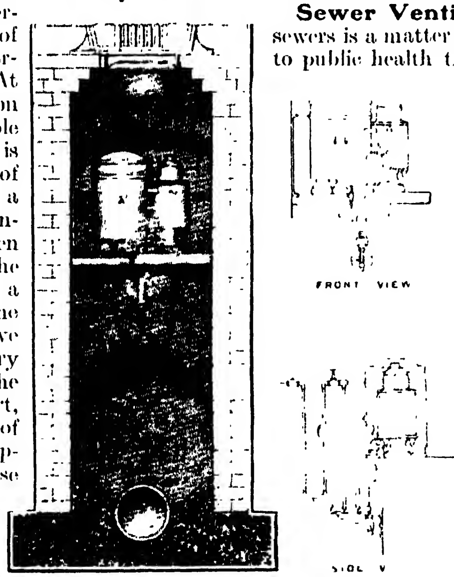
8. SEWER SYPHON

The thickness of sewers varies with the size, the nature of the ground, and the depth. A $4\frac{1}{2}$-in. ring of brickwork suffices for the smaller sizes in good ground. In larger sewers the thickness varies from 9 in. upwards. The thickness can be calculated by the formula

$$\frac{D \times R}{100} = \text{thickness of brickwork in feet,}$$

where D = depth of excavation, and R = external radius of sewer.

Manholes. Sewers must be laid in straight and not curved lines. The invert of the sewer must also be a straight line. Any alterations or depressions both interfere with the flow of sewage and assist the formation of deposits. At every change of direction of the sewer a manhole should be placed. This is carried to the surface of the road, and enables a man to go down and inspect the sewer between the manhole in which he is and the next one, a light being placed in the latter. It is usual to have means of inspection every 100 yards so that if the manholes be farther apart, owing to a long piece of straight sewer, a lamphole is placed at these intermediate points. Lampholes are small, vertical iron or stoneware pipes carried up to the road level so as to enable a man to lower a lantern to the sewer at that point.



9. REEVES VENTILATING APPARATUS

Syphons. When the sewer has to be carried under the bed of a stream, either in the form of a syphon or in the continuation of the gradient, it is best to make it of cast iron, as the flanged pipes can be bolted up on rafts or barges, lowered into position quickly and covered. Fig. 8 shows a syphon carried out by the writer in this way.

The syphon was tested by water pressure to see that it was sound, and the trench was filled with concrete, by means of wooden funnels, to prevent the stream washing away the cement. A copper wire cord ought to be passed through the syphon before it is put into position, and left there permanently to admit of a scraper being drawn through at any time the pipe may get blocked.

Open Grids. Covers are placed over all manholes and lampholes, with open grids or gratings in them for ventilation. These grids should form part of a system of ventilation acting as inlets for fresh air, the outlets consisting of iron pipes carried up the sides of houses or trees, and away from windows, or columns in the road placed at shelters, etc., and at a height sufficient to cause any foul gas to be diffused above people's heads. In certain cases these open grids have to be sealed. Some advocate the abolition of the trap on the house drain, so that the soil-pipe will act as an upcast for the foul air from the public sewer. This is open to the objection that the private house will then be receiving the objectionable sewer gas, which should be dealt with in some systematic and intelligent way by the public authority.

Sewer Ventilation. The ventilation of sewers is a matter of such importance in regard to public health that it deserves full consideration, and reference will be made to systems which have been employed to prevent the obnoxious gases which are generated in sewers from causing injury to the health of those who are exposed to their emission from gratings, or otherwise. In some cases surface gratings cannot be regarded as a solution of the problem even with upcast shafts, as the atmospheric conditions may at times be unfavourable to the removal of the foul air by means of the upcast. If the sewers have proper gradients and are self cleansing, the usual provision of gratings and upcast shafts will ensure the proper change of air; but there are many cases where the conditions do not exist, and it is well to record how to prevent sewer air, under such circumstances, from being a danger to health. One system which has been employed with success is called the Reeves system.

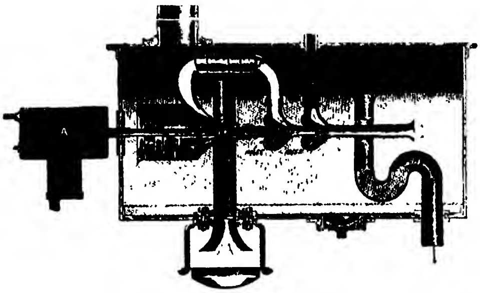
This is based on the use of chemicals in the sewers, whereby the noxious gases are deprived of their injurious properties. Fig. 9 will explain how this is effected.

A ventilating apparatus has been brought out by Messrs. Stone & Company which deserves mention. Fig. 10 shows the apparatus in a

tank ready to be fixed in the sewer, the foul gases in which it is desired to neutralise.

Fig. 11 shows the apparatus fixed in the sewer ready for use.

Construction of Sewers. In the construction of brick sewers only well-burnt and well-shaped bricks should be used, and they should be well soaked to prevent their absorbing



10. STONE'S VENTILATING APPARATUS

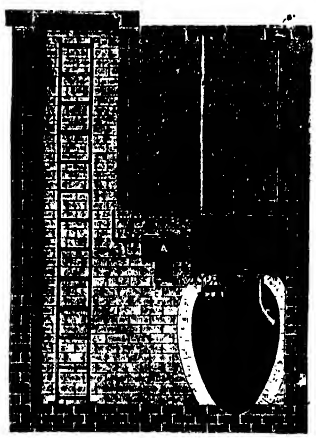
water from the cement. The sewer invert should have a smooth and hard surface to diminish friction and to prevent erosion. Blue Staffordshire bricks, glazed fireclay bricks, or hard blocks well glazed on the surface are generally used for inverts. The bricks should be radiated to suit curves so that no more mortar is used than is necessary to make the joint. The mortar should be made of one part of best well-seasoned Portland cement to one of clean, sharp sand. Good hydraulic lime or blue lias lime is sometimes used. The materials require great care in selecting, and the mortar should be used as soon as mixed. Brick sewers are sometimes built in sections in wooden moulds.

Where the nature of the ground requires it, a brick sewer should be strengthened by encasing it partly or wholly with cement concrete, and if there are several rings of brickwork a "collar joint" of cement about 1 in. thick between each ring ensures the watertightness of the work. The joints of brickwork should not be too thick, the faces being not more than ¼ in. apart. The trowel should be passed over the mortar to increase its density. The work ought not to be exposed to contact with water until it is well set. In very wet ground a subsoil drain should be placed under the trench to take away the water to the pumps, instead of its running at the bottom of the trench to the pumps. If the sewer be made where any settlement of buildings may occur great care should be taken to timber the trenches well, and even to leave the bulk of the timber in, in order to avoid the risk of subsidence.

Concrete Sewers. Some very good sewers have been made entirely of concrete consisting of six parts of gravel and sand free from earthy matter to one part of Portland cement. The invert of the sewer is first built, then concrete is well rammed behind a mould with a smooth surface—formed of sheet zinc or other material—and the top of the sewer is turned upon centres. If the interior be well rendered with cement, a good sewer can be made, provided the best well-seasoned cement and perfectly good materials are employed, otherwise concrete is liable to crack.

Stoneware Pipe Sewers. Stoneware pipes can be used for sewers up to 21 in. in diameter. Beyond that size sewers are generally made of brickwork, as the handling and jointing of pipes of large size results in their costing as much as brick sewers. Stoneware pipes should be made of good vitreous material having a clear ring when struck and having strength to stand shocks and strains. They should be well burnt at a high temperature with a salt glaze which permeates the body of the pipe and renders it impervious. They can be tested for impermeability by closing the lower end and filling the pipe with water. Any lowering of the water will disclose defects. By drying a pipe and weighing it, and putting it in water for a while and re-weighing it, a test of impermeability can be made.

The joints of ordinary stoneware pipes should be carefully made so as to be watertight. This requires the enforcement of certain well-known conditions. The bed has to be prepared on which to lay the pipes, with spaces taken out to receive the socket, so that the whole length of the barrel is supported. Where the ground is not thoroughly sound and solid, a bed of cement concrete about 6 in. thick should be laid at the bottom of the trench, with similar spaces for the socket. This layer of concrete can be carried up after the jointing is finished, so as partly or wholly to encase the pipes, according to circumstances. After the end of one pipe has been placed in the socket of the other it should be butted home and tarred gaskin should be caulked up to the face. The joint is then completed by filling the space with cement finished off neatly by a fillet outside. Either neat Portland cement or half-clean sharp sand and half cement can be used, but not clay. A properly made joint depends first on the pipes butting home, then on the gaskin being caulked up to the face of the socket, and, lastly, on the ring of cement being of equal thickness all round.



11. STONE'S VENTILATING APPARATUS IN SEWER

Special Joints for Stoneware Pipes. There are means of jointing stoneware pipes other than the ordinary way which has been described. The earliest departure was the Stanford joint, which was formed by the contact of two conical surfaces cast outside the ends and

inside the sockets of the pipes. The surfaces, when in contact, were relied on to make a watertight joint, and were found of service where sewers had to be laid in ground with much water. Such joints require the sewer to be much supported, as any settlement draws the joint. Improvements have been made on this by casting the ends of the pipes with annular rings on both spigot and faucet. These can be filled with liquid cement poured in through holes in the top without risk of its being washed out or disturbed, as is the case with ordinary cement joints. The "Hassall" was the first joint based on this principle.

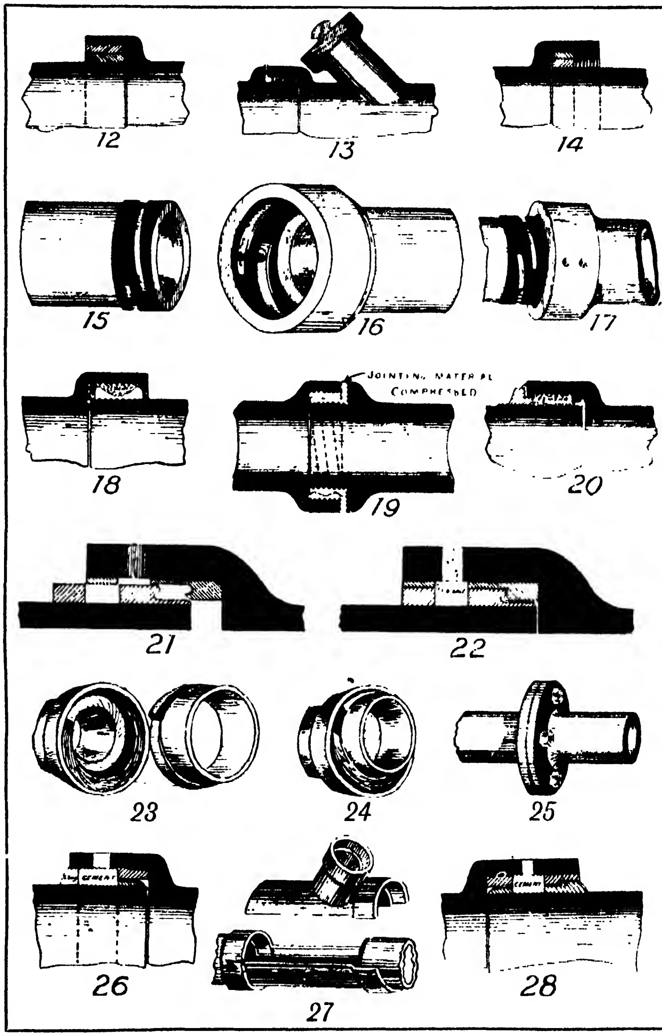
There are many more recent arrangements which have been patented for making joints in stoneware pipes, and we shall refer to some of them.

In making a tarred gaskin and cement joint in an ordinary stoneware pipe, dependence has to be placed in the barrel being kept in the right position by hand until the gaskin is rammed in at the bottom to ensure that the spigots and faucets of the pipes are in their right positions. If this is not done properly the space that has to be cemented may be greater at the top than at the bottom. The writer once inspected a long length of leaky stoneware sewer, where he found that the leaks were caused by the absence of any gaskin and cement at the bottom. Many forms of joints have been devised to prevent this, and some are shown from **12** to **28**.

Stanford Joint. Fig. **12** is the Stanford joint, the spigot end of which is provided with an annular bituminous band, which fits truly into a similar band in the socket. These bands are greased over before the spigot end is driven home, thus forming a watertight joint. Fig. **14** shows another form of this joint, where the bands are only half the width, thus permitting the joint to be finished with a fillet of cement.

Sykes Joint. The Sykes joint shown in **13** has been extensively used by the writer. The spigots and sockets of the pipe are provided with bituminous rings which, when in position, form a groove into which liquid cement grout is poured. The illustration also shows a screw stopper for plugging temporarily the branches on the main sewer provided for house junctions. Another form of Sykes joint is shown in **19**.

The Spiralitic Joint. This is a recent form of joint [**15**] in which the spigot end of the pipe has a band of bituminous compound cast round it, having a groove in it of a spiral or screw shape. The socket [**16**] is lined with a similar band of material also having a spiral groove. The socket has two holes side by side, one connecting to each end of the groove. When the spigot end is pushed home the two grooves form a cavity into which liquid Portland cement is poured in at one hole until it appears at the other, which shows that the spiral cavity is filled.



SEWER JOINTS

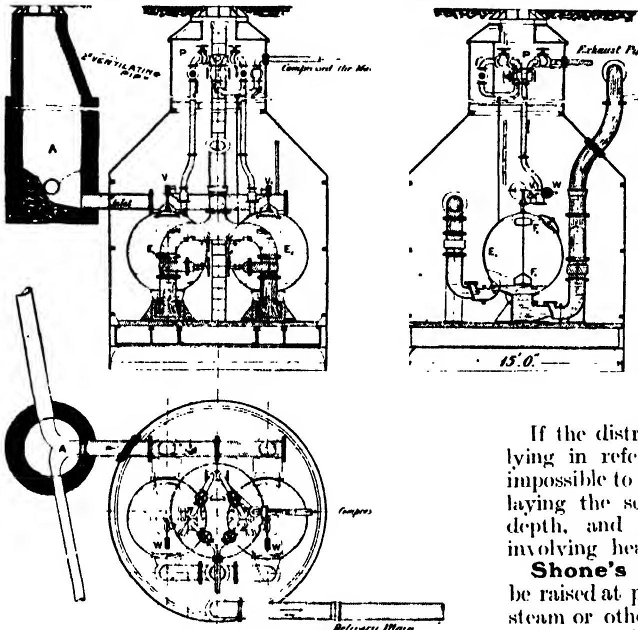
Other Pipe Joints. Parker's safety pipe joint is another form of joint for stoneware pipe sewers. Fig. **18** shows its construction.

The Archer eccentric pipe joint, as shown in **20**, is in substitution for the old joint of the same patentee, which was abandoned some years ago.

Brown's hydrotite joint is another arrangement, and is shown in **21** and **22**.

The Freeman-Hines joint [**23** and **24**] is a new form of joint, effecting rapidity of laying with watertightness. On to the spigots of the pipes

and to the faucets of the sockets are cast bituminous eccentric bands, which, when brought together and slightly twisted, form a small

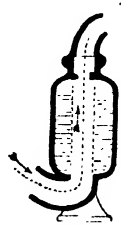


29. SHONE'S EJECTOR

cavity which, after being filled with bitumen, completes the joint.

Wakefield's insertion pipe or junction, as shown in 27, is useful when the barrel of a sewer has to be broken in order to form a house connection.

Hassall's single lined joint is somewhat similar to the Stanford joint, except that the sockets are much deeper. The spigot ends and sockets are provided with narrow bands of bituminous compound. The spigot end, after being pushed home into the socket, leaves a space which is filled with cement as shown in 26.



31. SECOND TRAP

Hassall's two-lined joint is shown in 28.

Cast-iron Sewers. In some cases it is found necessary to employ cast-iron instead of stoneware pipes for sewers. The usual method of jointing cast-iron pipes is that shown on page 4340. It is sometimes found more expeditious to use a turned and bored joint.

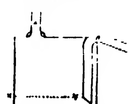
Another form of joint for cast-iron mains is shown in 25, and is the one generally used for syphons under rivers. The faces of the flanges are usually machined, the joint being completed by a rubber ring placed between the flanges preparatory to their being bolted together.

Sewage Pumping. In laying out a sewerage system, care should be taken to avoid unnecessary pumping if the levels involve the sewage being lifted to reach the outfall. In some cases the higher part of a district can discharge its sewage by a gravitation sewer, leaving only the lower part to be pumped, instead of bringing the sewage from the high district down to the low. The size of the "rising main," which conveys the pumped sewage, should be calculated so that the velocity in it conforms to what has already been stated as necessary to prevent the deposition of solids. If the rising main pass over a summit, an automatic air-valve should be placed there to prevent an air lock. Fig. 32 shows one manufactured by Messrs Ham, Baker & Co.

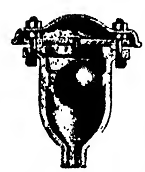
It is advisable to place a back-pressure or reflux valve [35] on the rising main near the pumping station. This prevents a rush of sewage taking place should a breakdown occur at the pumps.

If the district to be sewered be flat, and low-lying in reference to the outfall, it is often impossible to get the necessary gradients without laying the sewers in places at a considerable depth, and perhaps in waterlogged ground, involving heavy expense.

Shone's Ejector. When sewage has to be raised at places where the establishment of a steam or other kind of pumping station might be undesirable, or would raise opposition, the power necessary to lift the sewage at such points can be developed at any convenient spot at a distance, transmitted to these points, and applied to suitable lifting machinery placed in chambers beneath the surface of the ground. One appliance that is much employed is Shone's ejector [29], of which the following is a description.



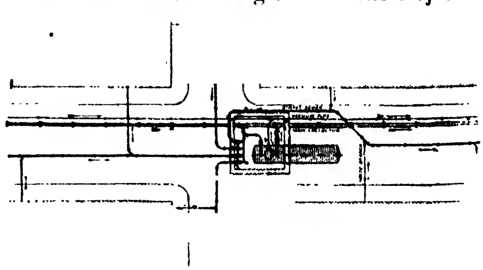
30. FIRST TRAP



32. AUTOMATIC AIR-VALVE

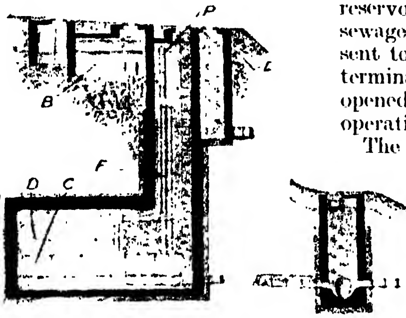
This is an automatic arrangement by which compressed air is applied to the surface of the sewage, collected in an airtight receiver from any number of low-level sewers. The pressure of air forces the low-level sewage from the receiver to a sewer at a higher level which conveys it to the outfall.

The illustration [29] shows a recent installation of this system consisting of two ejectors, E and E¹, placed in a circular cast-iron chamber, constructed below the ground. These ejectors



33. RESERVOIR ON THE LIERNUR SYSTEM

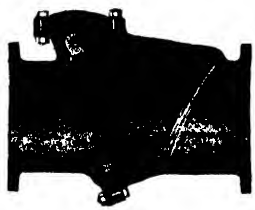
work alternately, being regulated by an ingenious arrangement of valves at P. The admission of compressed air, and also the exhaust air from the receivers, are controlled by automatic air valves V^1 and V^2, actuated by floats, as shown by F^1 and F^2 in the ejector, E, attached to rods which are connected to weighted levers, W. This device is arranged so that when the receiver is empty, its floats assume their lowest positions. As the incoming sewage rises, and eventually submerges the top float, the equilibrium of the lever is disturbed by the floats rising, causing the weight, W, to drop, thus operating a slide valve which admits the compressed air to the surface of the sewage, collected in, and filling the receiver. The contents of the receiver are then rapidly removed and discharged into the high-level sewer. The floats, falling with the sewage, cut off the compressed air supply, and also open an exhaust valve, which releases the expended air in the receiver.



34. ADAM'S SEWAGE LIFT

The Liernur System. The removal of the fluid refuse from houses by this system is effected by pneumatic agency. It was adopted many years ago at Amsterdam, where the writer saw it in operation with the late Captain Liernur. The system has been more recently successfully adopted at Trouville in France, Leyden in Holland, and at Stansted in Essex. The sewers have to be, of course, airtight, and are of iron.

Where a sewer receives solid matters which may deposit, as is the case especially in Oriental cities, where the underground conduits connecting with the sewers receive much coarse material, it is claimed that the Liernur system meets the difficulty.

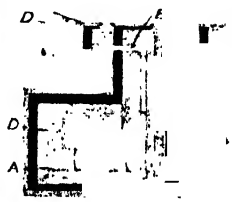


35. REFLUX VALVE

Fig. 33 is a diagram of a district reservoir into which the sewage from the area which it serves is discharged by this system.

Each district reservoir is constantly in connection with the vacuum pipe, in which a vacuum of not more than half an atmosphere is constantly maintained by the engines at the pumping station; and, in order that everything may be entirely removed from the district pipes and the house receptacles, these are put once a day into communication with the district reservoirs, with which they are connected. This is done by a man first proceeding to close the cocks R and opening the cocks M, thus establishing the communications with the vacuum pipe, which is always under depression, and the reservoir. He then proceeds to open the cocks R one after the other. As he does so the atmospheric air rushes through the soil pipes, or air inlet, causing strong pressur to be exercised in the matter in the receptacle R, and forcing the same into the street sewers and the reservoirs. After that, cocks R are closed again and tap A is opened, this making the communication with the main sewer (under vacuum), opening at the same time an air inlet over the reservoir, by which means the whole of the sewage collected in the district reservoir is sent to the main station. The operation being terminated, tap A is closed and taps R again opened, and ordinary conditions restored. The operation takes ten minutes.

The maintenance of the eals of the house traps is effected as follows. The first trap into which all the house liquid first passes is formed as shown in 30. A is the inlet, B the outlet. When the vacuum is brought into action the contents will be reduced to a level slightly above that of the line X Y, as shown, because the air will force itself through a small depth of water seal, and the water always remains above the level X Y.



The second trap is formed as shown in 31, being simply an enlargement of the soil pipe. During the action of the vacuum the fluid passes in the direction of the arrows, but the concentric ring of liquid between the dotted lines and the periphery of the trap is not drawn off, and hence remains to fall back after the pneumatic action is over, and to form a new seal.

Adams Sewage Lift. By this system, sewage in a sewer at a high level is utilised to lift sewage from a low level automatically, and thus save pumping. Figs. 34 and 35 show the working of the system.

The sewage lift is actuated by air compressed by a column of sewage, the only moving parts required being the inlet flap valves. The distance between the air and forcing cylinders is immaterial. In all cases the sewage to be raised gravitates to the "forcing cylinder," A, entering it through a non-return flap valve. Liquid is fed to a flush tank, B, in the air chamber and discharged through its pressure pipe, P, to the air cylinder, C, displacing the air therein, which passes by an air-pipe, D, to the forcing cylinder, A, exerting there its pressure upon the sewage to be raised, the latter being discharged through the rising main, E, into the intercepting sewer The air cylinder, C, when full, is emptied into the intercepting sewer by means of a syphon, F.

Group 14 **METALS** **5** Continued from page 4307	# IRON AND STEEL **Varieties of Iron: Cast Iron, Malleable Cast Iron, Wrought Iron and Steel. Iron Ores and their Composition**

By A. H. HIORNS

IRON is by far the most useful and the most used of all metals in virtue of its special properties, especially its great strength, its abundance in the earth, and its low price.

Varieties of Iron. It occurs commercially in different forms, and, with the aid of foreign bodies, possesses widely different qualities. In one case it is easily melted and cast, very brittle when solid, and cannot be forged. In another case it is soft at a white heat, easily forged and welded, offers considerable resistance to sudden shock, is almost infusible, and retains its softness after sudden quenching in water. In yet another case it is malleable, highly tenacious, and can be made intensely hard by sudden quenching in water. These widely divergent properties enable it to be employed in a greater variety of circumstances than any other metal. Up to about 50 years ago only three kinds of iron were recognised—cast iron, steel, and wrought iron—but at present a greater number of different kinds are manufactured, varying in properties with the nature of the foreign elements they contain, which really convert the pure iron into an alloy. Of these foreign bodies by far the most influential is carbon.

All kinds of iron may be classified under two chief heads:

MALLEABLE: Wrought iron and ingot iron; wrought steel and ingot steel.

NON-MALLEABLE: Pig or cast iron.

The difference between iron and steel is marked by the hardening or non-hardening properties. In wrought metal the structure is obtained by mechanical treatment at a welding temperature. In ingot metal the product is cast into moulds from the liquid condition. Ingot iron, in consequence of its non-hardening property, is also termed "mild steel."

Pig or Cast Iron. Pig iron is obtained by smelting iron ore with charcoal, coke, or raw coal in a blast furnace. Two chief varieties are obtained, dependent upon the furnace conditions and nature of the charge, termed grey and white irons.

Grey Pig Iron. Grey pig iron consists essentially of iron, carbon and silicon, but other elements, such as phosphorus, manganese, and sulphur are frequently present. The carbon generally varies between 2 per cent. and 4 per cent., and the silicon from 1 per cent. to 3 per cent. The peculiar character of grey iron is due to the mode of occurrence of the carbon, which is influenced by the amount of silicon present and the rate of cooling. Silicon tends to cause the carbon to crystallise out in the form of graphite. By very slow cooling these crystals become very large, and by quicker cooling, very small. Grey iron is, therefore, not one uniform mass like white iron, but it contains different bodies mixed together, the size of the grain largely determining the strength. With large flakes of graphite the iron approximates nearer in strength and malleability to wrought iron. Grey iron requires a higher temperature to melt it than white iron, becomes thinly liquid when melted, and expands when solidifying, which admirably adapts it to castings. It is also produced at a higher temperature in the blast furnace than white iron, which tends to make it more impure.

White Pig Iron. White pig iron contains its carbon chiefly in the combined form, is freer from silicon, and often contains more manganese than grey iron. It is a true alloy of iron with carbon, phosphorus, manganese, etc. It is intensely hard and very brittle. With much manganese, from 5 per cent. to 20 per cent., it is composed of large crystalline plates and termed *spiegel-eisen*. When the manganese content considerably exceeds 20 per cent., the crystals are much smaller, and the alloy is termed *ferro-manganese*. White iron is produced when the furnace is charged with a heavy burden of slags mixed with ore, and is then termed *cinder pig*, as distinguished from iron produced entirely from ore. White iron is also produced from easily reducible ores, which require less fuel than ones reducible with greater difficulty.

Mottled Iron. Mottled iron is intermediate between grey and white iron, and partakes of the properties of both. When broken, it shows a veined or mottled appearance. Pig iron is arranged into a variety of classes according to the colour, texture, size of the crystalline plates, and general character of the fractured surface. It is graded in numbers from 1 to 8, or more commonly from 1 to 4, for foundry purposes, and number 4 forge, mottled and white. No. 1 is the greyest and the richest in silicon. Passing from No. 1 to white iron the combined carbon gradually increases and the silicon diminishes.

The term *cast iron* is used to express the metal obtained by remelting pig iron and casting it into moulds of various kinds in the foundry. The greyer varieties of pig iron are termed *foundry pigs* and the others *forge pigs*, the latter being used chiefly for the production of wrought iron.

German Cast Iron. In Germany the following kinds are produced:

WHITE PIG IRON			
Ferro-manganese.	White Iron Proper.		
	Spiegel.	White.	Ordinary.
30 to 80 per cent. manganese	5 to 20 per cent. mangan-ese	1 to 5 per cent. mangan-ese	Less than 1 per cent. mangan-ese

GREY PIG IRON		
Half pig.	Deep grey.	Silicon iron
0 to 3 per cent. manganese 0·5 to 1·5 per cent. silicon	0 to 5 per cent. manganese 2 to 4 per cent. silicon	5 to 17 per cent. silicon

Malleable Cast Iron. When cast iron articles, produced from high class white iron, are embedded in powdered hæmatite, packed in iron cases, and heated to a cherry red heat for a few days, they become malleable, and are said to be annealed. By this action the combined carbon is set free, and some of the carbon is burnt off from the surface, which renders the cast wares malleable.

Wrought Iron. Wrought or malleable iron is a mixture of iron and slag, drawn out into fibres by mechanical treatment at welding temperatures. There is, however, this difference, that the iron is crystalline and the slag amorphous. Wrought iron is not pure, but contains, in addition to the slag, those elements in a smaller degree which are present in the pig iron. It possesses the welding property in a high degree. Its specific gravity is 7·8, and its melting point about 1,600° C.

Steel. This is a malleable and tough alloy of iron and carbon, the latter not exceeding 2 per cent., and generally less than 1·6 per cent. In special steels, elements such as manganese, nickel, tungsten, chromium, etc., are added in various amounts. When the carbon is less than 0·3 per cent. it is termed *mild steel*, and cannot be materially hardened by sudden quenching. Steel is finely crystalline in structure, and the higher the percentage of carbon the smaller the grain. The carbon exists chiefly in combination, forming the compound Fe_3C. Steel has a bluish-white colour, is generally destitute of fibre, except in wrought steel, and possesses great strength and tenacity. It can be made intensely hard by sudden quenching and again softened by slow cooling from a red heat. By cautiously re-heating hardened steel to 200° or 300° C. the tension is released, the metal loses its brittleness, and its intense hardness is modified. This is termed *tempering*. Hardened steel is capable of retaining its magnetism after being once magnetised, especially the variety known as *tungsten steel*.

The Early History of Iron. We can only conjecture when iron was first extracted from its ores and applied to the use of man. The most ancient samples have been obtained from Egypt and Assyria, some of them assumed to be 4,000 years old. When the Roman Empire was extended, the use of iron became widely known. Pliny mentions the hardening of steel by quenching in water and in oil. For centuries before the Christian era, iron was produced, and what is now known as *Styrian* and *Noric* iron was famed for its high quality. The ancient Britons were acquainted with the use and probably the extraction of iron, and during the Roman occupation the manufacture was enormously increased in the country.

In all ancient processes the iron was obtained from the ore in one operation. This is known as the *direct method*, and is the one still employed in some parts of India, China, Africa, South America, and, to a limited extent, in Europe. The furnace is a simple open hearth or small blast furnace. The fuel used is charcoal, and the blast is obtained by rude blowers or bellows. In the fourteenth century cast iron began to be obtained in small blast furnaces. All ancient iron furnaces were heated with charcoal. The increase of iron smelting in this country produced a scarcity of charcoal, which directed attention towards the use of coal and coke. Dudley, in 1619, produced pig iron from ore smelted with coke. This led to a practically new industry, that of coke making, which has been associated with that of iron smelting ever since. The invention of the steam engine led to the use of blowing cylinders for the production of the blast, which was obtained at high pressure and greatly increased the yield of iron.

Improved Processes of Refining Iron. In 1784 a great improvement in the method of refining pig iron was made by Henry Cort. Before that time iron was purified in small hearths with a great expenditure of fuel, but Cort's introduction of the reverberatory puddling furnace lessened the fuel consumption and enabled coal to be used instead of charcoal.

Another marked advance was made by Neilson, in 1828, by the substitution of hot for cold blast. This was soon followed by closing the top of the blast furnace, so as to collect the waste gases and utilise them for heating the blast.

In 1840, Huntsman greatly improved the manufacture of crucible steel. In 1855, the great inventions of Bessemer were given to the world, and in 1861, Siemens invented his regenerative furnace. In 1878, the introduction of the basic process of steel-making was made by Thomas and Gilchrist, and is now employed in the *Bessemer* and *Open Hearth* methods.

In recent years the development of the blast furnaces has resulted in increased height and capacity, greater facilities for charging, discharging, casting, and dealing with the pig iron obtained. In steel-making the great feature has been the invention of new types of open hearth furnaces, and in methods of treating, working, and using them.

Great improvements have been made in machinery, chiefly electrical, rather than in processes. The tilting furnaces of Campbell and Wellman for continuous practice, and the

Bertrand-Theil duplex method of working are the most prominent. Many kinds of special steels have been recently introduced, which require special treatment, and these have revolutionised machine shop practice.

Ores of Iron. Iron occurs in Nature in small quantities in the metallic state as meteorites, but the oxides and carbonates form the chief source of the metal.

Magnetite is a black oxide of iron, Fe_3O_4, and possesses magnetic properties. It contains, when pure, 72·4 per cent. of iron. Although occurring in various parts of the world the chief supply is obtained from Sweden and North America. From this ore the celebrated Swedish iron is obtained.

Hæmatite is the red oxide, Fe_2O_3, and contains, when pure, 70 per cent. of iron. It occurs in a variety of forms as *specular*, *micaceous*, *kidney*, *ochre* and *massive* hæmatite. The most important deposits in this country are in Cumberland.

Brown hæmatite, or limonite, is of a brown or yellow colour, and consists of Fe_2O_3 with combined water. It may be typically represented by the formula $2Fe_2O_33H_2O$. It is abundant in the English Midlands and various parts of the world.

Spathic ore, *chalybite*, or *siderite* is a carbonate of iron, $FeCO_3$, containing, when pure, 48 per cent. of iron. It is abundant in the Midlands, South-West and Northern counties. It occurs in enormous masses in Scandinavia, Central Europe, and North America. Clay ironstone and Blackband are varieties of this ore.

Iron pyrites, FeS_2, although it is very abundant, is not suitable for smelting on account of the sulphur which it contains. When heated in air or oxygen the surface becomes coated with the black oxide, Fe_3O_4. Iron is readily attacked by hydrochloric or dilute sulphuric acid, hydrogen being given off and chloride or sulphate of iron formed. If concentrated sulphuric acid be employed the metal is oxidised at the expense of the acid and sulphur-dioxide is evolved. Ordinary nitric acid attacks iron vigorously; but if the acid be concentrated the iron becomes passive.

There are three oxides of iron of metallurgical importance—ferrous oxide (FeO), ferric oxide (Fe_2O_3), and magnetic oxide (Fe_3O_4). Ferrous oxide is very unstable and rapidly oxidises in air; it unites with acids to form iron salts and is the principal base in all slags formed in the refining of crude iron. In combination with carbon-dioxide it forms spathic ores. Ferric oxide occurs native. It is a fairly stable compound, but at a white heat it gives up oxygen, forming Fe_3O_4. The magnetic oxide is the richest ore of iron; it is produced when iron is strongly heated in air, oxygen, or superheated steam, and is used as a protective coating from further oxidation of iron goods. The influence of silicon, phosphorus, sulphur, carbon, etc., is dealt with elsewhere.

Production of Pig or Cast Iron. Most iron ores are first calcined in heaps, stalls, or kilns, with the addition of a little fuel. The object of this is to remove water, sulphur, carbon, dioxide, and other volatile matter, to convert ferrous into ferric oxide, and to render the ore more porous and more readily susceptible to the action of the reducing agents in the blast furnace.

The calcined ore is put into the blast furnace with coal, coke, or charcoal, and a flux, which is generally limestone. About four tons of material will produce one ton of iron. Air is forced in at the bottom and rises towards the top; it thus encounters the solid materials which are descending, and by acting upon them, liberates the iron. The oxygen of the air combines with the carbon, and produces the necessary heat. The carbon and the carbon compounds formed reduce the iron oxide. The flux unites with the gangue of the ore, and forms slag. Thus we have the heat-producing action, the reducing action, and the slag-forming action.

TYPICAL COMPOSITION OF IRON ORES

—	Swedish Magnetite	Cumberland Hæmatite	New South Wales Hæmatite	Northampton Limonite	Styrian Spathic	Staffordshire Clay Ironstone	Cleveland Ironstone	Blackband

Chemistry of Iron. Pure iron may be produced in two ways:

1. By reducing pure ferric oxide by hydrogen in a porcelain tube at 700° C., when it is obtained as a dark powder. If the reduction is effected at a much higher temperature a silver-grey, spongy mass is obtained.

2. By the electrolysis of a solution of pure ferrous chloride or sulphate.

Iron is unaltered in dry air, but in the presence of moisture it rusts, forming a hydrated oxide. The oxidation is probably accelerated by the presence of carbonic acid. When it is strongly

Necessary Conditions in Iron Reduction. In order completely to reduce oxide

of iron, we must have a high temperature and contact with a deoxidising substance, such as carbon, carbonic oxide, etc. The reduction of oxide iron by carbon yields carbonic oxide, in which form it escapes, but the reduction by carbonic oxide yields carbon dioxide. These reductions may be expressed by the following equations:

$$Fe_2O_3 + 3C = 2Fe + 3CO;$$
$$Fe_2O_3 + 3CO = 2Fe + 3CO_2$$

Under the strongly reducing conditions required for the reduction of oxide of iron, elements other than iron are also reduced, such as phosphorus, sulphur, silicon, manganese, etc., and these combine with the iron. The fuel also contains sulphur, and sometimes phosphorus, and these contribute impurities to the iron. By contact with incandescent carbon also iron absorbs some carbon.

"Direct" Methods. Similar reactions take place when primitive or direct methods are used, but these are now employed only to a limited extent. In these furnaces a relatively low temperature and a short contact of the iron with the carbon prevents a little of the latter from uniting with the iron, and by the oxidising action of the blast the combined carbon is largely removed, and a pasty mass of metal, termed the *bloom*, is obtained and hammered into a malleable mass of wrought iron. By keeping the bloom longer in contact with incandescent carbon, a steel or steely iron is obtained. Such a method is termed *direct*, because iron is produced in one operation instead of in two, as in the blast furnace method, where pig iron is first produced, and then refined in the puddling furnace.

Direct methods can be applied only to very rich ores with little gangue, and charcoal is necessary as fuel. In addition to this, the labour is very great, and the loss of iron in the slag considerable. These conditions have led almost to the abandonment of the process. In order to prevent waste of iron, limestone is necessary as a flux, which forms a slag with silica; but this requires for its formation a high temperature, such as that of the blast furnace.

Molten Iron. It has been mentioned that the conditions in the blast furnace are favourable to the absorption of carbon by the iron, and the pig iron obtained contains 3 to 4 per cent. This, having a lower melting point than malleable iron, becomes perfectly liquid at the temperature of the furnace, and on account of its specific gravity falls to the bottom. The slag also is melted, and floats on the top of the iron, the gaseous products escaping at the top. In a general way the reactions may be expressed thus:

$$2Fe_2O_3 + SiO_2 + CaO + 3C = 4Fe + CaOSiO_2 + 3CO_2$$

But the reactions are not nearly so simple as this. Carbonic oxide plays an important role; the gangue of the ore contains alumina, magnesia, oxide of manganese, phosphoric acid, etc., so that the slag is a complex silicate. The escaping gases contain also nitrogen, carbonic oxide, hydrogen, and other volatile matters. It will be understood, then, that temperature is an important factor in determining the character of the reduced iron.

It is possible in the blast furnace to treat much poorer ores than in the forge furnace; the slag is almost free from iron, and the manual labour much less. Since pig iron is aimed at, coal and coke can be used instead of charcoal as fuel. In the forge furnace, also, 3 or 4 tons of charcoal are required for the production of 1 ton of malleable iron, while in the blast furnace 1 ton of pig iron can be produced with 1 ton of coke. It is true that pig iron has to be refined, but the combined cost of reduction and refining is much less than a single operation in the forge furnace.

Principles of Blast Furnace Practice. The aim is to secure regularity of working and fuel economy with maximum output. The ore should be of uniform quality, or a uniform mixture of different ores should be used, with a suitable flux to produce the quality and composition of slag best suited to the process of smelting. Neither a very lean ore nor a very rich mixture of ores yields the best results. The more refractory the ore, the more finely should it be crushed, so as to be readily reducible. Two dangers present themselves here. A very fine ore offers great resistance to the ascending gases, and a greater quantity is carried into the flue as dust; therefore increased blast furnace pressure is necessary. It is important that the sizing, or separating of the ore, according to relative coarseness, should be carefully considered, and the charging of very fine and coarse ores together should be avoided if possible. The best plan is to separate it into two or three different sizes, and either smelt separately or smelt the coarser ones together. The fine ones can be best used after making into briquettes or agglutinating in some convenient way. If coarse and fine ores are smelted together they should be charged in in separate strata, and a strong blast used.

The Flux. What has been said of the ores applies in a great measure to the flux. It should be broken into pieces of uniform size and all dust avoided. The slag performs a twofold function — physical and chemical. Physically, it acts as a filter, purifying the globules of reduced iron as they pass through; and as a shield, protecting the metal from oxidation by the blast. Chemically, it absorbs sulphur, and assists in regulating the silicon content in the iron. The proper composition of the slag is very important. Alumina should be as low as possible, as, although it does not reduce the fusibility, it reduces the fluidity, which is a vital point in the blast furnace. A good slag should retain the solid form up to the melting point, and then become quite liquid, and not pass through a stage which causes sticking and hanging, and has a tendency to retain globules of iron.

Fuel. The fuel for the blast furnace may be raw coal, coke, anthracite, or charcoal. Of these the raw coal is seldom used alone—anthracite is generally too dear, and charcoal too expensive and too scarce. Coke is the best possible fuel for

modern blast furnaces. The fuel, it should be remembered, performs a physical and a chemical part. Physically, it preserves an open passage for the ascending gases, and for this reason should be hard, coarse, and uniform in size. Fine dust or breeze is very objectionable, as it blows over with the gas. Chemically, the fuel generates the requisite heat by semi-combustion with oxygen, and the carbonic oxide formed is a necessary reducing agent for the reduction of the oxide of iron. Coke should be highly porous, so as to offer the maximum surface to the oxygen of the blast. The most objectionable impurity in coke is sulphur, and phosphorus for special irons. The composition of the ash is almost as important as its quantity. The alumina should be low and the silica high.

Blast. The blast should be regular in quantity, and, as far as possible, constant in volume. A regular temperature is very important, since every 100 degrees of heat added is equal to 3 per cent. of the carbon burned at the twyers. Temperatures corresponding to a red heat are constantly used for heating the blast, but beyond this limit it is not advisable to go, although theoretically the limit is not reached until the fuel reduces the quantity of carbonic oxide to just that quantity required to reduce the ore. The introduction of the hot blast regenerative stove has enabled higher temperatures to be obtained, but it is subject to greater variability of temperature than the old pipe stove. The loss of temperature in an hour's blowing is from 200° C. to 300° C., and this is equivalent to an increase of 7½ per cent. of fuel burned in the hearth. This may be largely avoided by washing the gases and using larger or more numerous stoves. For noting uniformity of temperature a pyrometer is necessary, and an autographic record will show the temperature each minute if necessary.

The composition of the blast varies with the humidity of the atmosphere, and, as one pound of moisture requires 1·3 lb. of carbon to be burned at the twyers to replace the heat absorbed by the decomposition of this water, an enormous amount of heat is thus lost. This consideration has induced ironmasters to use desiccating plants for removing the moisture from the blast.

The Charge. The temperature and condition of the charge varies in different parts of the blast furnace. In the top portion the materials are warmed, and the oxide of iron is partially reduced. Lower down, the limestone flux is calcined, forming lime and carbon dioxide at a red heat. A little lower down still the carbon dioxide oxidises, the carbon of the fuel forming carbonic oxide at a bright red heat, and the reduced iron takes up carbon. This action is continued in the lower zones, in which also the oxides of silicon, phosphorus, etc., are reduced, and the silicon and phosphorus unite with the iron. In the bottom portion the furnace is at an intense white heat, the carburised impure iron is melted, as well as the slag, and both fall into the hearth. Carbonic oxide cannot completely reduce oxide of iron, so that other reducing agents are necessary, chiefly carbon. The reduction of oxide of iron takes place at comparatively low temperatures in the upper part of the furnace. In the middle portion the iron-reducing tendency is about balanced by the iron-oxidising tendency, while the carbon-depositing tendency is equalled by the carbon-oxidising tendency. In the lower portion the iron is reduced by carbon and carbonaceous bodies, such as potassium cyanide.

Changes. The changes occurring in cold-blast charcoal furnaces are somewhat different from those for hot-blast coke furnaces, for the charge will pass a considerable distance down the furnace before reduction begins. The ore appears to pass from ferric to magnetic oxide, then to ferrous oxide, before being reduced to the metallic state, so that, while in the coke furnace reduction takes place in the upper part by the action of carbonic oxide, the reduction in a charcoal furnace takes place in the middle of the furnace at a comparatively high temperature.

One of the most important factors in the proper working of a blast furnace is the suitable distribution of the charge, and this has been emphasised since the introduction of automatic charging apparatus. The tendency of the skip hoist to distribute coarse or fine ore unequally is a defect not yet overcome. The ideal charging apparatus should be under control so that the material may be distributed evenly over the entire area of the blast furnace. The cup and cone system falls far short as a distributor because of its narrow limitations and its inflexibility.

Waste Gases. The blast furnace gases are important factors in smelting, both inside and outside the furnace. Inside, they distribute the heat and reduce the ores to the metallic form, and the proper performance of their functions is determined by analysis. The gas temperature is also a valuable guide. A hot top indicates insufficient heat at the bottom, with the consequent production of inferior iron and bad slag. The waste gases from a blast furnace consist of carbonic oxide, carbon dioxide, and nitrogen, with small quantities of hydrogen and hydrocarbons. With furnaces using raw coal the gas is richest in hydrogen and hydrocarbons. In coke furnaces the volume of carbonic oxide is double that of carbon dioxide, and in charcoal furnaces the greater volume of carbon dioxide is found.

Waste gases have been chiefly used for heating boilers and hot-blast stoves. In some cases they are used for heating kilns, ovens, and general heating appliances. Blast furnace gases, after purifying, are now used for driving gas engines, and in this direction great economy may be effected in the production of cheap electricity for furnaces. The cleaning of the gases for engine work is indispensable. Cleaning should take place in three stages—a preliminary dry cleaning; a wet cleaning for use in stoves, boilers, kilns, and furnaces; and a special cleaning for power purposes by means of fans. Fewer and smaller stoves, less heating surface for boiler plant, diminished consumption of gas, less cleaning and

repairing will result from proper cleaning of the gases.

Slags. Blast furnace slags differ in colour and appearance according to the charge and the working conditions of the furnace. With excess of lime, the slag is white and fusible with difficulty. With a moderate amount of lime, the slag is grey, hard, and compact. When the furnace is making white iron the slag is dark in colour and very fluid, which makes it very corrosive on the furnace lining. It often contains much oxide of iron, and is termed a scouring slag. The slag is tapped from the furnace into bogies running on rails, and forms a mould of a truncated conical shape. In some works it is run through a bronze twyer on to a trough, and thence to small pans fixed on an endless chain which, by its revolution, delivers the slag into trucks. In some cases the slag is removed at intervals in side-tipping ladles.

The harder kinds of blast furnace slag, if not too glassy, are used for mending roads, for levelling waste lands, for building breakwaters, and for ballast. In the form of large blocks slag is used for road-making. It is used also for building purposes when suitable. For this intention it is moulded into bricks, which are kept at a strong heat for several hours in a closed space, in order to devitrify them and make them harder. Good bricks are made of granulated slag and lime. If not too acid, slag may be burnt in a state of powder with lime and yields a good hydraulic cement. The following are analyses of slags used for this purpose:

—	Bilbao.	Middlesbrough.	Saulnes, France.	Choindez, Switzerland.	Hartzburg, Germany.	Belgium.
Lime..	47·30	32·75	47·20	45·11	48·59	44·75

Slag wool is made from blast furnace slag by blowing steam on to a thin stream of the slag in such a way that the steam encounters only half the stream. It is light and fireproof, and used for covering steam-pipes, etc.

The Blast Furnace. An English blast furnace of the old type was a massive stonework structure, circular in cross section, and the shaft approached in sectional elevation to that of two truncated cones joined at their bases. The lower cone was continued to the ground level or enlarged, forming the hearth, three sides being continued to the bottom, and the other left open for access. The interior was lined with firebricks. The dimensions varied from 9 to 10 ft. in diameter, and from 30 to 45 ft. high.

The blast furnace of to-day, compared with that of a century ago, is an efficient machine. Then, the consumption of fuel per ton of iron was often 10 tons; now, it is often less than 19 cwt. of coke. This has been mainly effected by the introduction of the hot blast and the utilisation of the waste gases for heating the blast. With some ores, cinders, etc., the consumption of coke reaches 30 cwt. per ton of iron. Approximately, 54 per cent. of the total heat is carried away in the waste gases, 6 per cent. in the slag, 3 per cent. in the iron, 6 per cent. in the water used, and 7 per cent. by radiation and conduction.

The modern blast furnace is an elongated barrel-shaped structure in interior vertical section, and generally circular in cross section. The height varies from 75 to 95 ft., the greatest width from 25 to 30 ft., and the maximum capacity of 50,000 cubic ft.

The body is formed of wrought-iron plates, half an inch thick, and riveted together. Within this is built the outer casing of ordinary masonry, the inside being lined with firebrick, about 18 in. thick, while in some cases between the two layers of brickwork is a small space filled with sand to allow for expansion and contraction. The body, or stack, is supported on a cast-iron ring, resting on pillars of the same material, and the lower part, from the top of the columns to the hearth, is also cased with iron and in some cases with water blocks. The hearth is independent of the masonry of the stack, and is built in after the stack is completed. It requires to be made of very refractory material of considerable thickness, having to withstand a very great heat in addition to the corrosive action of the molten slags.

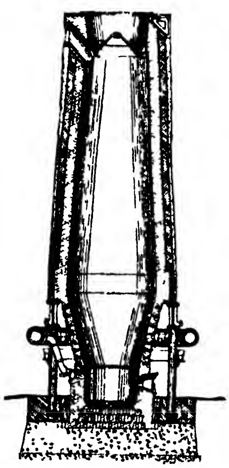
The hearth is perforated with six to eight holes for the introduction of the twyers, which convey the blast of air into the furnace. On the front or the working side the hearth was formerly extended, forming a rectangular cavity known as the fore-hearth, which was bounded in front by a very refractory stone, termed the *damstone*. The arch covering this was called the *tymp-arch*. The tymp was made either of a very refractory stone or of a hollow cast-iron box built in the masonry, and through this box a current of water constantly circulated to keep it cool.

Fig. 32 represents a modern American blast furnace. It is about 85 ft. high, 23 ft. wide at its greatest diameter, and of 11 ft. diameter in the hearth. The hearth is protected by water-cooled plates, and in the boshes are eight rows of bronze cooling plates, eight plates forming the circle, each plate having two watercourses. Cast-iron cooling plates are also placed between the twyers, the number of the latter being seven, each 6 in. in diameter. The cubical capacity is about 20,000 cubic ft. The charging bell is 12 ft. and the throat 15½ ft. in diameter. The volume of air blown in is 24,000 cubic ft. per minute. The temperature of the blast is 650° C., and the average pressure 8 lb. per square in. For flux 10 cwt. of limestone are required per ton of iron produced, and this amount is produced with 17 cwt. of coke. The output is about 2,000

tons per week. The following comparison between a typical English and a typical American furnace will show the different conditions in each case:

	Cleveland	Pittsburg
Cubical contents	25,500 ft.	18,200 ft.
Temperature of the blast..	704° C.	593° C.
Coke per ton of ore	19·99 cwt.	16 80 cwt.
Limestone	11 00 „	9·00 „
Ore	48 00 „	32 30 „
Weight of blast per ton of ore	87·15 „	71·20 „
Weight of gases	119·50 „	100·1 „
Temperature of gases	250° C	171° C
Tons of iron for 1,000 cubic ft. space of furnace per week	21 57	128 0
Slag per ton of iron	28 00 cwt	10 70 cwt
Calories produced per ton of iron	88 577	69·569

It will be observed by the above figures that the English furnace has much the greater capacity, the temperature of the blast is higher, and the calories of heat per ton of iron are more, therefore the fuel used per ton of ore is greater, the blast is hotter, the waste gases escape at a much higher temperature, the flux required and the slag produced are greater. The great reducing energy of the American furnace, with its high grade ore and rapid working, yields six times as much iron per cubic foot of space as the English furnace.



32. BLAST FURNACE

Pig Bed. This consists of a sand bed with a number of parallel grooves of a semi-cylindrical section, generally with their long axes towards the tap-hole, while the top ends of these furrows in each row are connected with a common channel running at right angles to them, and known as the sow, or feeder. These feeders themselves are put in connection with the main channel leading from the tap-hole. In some works the moulding is done by mechanical means, so that the pigs are of uniform size at equal distances apart, and are cast in groups of 30 or more. When cold, an overhead crane picks up each group and carries it to the pig breakers. Pig-iron casting machines are of various patterns, but have not yet come into general use.

Form and Dimensions of Blast Furnace. The horizontal section of the hearth varies with the pressure of the blast and the porosity of the materials employed. The height of the furnace must be limited when the fuel is friable (such as anthracite) or the ore fine, for if too compact the gases cannot circulate properly. Moreover, in a mass of different materials descending gradually, the effect of different densities becomes greater as the height of the furnace is greater. In some Cleveland furnaces the boshes are smaller than usual, while the greatest capacity is in the upper or reducing zone of the furnace. The inventors claim for this a lower fuel consumption and a greater regularity of working. The angle of the boshes as compared with the rest of the furnace varies in different districts; but the modern tendency seems to be in the direction of boshes low down in the furnace and at an angle of about 75°. The section of most furnaces is round, which economises heat and causes it to be more uniformly distributed. The hearth is circular in section. The greater the diameter of the hearth and the greater the vertical distance between the slag notch and the twyers, the larger is the output. The tap-hole should be on a line midway between the twyers, and the same remark applies to the slag notch.

Twyers. The twyers are made with a double casing that water may flow between. In some twyers the cooling water in the form of spray is driven from the end of a perforated pipe against the port of the twyer.

The Scotch twyer consists of a spiral wrought-iron tube enclosed in a cast-iron casing, and water circulates through the coil to keep it cool. The number of twyers varies according to the nature of the ore and fuel used. Excessive blast consumes too much fuel, cools the slag, and impedes the working. The cutting action of the blast on the lining is reduced by allowing the twyers to overhang, but this at the same time reduces the melting action of the hearth.

The blast is heated by causing it to pass through hot stoves, of which there are two chief kinds—cast-iron stoves, containing pipes heated by solid fuel, and stoves of refractory brickwork, constructed on the regenerative principle. Two principal forms of the latter are employed, invented by Cowper and Whitwell respectively.

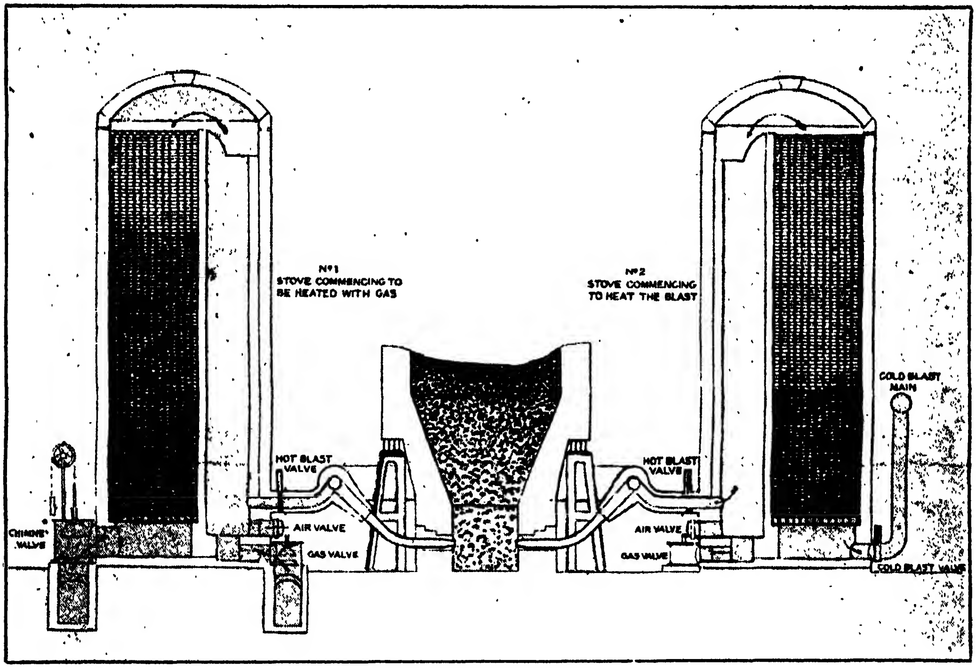
Stoves. The Cowper stove [33] is a circular, wrought-iron tower, 60 ft. high and 28 ft. in diameter, closed with a high dome-shaped roof and lined internally with firebrick constructed on the regenerative principle. About two-thirds of the interior is lined with a checker work of brick for absorbing the heat obtained from the combustion of the waste gases from the blast furnace. A large vertical flame flue receives the gases, in which they are ignited. The flame passes downwards through the checker brickwork and makes it red hot. When this has continued a sufficiently long time the air, gas, and chimney valves are closed and the cold blast admitted in the opposite direction, when it takes up the heat from the brickwork and passes on to the blast furnace through the hot-blast valve as shown in 33. It is necessary to have two stoves for each furnace, so that one may absorb the heat from the burning gases, while the other is heating the blast. The bricks are of spical shape, and when they are placed together form hexagonal passages with walls 2 in. thick. As compared with the pipe stoves

the Cowper stove gives a much higher temperature, and has led to an increased yield from similar furnaces of 20 per cent.; the fuel consumption is at the same time lessened. One disadvantage of regenerative brickwork stoves is the liability to become choked with dust, especially when finely-divided ores are being smelted; this necessitates occasional cleaning, and for this purpose Mr. C. Wood, of Middlesbrough, employs a brass cannon, which is charged with powder, run into the stove, and fired. The explosion displaces the dust, which is allowed to settle and then removed. Another method depends on the use of release valves which allow of the instantaneous discharge of the imprisoned air. A cloud of dust is immediately discharged and shot up into the air.

The Whitwell Stove. The Whitwell stove is cylindrical, with a domed top and lined with firebrick, but the internal arrangement is different from that of the Cowper stove. The regenerators consist of a number of firebrick passages made of 5-in. brickwork. This brickwork contains a main combustion flue for the burning of the waste gases, and air is admitted by special feed passages. The hot and partially-burned gases pass repeatedly up and down through the passages, giving up their heat to the brickwork. The reversals are much the same as in the Cowper stove, and two stoves are required to one blast furnace. Many modifications of the above are in use in different districts, some of which combine the advantages of both systems.

The Ford - Moncur Stove. The Ford-Moncur stove is one that has met with considerable favour of late years. The bricks are dome-shaped so as to prevent dust lodging on them. The stove is also divided into four different parts by vertical partitions, so that when it is desired to clean out the dust the blast may be turned on to each partition separately.

Lifts. The materials are brought to the top of the blast furnace by lifts of various kinds. The inclined plane consists of a railway on which runs a triangular platform with two unequal pairs of wheels. The power is supplied by a steam engine, working a winding drum, around which passes a wire rope or a flat-linked chain. Another form is the colliery lift similar to that used in a coal-mine. A pneumatic lift is often used, and consists of a cast-iron ram, working in a long cylinder rising the whole height of the furnace. From this pass wire ropes over large pulleys to a lifting table, which contains the loaded trucks or barrows.



33. THE COWPER STOVE

CHILDREN'S CLOTHING
continued from page 4357

DRESS FOR GIRLS

Frocks: Drafting, Cutting, and Making. A Princess Petticoat and a Circular Skirt. Overalls. Hints on Lengthening

By AZÉLINE LEWIS

FROM four to six years old and onwards, girls' clothing assumes a definite character, though simplicity should always be the keynote of children's fashions.

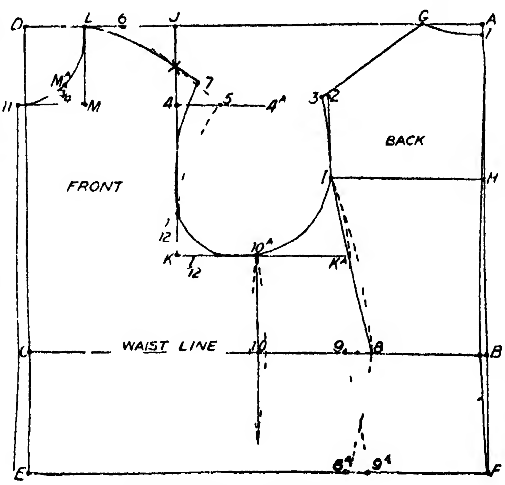
With respect to underwear, the patterns of combinations already given will be a suitable shape up to the age mentioned, unless chemise and drawers be preferred, for which draftings are given. The nightdress pattern also will be quite right if cut somewhat larger and longer. It can be made to fasten at the side if preferred. [For larger sizes, see UNDERCLOTHING.]

The princess form of petticoat is preferable to the banded affair, unless this be buttoned on to a plain under bodice, so that the weight rests on the shoulders. If the latter be preferred, the skirt portion should be gored somewhat, so as not to add to the bulk at the waist. For girls in the early 'teens, inclined to be stout, the princess form of petticoat is best. In this case it is better made with a deep frill, cut either shaped or straight.

Frocks. The plain shoulder yoke and smocked style should not be worn after eight years of age—and not then if the child is inclined to be tall and thin—certainly not by girls of 10 and 12 years of age, as we have seen, unless secured to the waist by a sash or loose belt. The Empire yoke, of course, can be worn by girls of any age, but it is not particularly becoming to a stout child.

Foundation Bodice. As was shown in our Dressmaking course, all garments are modelled or built upon a skirt and bodice pattern, so 46 gives a drafting suitable for a child of six to eight years of age. This follows on the lines of that in DRESSMAKING, with the necessary exceptions, and can be adapted to any size. Chest measurement, 25 in.; back length, 8 in. This last measure, however, is a very elastic one, as the waist is not clearly defined in so young a child and the drafting shows a short-waisted affair, which will do for the Victorian coat.

A to D, chest measurement; B to A and C to D, length of back plus ½ in. for neck curve; D to E and A to F, entire length. The waist-line can be altered to any depth without affecting or interfering with the drafting in any way, the only alteration needed being that darts or side pieces—if made—must be carried down to the waist line. A to H and H to I, one-third of chest measure; A to G, one sixth of neck measure less ¼ in. for curve. A to I, ¼ in. Curve from G to I for back neck. A to J, two thirds of chest measure; J to K, one-half of the same less ½ in.



46 BODICE DRAFTING.

Draw line from K at right angles towards back (this is merely as a guide for armhole); mark Ka.

I to 2, one sixth of half chest measure (this, however, varies with fashion, and may be less or more according to taste). 2 to 3, ¼ in. Draw a line from 3 to G for back shoulder and curve from 3 to I for back armhole.

J to 4 is same length as from I to 2. Draw a line at right angles to the right. Mark centre of J–4, then measure back shoulder, and draw same length for front from line 4 to line D A, with centre on the cross marking centre, as shown by broken line. Make dots one twelfth of chest measure on each side of angle K; curve from 5 to I, passing through dots on each side of angle K.

B to 8, 3 in. Draw a line from I to 8 and curve ¼ in. to right of this line for back.

Advance 7 one twelfth of an inch towards D, make L, and draw shoulder as shown by firm line.

8 to 9 is 1 in.; curve from I to these points; 8 to 10 is 3 in.; draw line to armhole and make 10*a*, then curve ½ in. either side of this at waist, for under-arm.

These lines are shown by a broken line, as they are quite optional, shaping at these portions not being always necessary. They should not be cut, but just marked with the tracing-wheel if made to the waist only.

Now measure pattern and add on what may have been taken in by the side-piece to make the chest measure correct, and mark 11. Draw L to M one-sixth of chest measure, then from M to 11. From M to M*a* is ¾ in.; curve from L to 11 for neck.

For the lower portion, make a point midway between 8 and 9, also one immediately below

on line E to F, and draw lines 8*a* and 9*a* the same distance—*i e.*, ½ in —to right and left

Extend lines on either side of 10 2½ in below waist, and curve from waist to point of these Trace round the pattern and cut out, following the firm line for the front shoulder and arm holes

This method can be used for any size up to 12 years of age After this period one or two darts may be required, and the various draftings already given in DRESSMAKING and TAILORING can be followed or modified according to requirement

With the aid of this pattern any kind of bodice can be made The method of obtaining a yoke of any shape has been fully explained in DRESSMAKING [see 39 to 43, page 479] If one of the Empire style be preferred cut to the depth required below the armhole, whilst if the long-waisted French bodice be the model, simply extend the lower portion as much below the waist as may be needed sloping it out slightly from armhole to lower edge It should not, however, extend too far, as this impedes the movements of the child If the bodice be gathered allow for the necessary amount in front or at the shoulders, according to the design If pleated model the pleatings on the pattern drafted, which as already remarked forms the foundation for all kinds of styles The neck portion may also be cut round or pointed or square, or any shape preferred

As to the skirt this can be obtained from the model shown in GIRLS TAILORING [p 2469] where full directions are given for drafting a circular skirt adaptable to any size and shape See also drafting for skirt of Victorian Coat [50], which will be equally suitable

The skirt portion of an Empire yoke may be either circular or straight pleated or gathered as preferred The frock part of one with a shoulder yoke, or saddle, should be sloped at the under arm seams, and also requires rounding slightly at the armhole The lower edge should be cut a little—a very little—shorter at the sides, as it always has a tendency to drop here

To cut an American blouse from the drafting just given, slope the fronts out half an inch at E; cut through 10 and 10*a* and slope out the sides each 1 in, as shown by the double line, when, of course, no side piece would be required, and the centre back must be placed to a fold

For the sleeve, any of the draftings already given can be followed according to fashion The drafting of a collar has been shown in several of the previous diagrams

Fig 47 gives a few examples of garments suited to girls of the ages mentioned, but from this period and onwards the various fashions may be consulted so these designs are merely given as models which may form the foundations of an endless variety of other styles, with slight alterations and additions These, however we think will readily occur to the worker who has followed either or all, of the previous courses

47 A GIRL'S WARDROBE

Chemise and drawers are not illustrated, as those already given for children of one to four years of age can quite easily be enlarged

The same remark, too will apply to the combinations

We will now describe the garments sketched

(*a*) A princess frock

(*b*) Here we have the divided skirt already mentioned in the garments for the toddler The method of obtaining this pattern is indicated in the drafting of the first knickers, by a broken line, so is not given again The material and trimming are, of course a matter of taste but for small children this is a much better shape for the flannel petticoat than the ordinary skirt form In this case it would be better without the frill and the edges finished off with a festooned hem The fastening is at the back the closing being accomplished by means of several buttons and buttonholes

(*c*) A Russian frock

(*d*) A plain overall or frock, cut all in one piece

(*e*) A German pinafore The shape of this quaint little model hailing from the Fatherland, is explained by the back view It is cut all in one piece, and fastens on the shoulder

(*f*) Long waisted French petticoat, with two circular frills for the skirt portion This shape sets out the frock very prettily at the lower edge Directions for cutting circular and shaped frills

have already been given in DRESSMAKING, whilst those for the shaped skirt part of the Victorian coat can also be adapted to the size required. This style of petticoat is better suited to cambric or longcloth for white summer ones.

(g) The long-waisted style, known as the French frock.

(h) A sailor style for either boy or girl. This is termed a quartermaster frock, and is cut exactly the same as the man-o'-war style [page 4355], the only difference being that the fronts are left open and faced.

(i) The flannel vest or bodice to be worn with this style of frock, which is made of fine white flannel or cloth.

(j) A princess petticoat.

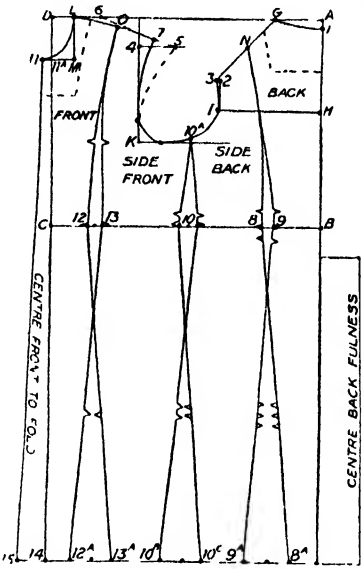
(k) Reefer coat and skirt costume.

(l) Red Riding Hood cloak.

(m) A Victorian coat.

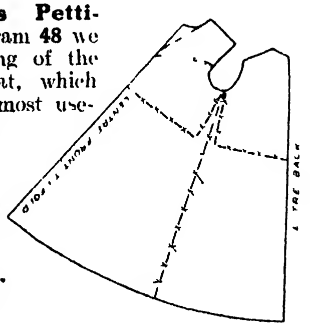
(n) Overall frock with yoke and box-pleated front, modelled as (i).

The making of a coat with step-collar and Norfolk coat, also of a girl's sacque coat, have all been fully explained in BOYS' AND GIRLS' TAILORING, and these styles, with slight modifications of size, style and length, are all suited to girls' outdoor wear, the loose Norfolk coat being especially neat and becoming to a young girl.



48. PRINCESS PETTICOAT

A Princess Petticoat. In Diagram 48 we have the drafting of the princess petticoat, which will be found a most useful one. This is drafted to a 28-in. chest measurement. The working of the upper portion is exactly the same as 46, allowing for the difference of measures, with the exception of 1 to 2, which is $1\frac{1}{2}$ in., to allow for the longer shoulder. 8 and 8a, 9 and 9a are omitted. Make 8 $2\frac{1}{2}$ in. from B, without sloping this in at centre-back. Make N midway between G and 3, and curve slightly from N to 8; make a dot $\frac{1}{2}$ in to right of 8, and curve from here to meet line N at width of back line. Now make 12, $2\frac{1}{2}$ in. from C on waist line; make O midway between L and 7, curve slightly from O to 12. Make a point $\frac{3}{4}$ in. to right on waist line, curve up from this to meet line O.



49 OVERALL

Curve from 10 to 10a as in 46.

Extend from 11a to length required, in this case 30 in.; make 14, then make a point 1 in. to left of this mark, 15, and slope from this dot to 11, to give a little extra width for centre-front. Make a dot $2\frac{1}{2}$ in. to right of 14, then make another 1 in. to right and left of this, and draw a line from 12 and 13 to these dots, as shown at 12a and 13a. Make a dot level with 10 the same distance as from C to 13; make dots $1\frac{1}{2}$ in. to right and left, and draw a line from waist to meet these, as at 10b and 10c. Treat line N to 8 and 9 the same for the side of back and centre-back.

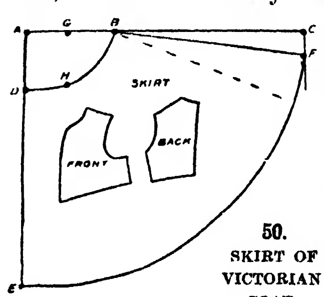
Two inches below B make a dot; then add on 2 or more inches for back fulness to the bottom, which make the same length as from 9 and 10. Trace the pattern round carefully and cut out, placing the various notches as shown, as these are a guide for putting together.

This drafting will do for the princess frock shown at A in 47, the only alteration being needed at the side and back, which are gathered on to the waist in the ordinary skirt fashion.

For this style the back of the bodice is cut slightly below waist at back, the skirt portion consisting of straight or very slightly gored widths, being made as full as taste may dictate. It is joined on to the side seam and the waist part of back of bodice, whilst the bodice trimming is carried over the shoulder to the skirt at back waist.

By altering the position of the side seam, as from N and O, to nearer the shoulder, the same drafting will do for the Russian frock marked at (c) in the same diagram. In this case the front portion is folded over towards the sleeve to form a pleat, which is stitched down quite flat. This frock fastens at the left side under the fold, so a narrow left-side front will be required.

It would also form a corselet or suspender frock, all that is necessary being to cut it to the approved height above the waist line. Should it be preferred with inverted pleats at the seams, the required amount for these can be easily added on at each seam, exactly as shown for the centre-back. Such an arrangement always looks better if the pleats slope upwards, in height, from the front, the highest being at the centre-back.

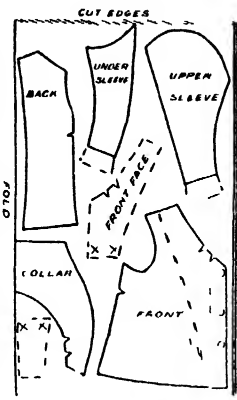


50. SKIRT OF VICTORIAN COAT

This design would make a very pretty little

frock, whilst the pleats could either be inverted, or box-pleated outside the seams, where they could be mitred off at the tops or finished off in various ways. Care must, however, be taken to keep them perfectly even, and not let them drop at the sides.

No. 49 illustrates the overall depicted at (*d*) in the sketch under consideration, which is easily obtained from the bodice drafting of 46, as the broken lines show, or the princess frock drafting of 48, by omitting the side seams. It will form the foundation of (*n*), and many others. This can be cut all in one piece, or with an underarm seam, as preferred. The broken line and crosses show the portion not to be cut. If made quite plain with the V-shaped opening, cut as shown by the broken line. If with the pointed yoke as at (*d*), cut this as indicated by the double broken line, and model the box pleat at the lower portion as already mentioned for the tunic suit and girl's skirt mentioned in GIRLS' TAILORING. If made V-shaped at back and front of neck, and pleated instead of quite plain, this makes a very pretty frock to be worn over lace vests.



51. REEFER COAT

To make a perfectly plain overall or frock, as at (*d*), 2½ yd. of 27 in. goods are required.

Circular Skirt. No. 50 shows the drafting of the circular skirt for the Victorian or Empire coat, the bodice being obtained from 46.

A to B, half of waist measure less 1 in; A to D, a quarter of same; D to E, skirt length, in this case 24 in., but it may be made any length desired. B to C, same length as from D to E; C to F, 3 in. Extend D to E, and draw line from B to F; G, midway between A and B; G to H, ¼ of waist measure (6 in.). Curve from B through H to D, measure from this the length of skirt; also midway between make marks for outer circle and curve from F to E.

If a pleated skirt be desired, the foundation need not be quite so full, and may be decreased as shown by the broken line. Upon this the pleated portion can be modelled. The sleeve can be obtained from the previous drafts.

For the making of the coat, see TAILORING—Ladies' Empire Coat [page 2328]—for which the instructions there given can be followed. If of fairly thick cloth, the bodice only need be lined, when the seams and edges should be neatened by binding.

The required quantities for this coat with circular skirt would be 2½ yd. of 44-in. goods, 1 yd. of Italian cloth for bodice lining, and a small quantity of fine French canvas for interlining.

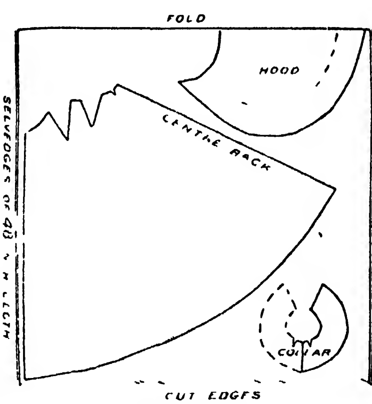
For children, separate collars are the best kind of neck finish, as they can be removed and laundered.

Number 51 shows the method of cutting out the reefer coat from 48-in. cloth, of which 1¼ yd. should be sufficient. The drafting and making of this jacket are similar to that of the sacque in GIRLS' TAILORING, to which we must refer the worker for instructions on this point. The collar can be easily altered to the ordinary sailor style if wished by sloping it off to the front. The facing will require joining, as shown by the crosses, the seams of which must be carefully pressed.

A cloak of the Red Riding Hood order forms a most welcome addition to a small girl's wardrobe, and, indeed, is useful at almost any age [52].

The cloak shown is made with a collar and hood, and is fitted to the shoulder by two darts. If made without the latter, it will need to be almost circular, and this adds the fulness at the lower part, which is therefore apt to fly about too much for the comfort and warmth of the small wearer; for this reason the shape shown is recommended.

This cloak will require 2½ yd. of 44-in material, and in the making care will have to be taken to keep the edges thin and the corner of the cape and collar quite sharp. When making the latter, be careful to ease the upper portion slightly 1 in. from each corner, as mentioned in Pocket-flaps [see BOYS' TAILORING, page 1291], when putting on, so as to get this to set over and not curl up. The upper edge should also come slightly over the under one, as in making boys' coats.



52 CLOAK

Girl's French Frock. For the girl's French frock, cut the bodice lining according to the drafting of 46 or 48, according to the age and size of the child, making this the length required. Model one side of front as sketched, making it cross over a little beyond the centre. If the worker is not very expert, she had better do this in paper. Cut it out carefully, then fold the material and cut two pieces exactly alike, marking the pleats to keep them even, and placing the crossover edges to the selvedges. This is very important, as, if placed on the bias, the fronts will stretch and soon get out of shape. The backs are pleated from the shoulder and neck, and do not cross over or require a vest of white as in the front.

The skirt is merely a straight length of material 12 in. to 14 in. or 16 in. deep, according to the age and requirements, but, as already remarked, should not extend below the knees. It may, however, be kilted instead of gathered, which has an extremely good effect. The directions already given for making the kilt can be followed if this style of skirt is preferred.

When making this frock, mark the turnings very carefully, then tuck the vest and tack in position. Hem the crossover edges of fronts, press well, and arrange these as sketched on the lining foundation, right crossing over left; gather lower edge and tack to foundation, allowing it to pouch somewhat. Turn in the edges of foundation back to the marks, machine-stitch, and make button-holes on the right side 1½ in. apart, and sew buttons on left to correspond.

Turn in the edges of material back to form an inch-wide hem, and machine this next at the edge. Arrange and tack material backs on foundation, the edges overlapping a little; tack fronts and backs together at shoulder and underarm seams, machine-stitch, open, oversew, and press. Then sew six or eight small hooks backwards on the inside of hem at centre-back on the stitching, and make silk loops on the left side to correspond. Gather lower edges, arrange, and pin in position on lower edge of foundation, and tack to this. Tack the collar and secure this to neck. Then place right hem of foundation over the left hem; stitch firmly together; arrange the right and left material backs to correspond, and secure together an inch or so above this to prevent gaping open when on.

Join the skirt portions required, open and press seams, turn up lower edge and make a hem from 1 in. to 2 in. wide. Mark centre of back and front, gather upper edges, using one thread for each division; place centres of front and back to those of bodice, being careful to have no seam in centre-front. Draw up gathers to fit bodice, arrange so that the fulness is graduated off to the back, pin and sew in place, then neaten with a strip of material or binding, which should be hemmed to foundation and fastened off securely at back.

The Sleeves. Join the sleeves by means of a French seam (unless the material be too thick), and gather the lower edges. Now join up the cuff portions, open and press seams, fold in half along the centre of cuff, then turn in upper edges to face. Draw up cuff edges of sleeve to fit, insert between them, stitch together and fasten off the ends neatly. Make the other sleeve and cuff to correspond, then gather the upper part, ascertain position of front seam, arrange in armhole, sew them firmly in place and oversew or bind neatly. Sew in the other sleeve to correspond.

Finish off waist part with folded belt.

This frock will take 2¾ yd. of 44-in. material, 1¼ yd. of lining, and ½ yd. of silk for vest and collar. It can, of course, be varied in many ways, and made with a square or pointed yoke, elbow or puff sleeves; also with open neck, which looks very pretty for small children's summer wear.

Hints on Lengthening. With regard to lengthening, the last-named style is one of great possibilities in this most important detail.

Sleeves are generally more difficult to deal with in this respect. The simplest way, however, is to make these either of the bishop or puff order, a little longer than the required length, when a few tiny horizontal tucks at the elbow will serve for ornament at first and length later on. If on a foundation a tuck should be run in this, just above the elbow.

For petticoats, the bodice part can always be made a little longer than is necessary and a tuck put in this, which is then easily let down when necessary.

For frocks, the skirt part can either be secured an inch or more above the lower edges of bodice, or a tuck made in the foundation, to be let down as needed. In other cases wide hems or tucks should be made, whilst the bodice should always allow for expansion and be an easy fit.

One point of importance should not be forgotten. It is important that the skirt should hang perfectly evenly all round, and, if anything, a trifle shorter at the back than the front, rather than have the slightest suspicion of a "dip" there. This detail, apparently a trifling one, is frequently overlooked, and makes all the difference between a well-dressed child and a dowdy one.

For a child's bathing gown, the combination pattern given will be suitable, whilst for a later period it is also better to have a combined under-garment and a separate skirt portion, both for bathing and gymnastic purposes. [See also UNDERCLOTHING.] Small girls, it may be mentioned, are often clad in a sailor suit for gymnastic exercises.

At about twelve years of age begins the awkward period of a girl's attire, when, however, the varying fashions may be more or less consulted and adapted. It would be impossible to deal with all these, but, as has been already remarked, simplicity should always be the guiding principle, with a certain regard for the type and characteristics of the young girl herself, who is usually gauche and awkward enough at the "between age" without having these peculiarities accentuated by her clothing.

A full frock with an empire yoke outlined with a thick-folded belt with large bow and long ends, and fichu-like drapery at the neck, would not rouse enthusiasm on a stout and short-necked girl, but worn by her slim sister the result would be charming. In the first case, lines of trimming, or folds, arranged to give length and decrease the apparent width should be selected. Injudicious or unbecoming attire has a very subtle effect on the character, particularly at this susceptible period, and shyness and self-consciousness are often increased thereby. Therefore, we repeat, let children's clothing be well chosen, but, above all, let it be very simple.

PARALLEL LINES

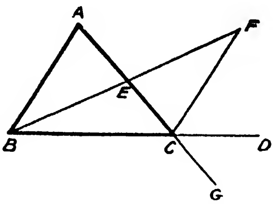
Theory of Parallel Straight Lines. The Value of the Angles of a Triangle, and of those of any Rectilineal Figure

continued from page 4331

By HERBERT J. ALLPORT, M.A.

Proposition 10. Theorem

If one side of a triangle is produced, the exterior angle is greater than either of the interior opposite angles.



Let ABC be a $\triangle$ in which BC is produced to D.

It is required to prove that the $\angle$ACD is greater than either of the $\angle$s ABC, BAC.

Construction. Bisect AC at E. Join BE and produce BE to F, making EF = BE. Join CF.

Proof. In the $\triangle$s BAE, FCE,

AE = CE, BE = FE

$\angle$AEB = vertically opposite $\angle$CEF (*Prop.* 3).

$\therefore$ $\triangle$s are equal in all respects (*Prop.* 4).

$\therefore$ $\angle$BAE = $\angle$FCE.

But $\angle$ACD is > $\angle$FCE.

$\therefore$ $\angle$ACD is > $\angle$BAE,

i.e., > $\angle$BAC.

In the same way, by producing AC to G and joining A to the middle point of BC, we can prove that $\angle$BCG is > $\angle$ABC. But $\angle$BCG = $\angle$ACD (*Prop.* 3).

$\therefore$ $\angle$ACD is > $\angle$ABC.

Corollary 1. *Any two angles of a triangle are together less than two right angles.*

For $\angle$ABC has been proved < $\angle$ACD.

$\therefore$ $\angle$s ABC, ACB are together less than $\angle$s ACD, ACB, *i.e.*, < two right angles (*Prop* 1).

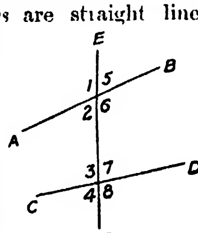
Corollary 2. *Every triangle must have at least two acute angles.*

For, if it has one angle equal to, or greater than, a right angle, then, by Cor. 1, each of the other angles must be less than a right angle.

Hence, a triangle is only called acute angled when it has *all* its angles acute.

Parallel Lines

1. *Parallel straight lines* are straight lines which *lie in the same plane* and which do not meet however far they are produced in either direction.



2. Let the two straight lines, AB, CD be cut by a third straight line EF. Then, of the eight angles formed,

1, 4, 5, 8 are called *exterior* $\angle$s.
2, 3, 6, 7 are called *interior* $\angle$s.
2 and 7 are called *alternate* $\angle$s.
3 and 6 are also alternate $\angle$s.

If we are referring to any one of the exterior angles, say 5, then 7 is called the *interior opposite angle on the same side of EF.*

3. *Playfair's Axiom. Two straight lines which intersect cannot both be parallel to a third straight line.*

Proposition 11. Theorem

If a straight line cuts two other straight lines and makes, either

(i.) *the alternate angles equal;*

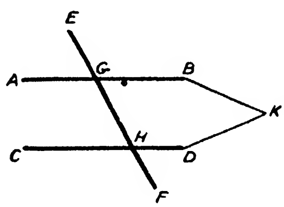
or (ii.) *the exterior angle equal to the interior opposite angle on the same side of the cutting line;*

or (iii.) *the two interior angles on the same side of the cutting line together equal to two right angles,*

then, in each case, the two straight lines are parallel.

Let the straight line EF cut the two straight lines AB, CD, at the points G and H.

(i.) Let the $\angle$AGH = the alternate $\angle$GHD.



It is required to prove that AB is $\parallel$ to CD.

Proof. If AB and CD are not $\parallel$, they will meet when produced, either in the direction of A and C, or in the direction of B and D.

Suppose they meet when produced towards B and D, in the point K.

Then, GHK is a triangle, with the side KG produced to A.

$\therefore$ The exterior $\angle$ of the triangle, $\angle$AGH, is > the interior opposite $\angle$GHD (*Prop.* 10).

But $\angle$AGH is given *equal* to $\angle$GHD, and they cannot be both equal and unequal.

$\therefore$ AB and CD cannot meet when produced.

$\therefore$ AB and CD are parallel.

(ii.) Let the exterior $\angle$EGB = the interior opposite $\angle$GHD.

It is required to prove that AB is $\parallel$ to CD.

Proof. Since $\angle$EGB = $\angle$GHD (*Hyp.*),

and $\angle$EGB = $\angle$AGH (*Prop.* 3).

$\therefore$ $\angle$AGH = $\angle$GHD.

But these are alternate $\angle$s.

$\therefore$ by (i.), AB and CD are $\parallel$.

(iii.) Let the interior $\angle$s BGH, GHD, together equal two right angles.

It is required to prove that AB is $\parallel$ to CD.

Proof.

$\angle$BGH + $\angle$GHD = 2 right $\angle$s (*Hyp.*),

and $\angle$BGH + $\angle$AGH = 2 right $\angle$s (*Prop* 1).

$\therefore$ $\angle$BGH + $\angle$GHD = $\angle$BGH + $\angle$AGH.

$\therefore$ taking away the $\angle$BGH from each of these equals, we have

$$\angle GHD = \angle AGH.$$

But these are alternate $\angle$s.

$\therefore$ by (i.), AB and CD are $\parallel$.

Proposition 12. Theorem

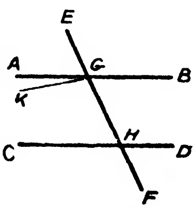
If a straight line cuts two parallel straight lines, it makes,

(i.) *The alternate angles equal.*

(ii.) *The exterior angle equal to the interior opposite angle on the same side of the cutting line.*

(iii.) *The two interior angles on the same side of the cutting line together equal to two right angles.*

Let the straight line EF cut the two parallel straight lines AB, CD at the points G and H.



It is required to prove that

(i.) $\angle$AGH = alternate $\angle$GHD.

(ii.) $\angle$EGB = interior opposite $\angle$GHD.

(iii.) $\angle$BGH + $\angle$GHD = 2 right $\angle$s.

Proof. (i.) If the $\angle$AGH is not equal to $\angle$GHD, suppose the $\angle$KGH is equal to $\angle$GHD and alternate to it. Then

KG is $\parallel$ to CD (*Prop.* 11).

But AB is $\parallel$ to CD (*Hyp.*).

$\therefore$ there are two intersecting straight lines AB, KG, which are both $\parallel$ to CD. But, by Playfair's Axiom, this is impossible.

$\therefore$ $\angle$AGH is not unequal to $\angle$GHD, *i.e.*, $\angle$AGH = $\angle$GHD.

(ii.) Since $\angle$EGB = $\angle$AGH (*Prop.* 3), and $\angle$AGH = $\angle$GHD (By i.).

$\therefore$ $\angle$EGB = $\angle$GHD.

(iii.) $\angle$AGH = $\angle$GHD. Add to each the $\angle$BGH.

$\therefore$ $\angle$AGH + $\angle$BGH = $\angle$GHD + $\angle$BGH.

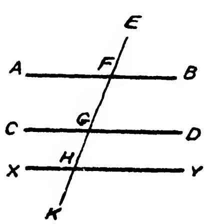
But $\angle$AGH + $\angle$BGH = 2 right $\angle$s. (*Prop.* 1).

$\therefore$ $\angle$BGH + $\angle$GHD = 2 right $\angle$s.

Proposition 13. Theorem

Straight lines which are parallel to the same straight line are parallel to one another.

Let AB, CD, each be $\parallel$ to XY.



It is required to prove that AB is $\parallel$ to CD.

Draw a straight line EK cutting AB, CD, XY, at the points F, G, H.

Then, since AB is $\parallel$ to XY, and EK meets them

$\therefore$ $\angle$AFH = alternate $\angle$FHY;

and, since CD is $\parallel$ to XY and EK meets them

$\therefore$ $\angle$FGD = interior opposite $\angle$FHY.

$\therefore$ $\angle$AFH = $\angle$FGD.

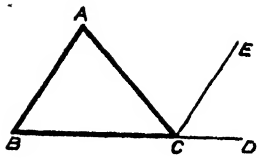
But these are alternate $\angle$s.

$\therefore$ AB is $\parallel$ to CD (*Prop.* 11).

Proposition 14. Theorem

The three angles of a triangle are together equal to two right angles.

Let ABC be a Δ.



It is required to prove that

$\angle$ABC + $\angle$BCA + $\angle$CAB = 2 right $\angle$s.

Produce BC to any point D, and let CE be the straight line through C which is $\parallel$ to BA.

Proof. Since BA and CE are $\parallel$, and AC meets them

$\therefore$ $\angle$ACE = alternate $\angle$BAC;

and, since BA and CE are $\parallel$ and BD meets them

$\therefore$ $\angle$ECD = interior opposite $\angle$ABC.

$\therefore$ $\angle$ACE + $\angle$ECD = $\angle$BAC + $\angle$ABC,

i.e., $\angle$ACD = $\angle$BAC + $\angle$ABC.

To each of these equals add $\angle$BCA.

Then

$\angle$ACD + $\angle$BCA = $\angle$BAC + $\angle$ABC + $\angle$BCA.

But

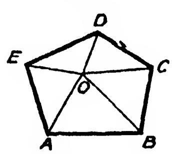
$\angle$ACD + $\angle$BCA = 2 right $\angle$s (*Prop.* 1).

$\therefore$ $\angle$ABC + $\angle$BCA + $\angle$CAB = 2 right $\angle$s.

NOTE. In the course of the proof we have shown that *if one side of a triangle be produced, the exterior angle is equal to the sum of the two interior opposite angles.*

Corollary 1. All the interior angles of any rectilineal figure, together with four right angles, are equal to twice as many right angles as the figure has sides.

Let ABCDE be a rectilineal figure.



Take any point O within the figure, and join O to each of the angular points. The figure is thus divided into as many Δs as it has sides.

Now, the three $\angle$s of each Δ = 2 right $\angle$s.

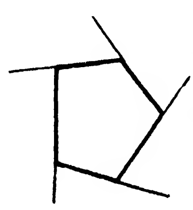
$\therefore$ the $\angle$s of all the Δs = twice as many right $\angle$s as there are Δs.

= twice as many right $\angle$s as the figure has sides.

But the $\angle$s of the Δs make up the $\angle$s of the figure together with the $\angle$s at O, and the $\angle$s at O make four right $\angle$s (*Prop.* 1. *Cor.*).

$\therefore$ $\angle$s of the figure + four right $\angle$s = twice as many right $\angle$s as the figure has sides.

Corollary 2. If the sides of a rectilineal figure which has no re-entrant angle (i.e., no angle greater than two right angles) are produced in order, the exterior angles so formed are together equal to four right angles.



The interior $\angle$ + the exterior $\angle$ at any angular point = two right $\angle$s.

$\therefore$ all the interior $\angle$s + all the exterior $\angle$s = twice as many right $\angle$s as the figure has angles, *i.e.*, as the figure has sides.

But, the interior $\angle$s + four right $\angle$s = twice as many right $\angle$s as the figure has sides (*Cor.* 1).

$\therefore$ the interior $\angle$s + the exterior $\angle$s = the interior $\angle$s + four right $\angle$s.

$\therefore$ the exterior $\angle$s = four right $\angle$s.

BORING, SCREWING & SAWING TOOLS

Different Classes of Bits. Taps and Dies and their Principles. Saws. Forms of Saw Teeth and Set of Saws

By JOSEPH G. HORNER

Woodworkers' Boring Tools. The differences between these and the drills and allied tools used by metalworkers are, as in other tools, chiefly those due to cutting angle, which again is governed by the difference in the softer and harder character of the materials operated on. The woodworkers' boring tools have a small tool angle; the angle of front rake, or that of the cutting face often approximates very closely to that of the face of the material being cut, and the angle of top rake is low, permitting of the free escape of the shavings. These points are seen in the numerous bits and auger bits. The term *bits*, with suitable prefixes, denotes a large and varied group of useful tools, some being seen in 38 to 42; but though these bits possess in common the features just stated, their variations call for some further explanation.

Two Classes of Bits. There are two kinds of holes required in timber—one in which location to a precise centre is not essential, the other in which it is. The ordinary shell bit [38], A, spoon bit, B, nose bit, C, and augers [39], A, do not bore accurately, because they possess no centring tit. The gimlets, and gimlet augers, B, and the twist gimlet, C, do possess this feature in the tapered screw. But they have disadvantages in other respects, in consequence of which they are unsuitable for work demanding a high degree of accuracy The numerous centre bits possess the centring faculty in varying degrees, because the hole is started by the tit placed in the centre, before the cutting edges come into action. Around this principle designs are varied to obtain equally balanced cutting forces, to produce clean severance of grain with the least effort, and to facilitate the escape of chips with the minimum of friction. From these points of view the common centre bit [40], A, is the worst of its class, because its cutting action is unbalanced. It has one nicker, *a*, and one cutting lip, *b*, on opposite sides of the tit. Directly the cutter, *b*, begins its work, practically all the stress is thrown upon its side of the centre, with much torsional effort. Its cutting edge also is too wide for easy work, hence these bits tend to *run*, and they will not bore with fair truth except in plank way of the grain. Try them in end, or diagonal grain, and they are almost useless. Neither is the tit of triangular section a good form for centring, hence many recent bits have a screw instead, B, but the other objectionable features remain.

Balanced Bits. Contrast this with the later forms [41], the Gilpin, the Jennings, the Irwin, and others. These comprise a fine central screw for centring, two nickers, and two cutters on opposite sides. Or cutting is an operation done without separate nicking, and the lips are generally formed in some fashion or another to give a shearing or detailed cut, and so lessen the severity of the task. In 41, A is a Jennings bit with screw and nickers; B differs in having double nickers, or *spurs*, going down and up, the latter helping to get the chips out of the hole; in C the spurs stand upwards only In Gedge bits, D and E, the curved cutting edges cut very sweetly, on the same principle that a gouge severs more material with less effort than a chisel does, due to the shearing action. E is a solid-nose auger, the chips passing up through the holes in the nose. F is a screw auger with lips which neither stand up or down; G and H are Irwin bits, or augers in two forms out of several, the features common to all being the solid circular forged shank. In the examples A to F, provision for getting out the chips, absent in the centre bit [40], is secured by the spiral twist. In some also the turned up lips assist in lifting out cuttings from deep holes. The spiral in A to F is imparted by twisting a flat piece of steel into a helical form. In G, H, and others the shape is that of a small cylindrical stem with a deep helix around it, and it is claimed that there is less friction and more strength in this form than in the other Some of these, termed *auger bits* and augers, are made in the same designs, but of larger size. These tools are made for use by hand and by machine also.

All these are rigid tools, each capable of boring only one diameter. The principle of adjustability is embodied in the expansion centre bits and the hollow augers, the first for holes, the second for pins and dowels. In the first [42] the cutting lip is adjustable to a considerable range of radii, and is clamped by a screw. Graduations on the face enable the diameter to be read. These bits will bore the exact size specified; centre bits always bore larger than the normal diameter. The hollow auger [43] has two adjustable knives, *a*, pinched with set screws, to produce a moderate range of diameters.

Well-sinker's Tools. The boring tools are not exhausted by the metal and wood workers. The well-sinker uses them for boring hundreds of feet down into the earth's strata. These are formed on identical principles with the others, but they are attached to rods, added lengths of which are screwed on as the depth of the boring proceeds. Some types predominate—the flat chisel, the tee chisel, the clay auger, and the circular chisel. A few are

shown in 44. A is a tee chisel. It combines the form of the chisel with the function of the drill. The curved side piece ensures the cutting of a circular hole by the rotation of the chisel. Flat chisels are used without the side piece, but they have to be lifted at every few inches and rotated rapidly. B shows four chisels mounted on a boring head. C is a circular chisel armed with teeth. Diamonds are frequently set in a tool of this kind, having a plain crown instead of teeth. They are used for drilling the hardest rocks, and often cost hundreds of pounds each. Ordinary rocks are pierced by rock drills. Some have four edges in the form of a cross, usually of chisel shape, though varied in forms, D. These are used in percussion boring, being lifted, dropped, and rotated, so breaking up the rock and producing round holes. The chips are removed by other tools termed shells. Clayey soil is removed by clay augers.

Tools for Screw Production. Few except engineers are aware of the large numbers of diverse tools and machines which are used in the formation of screw threads. The dimensions of screws, the degree of accuracy demanded, and the quantities required are the principal causes which control methods. And within each governing condition there are many methods, and many designs by which similar results are attained. The subject of screws, and the tools and machinery for producing them do, in fact, give sole occupation to numerous firms.

Screwing tackle may be broadly divided into two groups, one being that in which the cutting tool or tools have one function only, that of producing the correct section of the screw thread, the pitch and diameter being controlled by extraneous devices. This is the method of the screw-cutting lathe, the chasing lathes, and the hand-operated comb, or chasing tools. The other group comprises tools which not only produce the sections of the threads, but also size and pitch correctly. These include the taps and dies, both hand and machine operated, which, once started, have the capacity of self-guidance by virtue of the lead of the threads, and the use of three or more cutters in the circle.

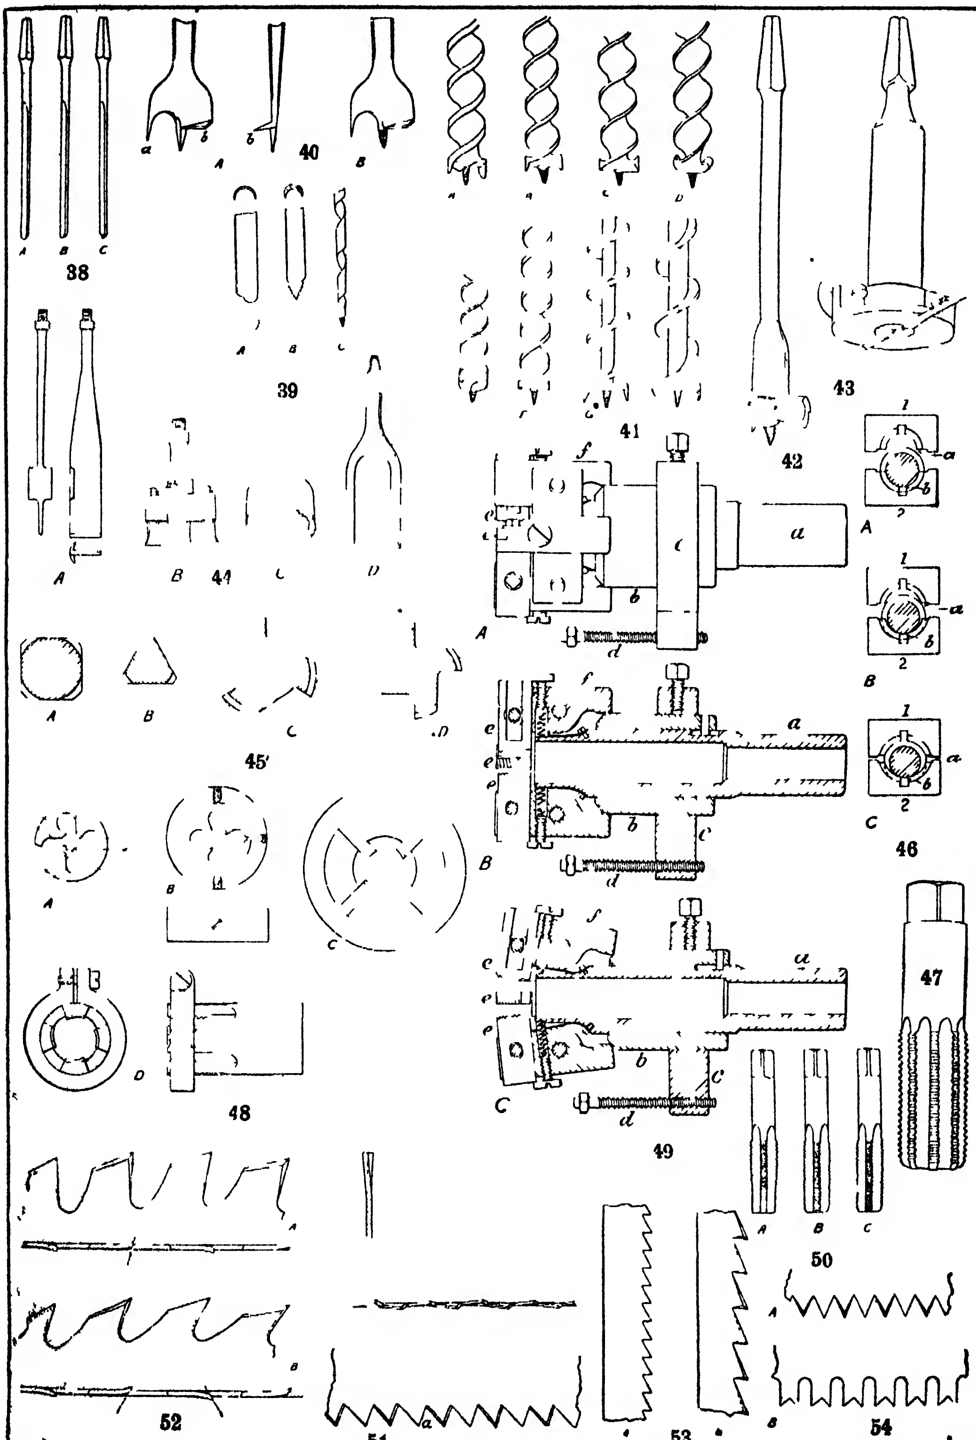
Of the first-named group little need be said. The methods of screw cutting in the lathe have been touched on in a previous article. With regard to the tools, they simply have the section of the thread, vee or square in plan, generally without top rake, acting, therefore, as scrapes. In square tools for square threaded screws, care has to be taken to give sufficient clearance at the leading edge, the amount of which depends on the slope or angle of the screw thread. The second group includes the common taps and dies, in which there are several important points to be noticed; and then the machine dies, which constitute a very large number, most of which are automatic in their action.

Taps and Dies. In their most elementary form these are simply screws adapted as cutting instruments. They have undergone a gradual process of evolution from forms in which friction and squeezing action were more in evidence as cutting, to present-day types, in which friction is of the slightest. In the old ones the screw threads occupied by far the largest portion of the circumference of the tap or die; in the modern types, the spaces predominate.

If we look at the tap and die in elementary forms, used still in small taps and screw plates, we see that a screw, external or internal, is made into a tool for reproducing other screws by cutting grooves down depthwise, the edges of which grooves act either by scraping, or by cutting.

Tap Sections. In the very smallest taps considerations of strength prevent them from being deeply fluted like those of larger size. Small taps—that is, those which are used with screw plates—are often of the sections in 45, A and B, in this respect resembling the flat-faced reamers, and coming, therefore, properly under the head of scraping tools. All taps were formerly of these sections. But taps of over about $\frac{3}{16}$ in., and even smaller in the best makes, are fluted, as at C or D, the front of the cutting edges pointing radially to the centre of the tap. Either three or four flutes are made, four being generally favoured, on account of the better guidance. A slight amount of clearance or relief is imparted to the back of the teeth by backing off the threads, C, D, in a similar manner to that described in connection with backed-off milling cutters. Formerly taps were relieved by tapering the entire thread down the length of the tap, but such is bad practice, and is never followed now, because the tap loses thereby its proper guidance. But backing-off can never be very pronounced because of the weakening effect of each on the cutting edges; hence the friction of tapping is severe. In the best taps there is seldom any front rake. But good results are secured by lessening the segments of the thread, either by increasing the number of grooves, or by giving them greater spacing, which applies to both taps and dies. Though the incisive action is not increased directly, it is indirectly, by lessening the amount of screw thread which is buried in the work, and thus lessening friction. Simple though these principles are, yet on the due balancing of the relations of these elements in die construction, and in a lesser degree in taps, depends a difference of perhaps 200 or 300 per cent. in rapidity of output.

Die Sections. In the dies the typical form is not so apparent. The cutting face is formed by grinding the leading edges, either parallel with the face of the die, or radial [46]. But it is obvious, on a moment's consideration, that the cutting action of either one of the edges or corners is of a variable character, because of the varying diameter of the thread which is being cut, and the unalterable size of the dies. Dies are cut over hobs [47], which are either one or two threads larger in diameter than the screws which they have to cut, and as the thread to be cut has two diameters, one at the bottom and the other at the top of the thread, true coincidence between thread and dies can take place only in one position.



TOOLS FOR BORING, SCREWING AND SAWING

38. Woodworkers' bits, of shell and allied types 39. Nose and gimlet types 40. Common centre bits 41. Balanced augers and auger bits 42. Expanding centre bit 43. Hollow auger 44. Well-sinkers' tools 45. Sections of taps 46. The action of screwing dies 47. Master tap 48. Spring dies and chasers 49 Opening die head 50 A set of taps 51. Handsaw teeth 52. Circular saw teeth 53. Band or frame saw teeth 54. Cross-cut saw teeth

The action of the dies is seen clearly in 46, where 1 shows the position of the die when commencing to cut the thread, and 2 its position when the thread is finished, so that the cut is commenced with the corners *a*. Then as the thread deepens they are thrown off, and a squeezing action occurs between *a* and *b*, and afterwards the corners *a* quite cease to cut, and all the work is therefore thrown upon the internal corners *b*. The only angle of clearance then is that slight amount which is present when the surface of the thread being cut is not in exact coincidence with the surface of the die—that is, at the periods when the corners *a* or *b* are actually cutting. Also, the slight alteration in the angle of the thread, which is continually taking place as the diameter of the screw is being reduced, throws extra work on the dies, causing excess of friction. It is thus apparent that dies are not good cutting tools. Chasers are superior as cutting tools, because they have the proper angles readily imparted to them.

Out of this action arises the question of the best curvature to impart to dies. As these are cut by a hob or master tap [47], their curvature is obviously that of the tap, and unalterable. In 46, A shows a practically impossible form in hand dies of the style shown, cut over a hob of the same diameter as the thread to be produced. Obviously, though these would cut at the start, 1, at the finish, 2, the cutting action would have ceased. But in those shown at B, made over a hob one thread deeper than the thread to be cut, they are still operative at 2 when the thread is down to size, for the edge *b* still has relief, due to the difference in curvature of the thread and the die. At C, dies cut over a hob two threads deeper than the screw to be cut do not cut well at first, but when the thread is finished they are fully operative.

Now, though these are, and have long been, the standard design used in England for hand dies, they are not the best possible. American dies have wider spaces, and smaller arcs in operation Fig. 48 illustrates a few.

American Dies. The feature in these is that they are solid, and do not therefore permit of being closed inwards at intervals as the thread is cut, like the dies just illustrated. One run over is sufficient to cut the screw, and there is far less of the squeezing action which causes the ordinary dies to work so hard. The appearance of a solid die in plan is shown in 47, A. The cutting faces have a slight amount of front rake, and the dotted lines indicate the relative angles of the faces behind the thread, which slope away in a direction that gives strength to the die. The threads are backed off to give clearance similarly to taps. Although these are solid dies, provision is introduced for varying the diameter of the screw cut, either to compensate for wear of the die, or to effect differences in the fit of screws in their holes, tight or easy, as desired. A common method is that at B, where the die is split at one side, and being placed within a ring or *collet*, is expanded by screwing in the pointed screw at the side, or contracted by the two screws at right angles; the elasticity of the die being sufficient to allow of a small amount of springing. There are many other devices for producing the same effect, being chiefly tapered or pointed screws. The outer collet is held in the die stock, or, in the case of lathes and screw machines, in a circular body.

In some dies, especially those of the larger sizes, steel is saved, and convenience of grinding secured by fastening flat pieces, or *chasers*, in a body, C, provision being made for easy removal, and for adjustments to and from the centre. Another class of die, D, used on some machines, has four or more cutting portions and is encircled by a clamp ring, so that the die may be closed in or allowed to expand in order to thread to very fine limits. Sharpening is easily done by means of a grinding wheel passing down the flat faces in the gaps.

Machine Dies. The dies for use in machines are much more elaborated than the taps. There are some dozens of different designs of these *die-heads*, as they are termed. But they nearly all have the property of adjustment, or *sizing*, to compensate for wear, and to work to minute limits of tolerance. Hence the mechanism in some is highly elaborated. In the simpler forms, used largely in screw machines and turret lathes, a spring action is embodied, the dies being split as in 48, and encircled by a ring or collar by which they can be closed to a minute amount from time to time. In others, the closing in or opening out is effected in a way which is regulated by graduations, so that the diameter of the thread can be read on the edge or face of the holder. In more advanced designs provision is made for the automatic opening of the dies when a thread has been cut, in order to avoid the reversal and running back of the die off the thread. These are *self opening dies* a numerous group. In all, the flat chasers are used, of the style C in 48. All these make an interesting and wide study in themselves.

Opening Die-heads. In the opening die-heads mechanism is included by which the chasers, usually four in number, may be suddenly drawn back from the thread, so that the head can be withdrawn by the turret in which it is held. This movement of the chasers is either a direct radial one, the chaser holders sliding in grooves, or a pivoting action is given, an example being shown here. A stop piece is provided, which is struck sometimes by the end of the work, sometimes by a part of the machine, to cause the chasers to fly open, under the pressure of a spring When another thread has to be cut they are closed in again by hand, or automatically, and the cycle is repeated. Previous to the introduction of these time-saving die-heads, the direction of rotation of work in the screw machines had to be reversed, so that the head ran itself off the thread.

The Tucker die, made by the Pratt & Whitney Company, may be taken as an instance of the pivoting type [49]. In the three views, A shows the outside elevation and B a section with the chasers closed in, while C indicates the appearance when opened off the thread; *a* is the shank, held in the turret hole, and carrying a sleeve, *b*, which has a limited amount of sliding motion.

A ring, *c*, is fixed in any position on *b* by a set screw, and a long screw, *d*, in *c* projects out more or less as required, so that it may be struck by a portion of the machine when the turret has travelled up to the required distance. The result of striking *d* is that *c* is slid back, carrying with it *b*, which causes the dies to open, in the following manner. The chasers, *e*, are clamped with square-headed set screws, and adjusted with slotted head screws endwise in holders, *f*; the latter are pivoted in a ring, and coiled springs are inserted in the holes below the slotted screws which adjust the chasers. The flat springs shown in black on the end of the body, *a*, serve to keep out dirt and cuttings. It will be seen that as long as the sleeve, *b*, remains in the position shown at A and B, the dies are closed, ready for work; but when the thread is finished, and the screw *d* struck, *b* is slid back and its bevelled end allows the ends of the chaser holders, *f*, to slip down, the coiled springs mentioned causing the tilting action, the result being that shown at C. Reclosing is effected by sliding the ring, *c*, and sleeve, *b*, back again to the position at A.

Kinds of Taps. Leaving the sectional forms of taps and dies, we note the longitudinal shapes of taps [**50**]. In taps operated by hand, two separate ones are required to cut a thread, and in some cases three. First, as the tap must enter a hole of the same diameter as the bottom of the thread, the lower portion of the tap is ground away to that diameter, thence tapering upwards until only about five complete threads are left at the top. This is the *entering* or *taper* tap [**50**], A. The next, or *middle tap*, B, has all its threads full, save four or five at the bottom, and this completes the thread, provided the hole is a *thoroughfare one*, so that the tap can run right through it by four or five threads. But if a hole terminates in a blank end the *bottoming* or *plug* tap has to finish. This has full threads to the end, C. The illustrations are those of American taps, in which the same proportions exist as in dies—namely, narrow cutting arcs and wide spaces. English made ones have about twice the width of threads. Machine taps are longer than hand taps, often very long, and they are gripped differently. When very exact dimensions are required, expanding taps are sometimes employed, in which the cutters are capable of radial adjustment, similarly to those of the reamers.

Saws. Saws include both scraping and cutting tools, whether we regard the action of individual teeth or their total action. It is seldom that the angle of front rake is less than 90 deg.—it is usually more, the teeth leaning back, in most saws, until we arrive at the equilateral triangular form of the cross-cut and hack, or metal-cutting saws. Hence the material is removed as dust, except in the case of very wet stuff, when it becomes somewhat stringy, but never approaches to the character of a shaving. Yet, viewed in one aspect, most saw teeth have a formation which causes their action to approximate to that of true cutting tools. All saws, except those used for metal, are sharpened at a bevel, by which friction is diminished, the saw cutting sweetly and attacking the material in an oblique line, with a resulting shearing operation. Thus, in **51** and **52** bevelled lines represent the direction in which the file is held when sharpening the tooth faces, so that the tooth face meets the material like the iron of a skew-mouthed rebate plane, or like a turning chisel. Though the tooth is so thin, this bevelling exercises a very marked influence on the sweetness of the action of the saw teeth.

Forms of Saw Teeth. There are various practical considerations which govern the sizes and forms of saw teeth. The main requisite to be fulfilled is that the teeth shall operate as freely as possible. As a general summary, we may say that the harder the material the greater the backward slope of the faces of the teeth; in technical language, the less *rake* present, and the finer the *pitch* or distance between teeth, relatively to the size of the saw, the less the *set*, or amount by which the teeth are bent to right and left of the plane of the blade.

Teeth, when cutting through wet wood, must have more set than those working in dry stuff, because the material removed is more apt to clog and hinder the saw's action, and they require larger pitch, which means more *spacing* in order to allow freedom for the dust to get away without choking.

The Set of Saws. In many saws, especially for metal, the set is imparted by a thinning back of the blade behind the teeth. Fig. **51** may be termed the hand saw type of tooth, varied in the slope of front and back rake, and in sizes of teeth. It will rip, or cross-cut hard or soft wood, but is more suitable for the first kind than the second. For soft wood only, the front, *a*, of the teeth, should be nearer the upright position, and the backs might have more slope. The set seen in the plan [**51**] is slightly exaggerated, being suitable only for use in cross-cutting soft woods. For ripping hard or soft woods its amount should be considerably less.

Fig. **52** illustrates the teeth of circular saws for hard and soft woods. The teeth of A have little rake, those of B have. A has less set than B, and its sharpening angle is less, as indicated by the dotted lines. Note the large size of the *gullets*, which are necessary to permit free escape of the sawdust. Rapidly running saws, like circulars, require more space than the hand, or pit saws, or even the frame saws.

Fig. **53** shows the blade saws, used as band saws and frame saws. A would be suitable for hard woods, B for soft. Fig. **54** illustrates two types of cross-cut, the triangular toothed A, and the M-toothed B, variations in which occur. They scrape only, and operate equally well in both directions.

Saws are either *rectilinear* or *continuous*. To the first class belong the hand, tenon, bow, fret, compass, cross-cut, and kindred kinds. To the latter the band, circular, and cylindrical forms, all of which are too familiar to call for any observations or illustrations.

ACCORDION, FLAGEOLET, & CONCERTINA

Construction and Peculiarities of the Instruments. Attitude of Player. Fingerboard Scales. Positions. Exercises

By ALGERNON ROSE

ACCORDION

The accordion or melodeon may be regarded as a large edition of the mouth organ, its sounds being obtained much in the same way. It consists of a pair of oblong shaped hand bellows with seven or more folds. To the right side of the instrument is affixed a number of levers arranged in rows. Sometimes these keys are like the stops of a concertina. According to the make of the instrument, so there are 8, 10, 12, or 21 keys. Besides these, there are three larger valves, known as the wind, accompaniment, and bass stops. In the largest variety there are 21 keys in two rows. The upper series gives an irregular scale of G major [Ex. 1].

An inverted V over a note implies that the bellows have to be drawn out. Notes without such a mark are obtained by pressing in the bellows. The lower series gives the scale of C major [Ex. 2].

Each key or lever sounds two notes. The first is produced when the bellows are pushed in and the second when they are pulled out. The reason for this is that as each key is pressed a valve inside the hand board is opened. Within the opening are two little tongues of metal, one bent forward and the other backward. According to the small or large size of the tongues so is the pitch of the sound produced high or low. When a valve is opened and the air is compressed it causes one of these tongues, or reeds, to vibrate quickly, and its motion magnified by a sound-board, causes the musical tone. Then, when the bellows are expanded, the other little tongue is made to vibrate by the opposite current of air. Thus the second sound is produced.

The best way of playing the accordion is to rest it upon the knee. By making a pivot of the knee a pushed bass note and a pulled melody note may be sounded at the same time. Pass the right thumb through the loop provided for it. This leaves the other right fingers free to press the keys. Put the left hand on the other side; its chief duty is to work the bellows. According to the force used in pressing or drawing out the latter, so is the intensity of the tone regulated. It requires considerable skill to make a good crescendo or diminuendo. An overblown accordion sounds at its worst, whereas when played with even softness it is often heard at its best. Place the second and third left fingers through the strap; the left thumb can then press the wind stop. The bass valve is worked by the left little finger. It gives two deep notes, C  when the bellows are pressed in, and G below the C  when they are drawn out. The first left finger is used for the accompaniment stop.

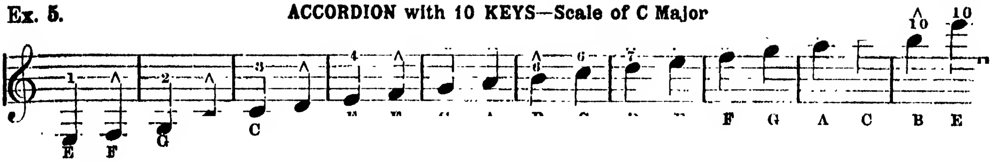
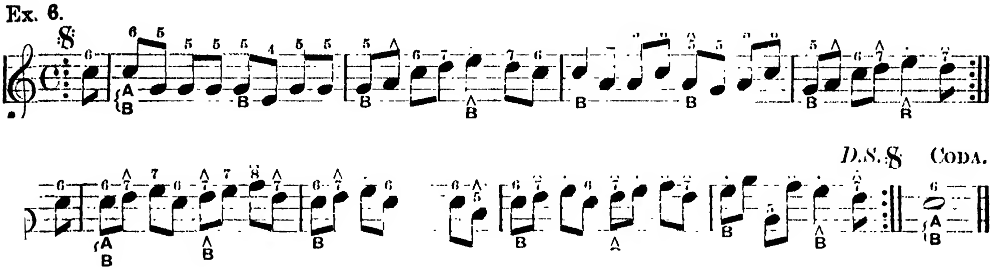
Ex. 5. ACCORDION with 10 KEYS—Scale of C Major



Ex. 6.



This gives the chord of the sub-dominant of G when the bellows are pushed in  and the chord of the tonic of G when hey are pulled out , a couple of chords such as an organist in church usually employs for the "Amen."

The student who wishes to make the most of this instrument should peruse the course on Harmony [page 37], in order to avoid sounding the accompaniment and bass stops with wrong notes of the melody, as is done by unmusical street players. Nevertheless, the best of these instruments, when performed upon skilfully, are not without a certain artistic value. As an incentive for the non-musician to prepare himself to learn the English concertina, the accordion has been, and is, undoubtedly helpful.

Before beginning to play, press the wind stop. This inflates the bellows. If they are already full, and a "drawn-out" note has to be sounded, press the stop to let some of the air escape. The bellows can then be further drawn out and the necessary notes obtained.

Having given the notes for the accordion with 21 keys, for the sake of reference we tabulate the scale of the smallest variety, that with 8 keys [Ex. 3].

The scale of the accordion with 12 keys is given in Ex. 4.

But the most popular style of accordion at present sold is the instrument with 10 keys. We have therefore reserved the fingering of its compass [Ex. 5] to the last.

B means bass stop, A accompaniment stop; if both letters occur together, both stops must be used at the same time.

As an exercise, in conclusion, the student who has followed these instructions carefully may practise with profit the quaint old country melody which is given in Ex. 6. Strict attention must, however, be paid to time.

FLAGEOLET

The English instrument has six finger-holes. From these three octaves and a half, with all the intermediate semitones, can be produced, if the student only knows how.

The cheap flageolet can be bought in various sizes. They are all fingered alike, but the longer the tube the deeper the tone. Get the most usual size, marked "D." Its lowest note should be in tune with the D below treble staff.

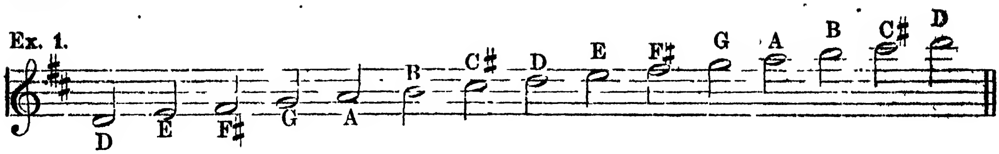
Cause of the Tone. Everybody is familiar with the tin whistle, but few understand that the whistle, in itself, has no sound. The plug of wood filling up most of the tube forming the mouthpiece serves to shape the breath into a thin flat sheet. This air strikes against the sharp lip, slightly bent in, of the aperture, the result being that the sudden contact brings about those pulsations or vibrations, which produce the musical tone. Do not play the top notes with the right hand. The left hand must finger those nearest the mouthpiece, and the right hand the three lower notes.

Place the left thumb behind the upper half of the tube and let the right thumb steady the lower half. Keeping the fingers off the holes, blow gently. This (in a "D" tube) sounds C♯, nearly an octave above the lowest D. Put down the first finger of the left hand. Blowing as before, the sound will be B, third line treble clef. Depress the second left finger to get A; the third left finger for G below; the first right finger for F♯ (in the key of D major); the second right finger for E; and the third right finger for D. All the holes are now covered.

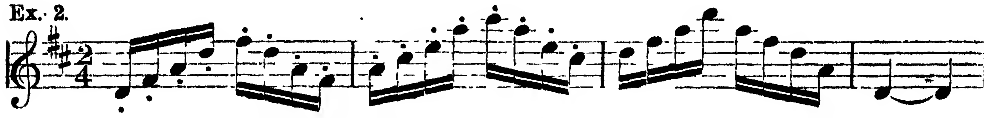
Natural Notes. Now tackle the scale of D major, uncovering the holes successively and sounding the notes softly as the scale is ascended. [Ex. 1.]

After reversing the order of the six notes first played, to get the octave D above the lowest note, put down all the fingers excepting the first of the left hand. Blowing with somewhat more force, take off the third right finger as the first left finger is put down, the octave above the previous E sounded will be heard. To get F♯, G, A, and B, uncover the notes exactly as before,

Ex. 1.



Ex. 2.



but increasing the pressure of the breath. The reason for this increased pressure is that the air-motion inside the tube needed for a note of high pitch must be quicker than that for one of low pitch. For the lowest note, the breath must cause, as in the case of a string, the whole tube to pulsate in one large segment [see VIOLIN, page 2511]. By increasing the rapidity of the air, this segment splits itself up into two, and the same effect is obtained from a tube as from sounding only half the length of a string. For the octave above the C♯ sounded when all the holes were free, put down the second and third left fingers and the first right finger.

To get the next note, D, two octaves above the lowest sound, lift the first right finger. For the E above, open the two centre holes, but put down

Ex. 3.

the first and second left, and second and third right fingers. To get the F♯, two octaves above the first F♯, put down the first and second left fingers and the first and second right fingers. For the G, two octaves above the first G; depress the first, second and third fingers and blow hard. Lastly, to obtain the highest note the instrument gives, cover the four centre holes, leaving top and bottom holes open. Thus, the ordinary flageolet easily sounds nineteen notes. The beginner whose ear is musical will soon learn them, especially if he gets the sound he wants well into his mind by referring to a piano or harmonium. These are called the natural notes of the instrument, and suffice for the playing of ordinary tunes. If in earnest, the student may learn much on the tin whistle, which will be helpful, should he desire, later on, to take up the fife or flute. After memorising the notes given, he will soon be able to play by ear "God Save the King," "Home Sweet Home," and other familiar melodies. Rather than wasting his leisure in such a way, we would point out the desirability of practising daily, in correct time, exercises which will familiarise him with the fingering of the instrument, because, without such training, he can never hope to excel. [Ex. 2.]

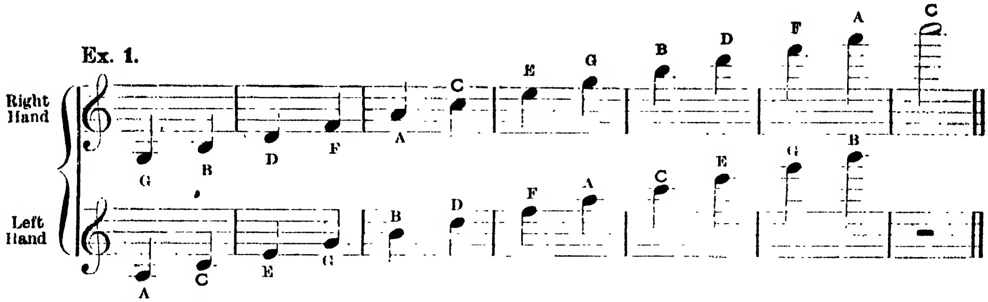
In this exercise each note must be played distinctly and with a separate breath. Do not hurry. The main point is to play slowly and steadily in correct time. Make each sound last during so many ticks of a clock. Increase the speed gradually by diminishing the number of ticks, but avoid playing three or four notes quickly, then pausing to find out the next, and then making another rush. Next try playing several notes with one breath, so that they appear to be linked together by a slur. [Ex. 3.]

Chromatic Scale. We now come to a greater difficulty, which ordinary players imagine is impossible of accomplishment on a flageolet without keys. It is to insert between the natural notes those sharps or flats necessary to enable the player to run up or down the scale by a series of semitones. This is done partly by difference in fingering and partly by the graduated force of the breath. If mastered, it enables the student to play in almost any key, and invests his instrument with musical attributes unknown to ordinary players. The student should, therefore, not rest content until he has made himself thoroughly familiar with this fresh complication. Sound the low D as before, with the six holes covered. To get D♯, blow a little more strongly. "Will" to get the half-tone above. The sound wanted will come. Take off the third finger for E. To get F♮, half a tone above, lift the second right finger, blowing softly. As the instrument is in D, and D major has two sharps, F and C, the next natural note will be F♯. Play that as before, by taking off the second and third right fingers. Sound the G as before by taking off the first right finger. For G♯, take off the third left finger, as for A, but put down the first, second, and third right fingers, blowing softly. Sound the A by removing the three right fingers.

To get A♯, take off the second left finger as for B, covering all the other holes. Sound B. To obtain C♮, take off the first left finger as for C♯, but put down the second left and the first and second right fingers. Play C♯ as before, with all the holes open, and D, an octave above the lowest sound, by closing all the vents, excepting the top one. To get D♯, do precisely as for the previous D♯. Make E, F, F♯ and G as before, altering the pitch by increased pressure of the breath. To get the G♯ an octave above that first sounded, finger as for A, with the first and second right digits down; close the fourth hole with the first right finger. Sound the A as before.

For the A♯, an octave above the first A♯, finger as for B, with the first right finger down; but put down also the third right finger. To get C♮, an octave above the first C♮, finger as for C♯, with the second and third left fingers and first right finger down, but depress also the second right finger. Then take off the

Ex. 1.



latter for the C♯. Take off the first right finger for the D. To get D♯, put down the second and third right fingers, as for E, also the second and third left fingers. Then lower the first and second left fingers as before for the E. To obtain the F♯ two octaves above the first F♯, put down the first and second left and first and second right fingers, and blow hard. Sound top G as before, with the first, second, and third left fingers.

For G♯, two octaves higher than the first G♯, when all the notes were closed except the third, reverse the process by leaving all open except that hole. Lastly, sound top A as before.

Exercises. Facility in playing chromatically cannot be gained all at once. But as the rules controlling the production from a simple pipe of the different sounds enumerated are governed by acoustical laws, they apply not alone to the flageolet, but to other tubular instruments proportioned in the same way. The sooner, therefore, the student familiarises himself with them the better, although later, the necessary sharps or flats may be obtained more conveniently by keys.

CONCERTINA

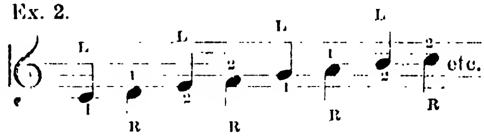
The musical student who has an opportunity of becoming the possessor of an English concertina may rest assured that it is well worthy of serious attention. It is no mere toy, as is too often supposed. Not only has the concertina great purity of tone, but it is capable of remarkable rapidity of execution, whether in single or double notes. Moreover, the simplicity of its fingering and power of crescendo and diminuendo are most effective. The English concertina, being furnished with a double action, produces the same note both on drawing out and pressing in the bellows.

Not only is it capable of being played in any key, but in some ways it is superior to the pianoforte, owing to its power of sustaining and modulating the tone, its portability making it possible to be carried from place to place, and its smaller cost which places it within the reach of more pockets. Without difficulty the executant can negotiate intervals of thirds, sixths, octaves, tenths, and extended harmonies. At the same time it is capable of performing music written for the flute, hautboy, etc.

A Minor Derangement. The only trouble this instrument is likely to give a player is when a note sometimes goes dumb. This is usually caused by a particle of dust getting between the frame and the vibrator. Loosen the six screws in the plate of the side which needs attention sufficiently to allow the action to be removed. Take out the action. The note will be easily discovered, as its name is stamped on the top of the frame. Displace the reed by drawing it from the groove. Hold it up to the light. The dust which interferes with the sound will be visible. Remove this with a penknife. In replacing the parts, note that R and L stand respectively for the right and left hand. These letters must correspond with the R and L and number on the top of the pan to ensure correct adjustment. Observe the same figures in replacing the action.

The complete concertina family consists of four instruments. First, we have the soprano, used

Ex. 2.



for solo work, with a compass of three and a half octaves from fiddle G, two ledger lines below treble staff. The tenor, bass and double-bass concertinas extend the compass downwards, so as to make altogether six and a half octaves.

Attitude. The concertina may be played either sitting or standing. To diminish the weight on the thumbs, especially with the larger patterns, a ribbon is secured to the middle buttons and carried round the neck. Be careful, when the instrument is played sitting, that the folds of the bellows do not rub against the clothes or dress. Place the left-hand side of the instrument on the left knee. Each thumb must be passed as far as the first joint into the loop provided for it. If this is too tight, or too slack, regulate it by screwing or unscrewing the metal button. Place the fourth finger lightly in the finger rest. It should stop there except when, by moving it, the hand can assume an easier position while playing. Do not draw out or press in the bellows unless a key is touched. The pressing in and drawing out is done with the right hand. Force of sound depends on the degree of pressure or pulling applied.

The beginner should practise his exercises at first with the least degree of force. It saves the wear of the instrument, and makes it almost inaudible in another room. To facilitate the pressing in or drawing out, rest the fleshy part

of the hand against the instrument. The attitude of the player should be natural. Keep the position of the arms easy. Never overforce the bellows. This produces a discordant sound, and is sometimes injurious to the instrument. Draw out and press in steadily, in a straight line. Do not turn or twist the instrument. Cultivate a habit of pulling out to the full extent, and then pressing in without break in the sound. Do not change the direction of blowing in the middle of a phrase. Exactly as the lungs act when singing, so let the instrument take a fresh breath before and after a passage. Utilise any rest which occurs for such inflation. Remember that lower notes require more reserve force than upper ones.

Fingerboard. The system of fingering and position of the notes on the English concertina make it distinct from any other musical instrument, and give certain peculiarly artistic attributes. On either face there are four parallel rows of stops. The two centre rows are akin to the white keys, or naturals, on a piano, the outer, or first and fourth black rows, furnishing the sharps or flats. The C's, to distinguish them from the other notes, are coloured red, an idea probably borrowed from the harp. The treble concertina usually has 48 keys, comprising 25 naturals and 23 accidentals. Now, when the thumbs are in the loops, the first finger negotiates the whole of the second column of keys, that digit being moved to the first row when required. The second finger negotiates the third row, and the third finger the fourth row. The place of the little finger is, as has been mentioned, on its rest, except when it is used to simplify execution. When sounding passages of sixths, octaves, and tenths in sharp or flat keys, it is of particular service. Finger pressure must be elastic and delicate, but firm. Do not thump the studs. Let the finger tips glide from one note to another.

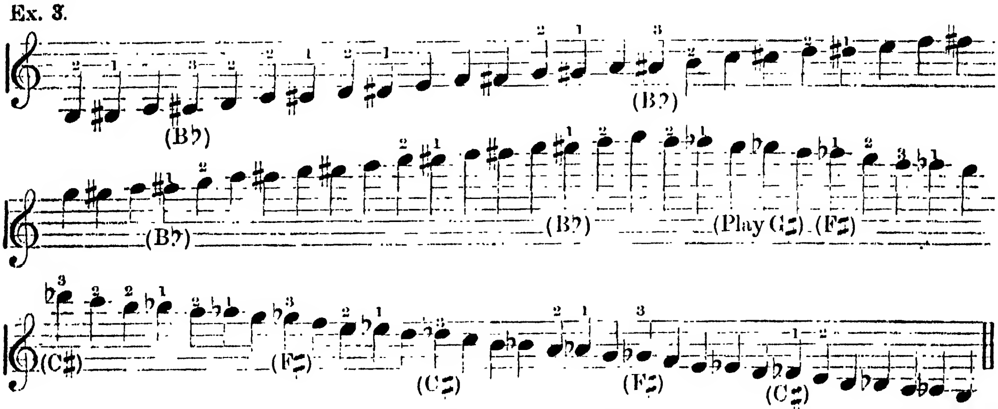
For staccato playing, however, raise the finger slightly above the note, so that it may be struck sharply, and immediately released. In passages which are slurred, each note must be held down until the next finger is ready, that there may be no break between one sound and another.

Scales. Take Ex. 1. Here we give two staves. The top staff shows only notes which are on the spaces, whilst the bottom staff only those notes which are on the lines.

Thus G is the lowest of the second column on the right hand, and A the lowest note negotiated by the second finger of the left hand. B is the lowest played by the second right finger; C, the lowest played by the first left finger; and so on, zigzagging from key to key. To run up a scale, therefore, the hands are used alternately, whereas, on a harmonium, one hand has to do the work alone. The difference in fingering thus between the two instruments is capable of producing quite different effects. Play the natural key of C [Ex. 2].

Chromatic Scale. The chromatic scale is important and needs daily repetition. Be careful to press each note equally, so as to obtain evenness of tone. Practise slowly. The student should observe that the concertina, unlike the piano, has separate notes for G♯ and A♭, and for D♯ and E♭. These are not tuned in unequal temperament, but are added in order to simplify the fingering. Therefore, when D♯ or G♯ is required, play the note next to D♮ or G♮. When A♭ or E♭ is needed, press that next to A♮ or E♮. [Ex. 3.]

Ex. 3.



Although, as a general rule, each column of keys is manipulated by the same finger, certain effects are facilitated by repeating the same notes with different fingers. In such a case, keep the two fingers used for the change close together to avoid unnecessary movements.

If artistically produced, the *tremolo* effect closely resembles the human voice. It should be done by making the finger quiver over the note itself, and not by shaking the bellows.

If the student forgets the place of any note, looking at the instrument itself is a bad habit. When the thumb is placed in a loop and the little finger in its rest, the second finger of the right hand should drop upon the red note, C. and the second finger of the left hand upon B. Those two notes are useful guides to the beginner in finding the others, but the best way of impressing their position on the memory is for the student to make a diagram of the four columns of keys for each hand, adding to them the names of the notes. If he has this diagram before him, he will see at once the position of any key.

Accordion, Flageolet, and Concertina concluded

PRINCIPLES OF CHEESEMAKING

Necessity for Rich Milk and Pure Water. British and Foreign Cheeses. Processes Used in Making Cheese. Rennet. The Uses of Bacteria

DAIRY FARMING
continued from page 4281

By Professor JAMES LONG

ALTHOUGH our forefathers are often credited with great skill in the production of fine cheese, we may take it for granted that, except perhaps in occasional instances, nothing was produced in the past which can compare in quality with the finest cheese that is made to-day. This fact is owing to the formulation and comprehension of principles. The reasons for the various operations are now known, and the maker is therefore placed in a position of control which enables him to conduct his work with much greater success and certainty. The object of the cheesemaker is to obtain a maximum quantity of cheese of high quality from a given quantity of milk; but he cannot accomplish this, however extensive his practice, without recognising the principles involved. The production of good cheese depends upon the soil upon which the cattle feed, upon the quality of the milk, and the skill of the maker, especially in his control of temperature and acidity. Cows fed on soil rich in lime usually produce milk which contains a larger percentage of lime than is common in milk produced on other soils, for which reason the acidity of the milk is slightly delayed, while a variation in the temperature, of the quantity of rennet employed, and the work of manipulation are often necessary. Difficulties which arise owing to the richness or poorness of milk in mineral matter and fat are easily removed by those who have mastered the principles involved, but they present striking obstacles to those who have not.

The Value of Rich Milk. To obtain fine cheese it is essential that the milk should be rich, a fact which has long been disputed, while quality also increases the yield. In the first place, then, rich milk produces a mellower cheese, for the reason that it contains more fat; while next it adds considerably to the weight produced per gallon, for not only does an increased quantity of fat tell, but with that increase, as we shall see later, there is also an increased appropriation of the casein and of the water employed. It has been estimated on the basis of exhaustive experiments that for each pound of fat present in milk the yield of cheese is increased to the extent of 2·7 lb. At the great American trials at Chicago, which were attended by the writer, the Jersey herd produced in one month cheese which was worth £11 more than that produced by a similar number of Shorthorns, although the latter breed is in England regarded as the best type of cow for cheese production.

Pure Water. It is important that in the cheese dairy the water employed should be of the purest, and that the food supplied to the cattle, whether on the pasture or in the stall, should be absolutely free from anything likely to convey an undesirable flavour or odour to the milk. The cheese plant or equipment should be of the best modern construction, intended to facilitate the work and to prevent as little trouble and difficulty in cleaning as possible. On these points the intending cheesemaker may obtain many hints by paying a visit to the British Dairy Institute at Reading, the Midland Institute near Derby, or the Scottish Institute at Kilmarnock.

Varieties. The principal varieties of cheese are set out in the table on the following page. Among minor varieties not referred to in the table are the Cotherstone (blue veined), the Slipcote (soft curd), the York (soft curd), the Caerphilly, the Dunlop cheese of Scotland, the Yorkshire cheese known as Liberton, the Wilts loaf cheese of Cheddar type, the blue skimmed milk cheese of Dorset, and a variety of local curd cheeses which include the New Forest and the Colwick. In France there are many varieties, apart from those mentioned, including the Coulommiers, which resembles the Camembert, the Mont d'Or, the Geromé, all of which are soft varieties; and the Livarot, a strong-smelling soft cheese made from skimmed milk. Germany, Denmark, Sweden, and other European countries, like America, have no special varieties of either pressed, blue, or soft cheese which are recognised upon the great markets of the world.

The Action of Rennet. In beginning the process of cheese manufacture, it is essential first to coagulate the milk. In some cases the evening's milk is kept until the morning, when the morning's milk is added under conditions which will be subsequently referred to. The milk having been brought to the required temperature—usually in a jacketed vat—and its volume ascertained, the requisite quantity of rennet is measured, mixed with four times its volume of water, and stirred in the milk. Where the evening's milk is kept until the morning, a slight amount of acidity will have developed, unless the temperature be low. As acid possesses a power of coagulation, it assists the rennet, and allowance must therefore be made on this score. The action of the rennet largely depends upon heat, for the quantity of rennet required is in an inverse ratio to the temperature of the milk, while within undefined limits the time of coagulation is in an inverse ratio to the quantity of rennet used. Thus, theoretically speaking, if one part of rennet converts 10,000 parts of milk at 95° F. into curd in forty minutes, it would coagulate one-tenth the quantity of milk in one tenth of the time, the same temperature being

observed. But we have to deal with probabilities. Thus, the larger volume of milk would retain its heat more perfectly than the smaller volume, hence practice does not exactly correspond with theory.

Coagulation. Milk is set at various temperatures, in accordance with the variety of cheese to be made, a from 65° F. in small varieties made from a mixture of milk and cream, to 95° F., which is adopted in the manufacture of some of the pressed varieties. Rennet however, possesses very little activity below 65° F. The time occupied in the coagulation of milk, then, depends upon the temperature of the milk and the quantity of rennet employed. Thus, a small quantity of rennet prolongs the period, while a large quantity hastens it. These periods are further expanded in accordance with the temperature of the milk. In making firm or pressed cheese, forty minutes to two hours are usually occupied; but in making soft cheese, from two to fifty hours may be occupied. The higher the temperature, too, and the smaller the curd is cut, the more rapidly does it part with its whey; while the lower the temperature, and the larger the curd is cut, the more slowly it drains. Although drainage is promoted by cutting the curd fine in the hard cheeses, such as Cheddar, Cheshire, Dutch, and Gruyère, all are subsequently pressed for the removal of the surplus whey or serum. Blue-veined cheeses, like Stilton and Gorgonzola, however, are not pressed, while the delicate varieties of soft cheese, like Caerphilly and Port du Salut, are pressed but slightly.

Cutting the Curd. The true soft cheeses, whether ripened or fresh, as Brie, Camembert, or York, part with their surplus whey, by gravitation and evaporation; and here heat plays an important part, for unless the dairy employed be sufficiently warm the serum is held by the curd and the cheese spoiled; while if too warm the whey drains too freely, and the cheese becomes dry and inferior. The finer the curd is cut the larger the area of drainage. In the best varieties the curd is cut into cubes by the aid of two many-bladed knives, one horizontal, the other vertical. The whey is therefore induced to exude from each face of each cube, thus forming as it were by contraction a toughened coat, which largely prevents the remainder of the whey leaving the curd. When heated, however, as it usually is within the large volume of whey which has already collected, this whey is in large part removed, for heat assists the process of drainage. In making soft cheese, the tender curd is handled as little as possible; such cheese contains more moisture than pressed cheese, and care is thus taken to prevent its loss. The presence of more moisture in soft cheese means also the presence of more sugar, which is the chief cause of its more rapid fermentation. Where the temperature is too low, an excess of whey is retained in the curd, carbonic acid gas is formed, and the cheese swells and spoils. This especially applies to Stilton and other unpressed varieties.

The small cheesemaker often fails to produce high quality on account of the small volume of milk with which he has to deal. He is unable, unless very highly skilled, to maintain the heat necessary to perfect coagulation; nor is he often assisted by a perfect dairy apartment, the temperature of which he is able to control. In making cheese on a large scale, it should be possible to maintain a temperature of 65° F., while in a small dairy the average temperature should scarcely be less than 70° F.

Quantity of Rennet Required. Rich milk requires less rennet than poor milk, hence the importance of knowing the fat percentage. The quantity of rennet required and the time of coagulation vary with the temperature of the dairy, and therefore with the season and climate, which so largely control it. This, too, is the reason why more rennet is required in spring than in summer and autumn. It is essential that rennet should be carefully kept, that its strength may be maintained, and that the same variety should always be employed—a standard rennet being that in which one part coagulates 1,000 parts of milk in a given time at a given temperature. It should be

remembered, however, that as cows which have calved in spring fall off in their yield, their milk increases in quality, so that an alteration in the quantity of rennet employed may be necessary. Again, as lactic acid, which possesses the power of coagulation, forms more quickly in warm weather, there is a further influence which bears upon the quantity of rennet employed.

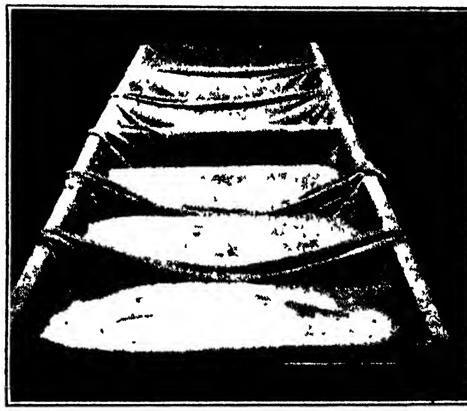
How and When to Remove Curd. In cutting or removing curd from the cheese-vat or tub, great care must be taken. It must not be cut too soon or too late, or roughly handled. If the tube of a glass thermometer be dipped in the curd, small particles will adhere if it is unfit; but if ready to cut and remove the tube will come out clean. If the curd has passed the proper period for cutting it will fracture, and whey will collect. As curd for pressed cheese is cut fine, as already remarked, that intended for unpressed and soft cheese, on the contrary, is removed in large layers or slices by the aid of hollow, plate-like metal skimmers. Dry curd, not the production of fine cutting, may be obtained, as in the manufacture of Stilton, by slightly longer coagulation and by the removal of large slices of curd at the right moment into cloths laid in suitable draining vessels [32], the cloths being subsequently tied from corner to corner, and tightened gently from time to time [33]. The temperature of the curd should exceed 70° F. If large pieces of curd are left after fine cutting, the presence of the whey within them will cause local fermentation, swelling, and damage.

Avoidance of Skimmed Milk. The employment of skimmed milk is fatal to both quality and quantity of cheese. In the manufacture of Cheddar, 1.13 lb. of fat should be present per lb. of casein; the proportion of fat, indeed, should never be below the proportion

33. METHOD OF TIGHTENING STRAINING-CLOTH
(From the Journal of the Royal Agricultural Society)

of casein. There is, too, a greater loss of fat in the making where skimmed milk is used at all. If cream be added to new milk, the loss of fat is diminished, while the weight of the cheese is increased by more than the weight of the increased solids added.

Source of Rennet. The rennet employed in cheese manufacture is an extract from the mucous membrane of the fourth stomach or "vell" of the milk-fed calf. No other material known to man can be employed for the same purpose in cheese production. Rennet is always reliable in action if pure and its strength main-



32. STRAINING-CLOTHS CONTAINING CURD
(From the Journal of the Royal Agricultural Society)

tained; it not only coagulates milk, but it helps to ripen the cheese, and unless it be imperfectly made, as we have seen it in Italy, where macerated pieces of the actual stomach of the calf are sometimes employed, it is never hurtful to cheese. Although occasionally made on the farm, rennet is now a standard product of commercial manufacture. It is sold in liquid, tablet, and powdered forms, the first named being the most simple and reliable; but its strength or quality varies in accordance with the make. The cheesemaker having selected a variety, should adhere to it, or he may spoil a batch of cheese. The coagulating power of rennet is affected by soda and other alkalis. Below 50° F. rennet produces no normal coagulation; between 100° F. and 108° F. its action is quickest, while from 108° F. to 122° F. the period of coagulation increases, partially losing its influence at the latter temperature. If we use too much rennet for a given quantity of milk, or adopt too high a temperature, the resulting cheese is tough; if we use too little, or adopt too low a temperature, the curd becomes too tender, the fat is lost, and the quality of the cheese diminished. The loss of fat is denoted by the whitish character of the whey, which should be clear and of a greenish tint.

Proportions of Rennet to be Used. It is important that rennet should be accurately measured, and either the ounce or the cubic centimetre (c.c.) may be employed. The latter is almost imperative in making soft cheese, but it is, under all circumstances, superior to the former. A measuring glass divided into hundredths should be used. There are 1,000 c.c. to a litre (10 litres = 2·2 gallons). If we take 1 c.c. of a standard rennet, therefore, and add it to a litre of milk at a temperature of 95° F., it will

coagulate in four minutes—assuming that the temperature is maintained constant; similarly, 10,000 c.c. (2·2 gallons) will coagulate in forty minutes. The principle involved in these figures should be especially recognised, but in all tests accuracy is impossible unless the temperature of the milk be controlled. If the time occupied in such a test be five minutes, instead of four minutes, it is proof that the rennet is not of a standard quality, but that 1 c.c. is capable of coagulating only 800 c.c. of milk; so that in practice if we employ it in our work we should require not 1 c.c. per thousand, but 1¼ c.c.

Value of Acidity. Acidity is imperative in cheesemaking, for upon it depends not only flavour, but mellow or salvy consistence. Acidity develops more freely in curd than in whey, but in practice it is whey that is tested. The proportion of acidity in the whey is now ascertained, and in the West of England experiments of Mr. Lloyd the best results were obtained when they contained ·22 per cent. of acid, as indicated by the particular method of testing which he employed. Excess of acid is fatal to quality in most varieties of cheese, but it is largely owing to deficiency that causes cheese made in spring to be inferior to that made later, for acidity is developed by heat.

In the manufacture of pressed cheese, like Cheddar or Cheshire, acid is developed by heating or "scalding" the curd and whey in the vat to a higher temperature. Where the curd is slowly formed, the acid present is larger in quantity; hence the excess of acid in tender curd which holds the whey longer than curd which is drier. In the manufacture of such a refined soft cheese as Camembert acidity is especially needed, as the moulds or fungi which are essential in the ripening process grow more freely upon the crust. As the moisture of this cheese evaporates during maturation, the *mycelium*—a network which is comparable to the tiny rootlets of a green or chlorophyll-containing plant—penetrates the curd and neutralises the acidity, with the result that the bacteria present are able to begin their work of decomposition, and the practical conversion of an insoluble to a soluble material. In curd which is drier than is necessary, there is less acidity because the sugar, the great medium through which it is produced, has largely escaped in the whey.

Scalding. The Cheddar manufacturer promotes the development of acidity by the addition of sour whey to the milk; but this plan is not essential during normal cheesemaking weather, or where the temperature of the dairy is under control. Acidity may be developed in the evening's milk, and this development may be assisted if necessary by scalding the mass in the process of manufacture. In spring, or on any occasion when the temperature is abnormally low, sour whey may be necessary, even though scalding be resorted to; but in all cases an allowance must be made for the increasing richness of the milk as the season advances.

The success of cheese manufacture largely depends upon cleanliness and the consequent prevention of the introduction into the milk of foreign or destructive bacteria, which are not only the cause of ill flavour and bad texture, but of abnormal decomposition and decay. This is particularly noticeable in the production of Stilton. In the manufacture of Camembert cheese, for example, it is practically proved that three varieties of bacteria are essential to success, while their activity and perfection of the cheese depend upon the presence of sufficient acidity.

Blue Mould. Again, there are many varieties of cheese, chiefly those which are pressed but slightly or not pressed at all, upon or within which the successful growth of fungi is necessary, and we may especially refer to Camembert, Brie, Coulommiers, and Neufchatel among soft cheeses, and to Stilton, Wensleydale, Gorgonzola, and Roquefort among blue-veined cheeses, in which the blue mould, *Penicillium glaucum*, plays a most important part. The spores or seeds of these parasitic plants are apparently present in the atmosphere of every milk-room, whether perfectly clean or the reverse. They find the curd of milk a suitable soil; but their successful culture depends upon moisture, air, and sufficiency of heat. They are practically excluded from growth in pressed cheese by the pressure which is exerted, while in cheese like Stilton, which is composed of pieces of unpressed curd, between which there is no real union, interstices are formed which leave room for the development of the spores. Varieties of soft cheese, such as those already mentioned, first develop a white, velvet-like fungus, which is followed by the blue, and in the Brie in particular by patches of a vermilion mould, believed to add to the piquancy of the flavour.

How Fat Affects the Weight. With reference to the influence of the solids of milk on cheese production, it should be pointed out that, as the result of experimental work of a most extensive character conducted at the stations in the States of New York and Wisconsin, it was found that with every increase of one pound of fat there was an increase of ·60 of casein and albumen and of one pound of water. When rich milk was employed, the percentage of solids extracted from the milk in the process of cheesemaking was larger than when it was poor in quality. The fat lost when the richest milk was used was ·17 per cent., while it reached ·49 per cent. when cheese was made from poor milk, the average being ·29 per cent., or 6¾ per cent. of the total fat. The quantity of casein and albumen lost under similar conditions was equal, on the average, to 23·3 per cent. of the total. On the basis of the work of one year, too, it was found that the green or unripe cheese produced per 100 lb. of milk was equivalent to the weight of the fat present in that milk multiplied by 2·75. Thus, if the milk contained 4 per cent. of fat, 100 lb., or 10 gallons of milk, produced eleven pounds of cheese, while where the milk contained 3½ per cent. of fat, which we may take as a fair average of the cows of our country, the cheese produced would reach 9·6lb.

EARTH AS THE HOME OF MAN

Distribution of Land and Water and its Effect. Climate and Temperature. Winds. Mountains and Rivers. Plains and Soils. Coasts and Tides

Following on POLITICAL GEOGRAPHY page 4290

By Dr. A. J. HERBERTSON, M.A., and F. D. HERBERTSON, B.A.

OUR survey of the world has brought out its great diversity. Few regions, if any, yield abundantly all that is required for the development of the highest civilisation. Commercial geography deals with the struggle of man to win subsistence in such a world. This he does partly by adapting himself to his environment, whether harsh or genial, and partly by attempting to modify that environment to suit his needs. One of his efforts in the latter direction is commerce, which seeks to equalise the distribution of useful commodities.

Two factors must be considered, the geographical and the human. The first deals with permanent geographical conditions, the distribution of sea and land, of heat, cold and moisture, which man can do little to modify. The second is concerned with man's increasing power of availing himself of the possibilities they offer.

The Land of the World. Only two-sevenths of the Earth's surface consists of land. Only two-sevenths, therefore, is fitted for the permanent home of man. The remaining five-sevenths consists of seas and oceans, at first a barrier, but often later a pathway to better conditions of existence.

The known lands of the world are about 52,000,000 sq. miles in area. Of this about twelve-thirteenths is grouped into two immense islands—the Old and New World. Australia accounts for nearly three-quarters of the remainder. By far the greater proportion of the land lies in the Northern Hemisphere. This results in a considerable extension from north to south, giving a complete series of climatic zones and consequently of economic products. It also brings the land portions of the world into closer proximity by contracting the breadth of the oceans between them.

The bulk of the land lies in temperate latitudes. With the exception of Greenland and a possible Antarctic continent, little land lies within the Polar circles. No part of the mainland of Europe reaches the tropics, and no part of the mainland of Asia reaches the equator, which crosses only two continents—Africa and South America. The dissection of tropical Asia into tapering peninsulas separated by wide seas, and the hollowing out of tropical America by the American Mediterranean, considerably reduces the area of the tropical lands.

The Influence of Climate. Of the factors affecting the distribution and development of the human race, climate is the most important. This is not because man is hypersensitive to extremes of heat and cold. On the contrary, he has a wider climatic range than any other living creature. The check operates indirectly through the great climatic sensitiveness of plants, on which both man and animals depend for subsistence.

Plants, which are fixed to the soil, have less power of adaptation than animals, which can move from place to place, and which, along with this mobility, and perhaps as a consequence of it, have developed great variability. Each family of plants is exacting in its demands. Tropical fruits, some of which for example, the banana —form the mainstay of large societies, require a high temperature to ripen them. Some, such as the coco-nut palm, prefer in addition proximity to the sea. The olive, a characteristic Mediterranean fruit, not only requires a rather hot summer, but cannot bear winter frosts. Hence it cannot be grown in Lombardy, where the summer temperature would suit it admirably. Maize needs a hotter summer than wheat, which in turn is less hardy than rye or barley. Not even the latter will ripen below a certain summer temperature, and within the Arctic circle the vegetable kingdom is represented chiefly by mosses and lichens. Still nearer the Pole even these disappear. Other plants require special conditions of moisture. Cereals are more sensitive to excess or defect of moisture than grasses, which thrive in regions too wet and too dry for the former. Rice, which needs swampy or flooded soil, suits hot damp climates, but cannot be grown in the hot dry climate which brings the date to perfection. Each group of economic plants therefore has a definite geographical range, a circumstance which influences not only the distribution of man, but even the type of civilisation within a given area.

Temperature: The Hot and Cold Lands. Temperature, one of the chief elements in climate, varies with distance from the equator and with distance from the sea-level —that is, with latitude and elevation.

The relation between latitude and climate has already been considered. [See page 293.] Here it is sufficient to recapitulate the main climatic divisions as determined by latitude.

1. Intertropical lands, hot all the year round.
2. Warm temperate lands, with hot summers and mild winters.
3. Cool temperate lands, with warm summers and cool or cold winters.
4. Polar lands, with long cold winters, and short cold summers.

The intense heat and moisture of tropical lands favour the growth of dense forests, but are not well suited to agriculture. Owing to the density of vegetation and the fatigue attending exertion in a hot climate, the initial difficulty of clearing the soil is great.

When cleared the soil is fertile, but without constant precaution it quickly relapses into the wild state. Deserted clearings in the tropical forest are overgrown by jungle in a surprisingly short time, and the excessive heat and moisture are demoralising to many temperate plants, which run riot in stem and leaf without maturing root and fruit. The influence on man is equally marked. The enervating climate is unfavourable to steady industry, and the reeking soil breeds many diseases For these and other reasons tropical lands rarely develop high types of civilisation.

In the Polar regions the long cold winters and the protracted darkness make agriculture impossible. Man contrives to exist far beyond the northern limit of cereals, but he is stunted in body and his energies are absorbed in the struggle for existence. On the margin of the Polar region the long summer daylight permits almost continuous growth, and greatly reduces the period between germination and ripening. This gives the cereals a greater Poleward range than would otherwise be the case.

In the temperate lands the seasons are regular. The summers are not too hot or the winters too long and cold for cereals and other useful plants to survive. Thus there is a continuity of effort which ensures progress. The inhabitants of the temperate lands are the most highly endowed physically and mentally, and have founded all the great civilisations of the world.

Climate and Elevation. The relation between temperature and elevation has already been explained. A rise of 300 ft. above sea-level corresponds with a fall of 1° F. in temperature. Climate, as determined by latitude, is thus greatly modified by elevation. Temperate and Polar conditions may exist in tropical lands at a sufficient height. Elevation is sometimes advantageous, and sometimes the reverse. In the Andes many flourishing cities are found several thousand feet above sea-level. Here elevation acts beneficially, affording more favourable conditions than the hot, unhealthy lowlands of the coast. The nearer we go to the equator the higher can human settlement be pushed; the farther we go from the equator the nearer sea-level must man make his home. In tropical lands the existence of highlands may increase the area suitable for settlement, in temperate lands it almost inevitably contracts it. This is well seen in France, where the Central Plateau has a mere sprinkling of inhabitants though the surrounding lowlands are thickly peopled.

Rainfall. The second climatic factor is the distribution of rainfall. Many fertile regions are uninhabited because they are rainless. Such areas are either remote from the sea, the ultimate source of rain, or in the lee of mountains, which intercept the rainy winds, or in the track of dry winds. Some of the drier regions are grass lands, but the most arid are deserts, except where irrigation is possible. Deserts, when irrigated, are often exceptionally fertile, because the chemical constituents from which plants build up their tissues have not been washed out of the soil by rain. A typical area of this kind is the Great Basin of Utah, where irrigation, round Salt Lake City, has converted the desert into a garden.

In some regions the rainfall is excessive. Even in our own country cereals do not do well in the wetter west. The wettest place in the world is the Khasi Hills of Assam, where over 400 in. of rain fall annually. In such regions only very special forms of agriculture are possible.

The Distribution of Rain. Not less important than the total rainfall is the manner of its distribution over the year. In many dry regions a long drought is followed by torrential rains, which are wastefully expended in flooding the watercourses for a few hours, leaving them empty soon after. Regular distribution is necessary, as well as a sufficient total precipitation. This may be either fairly uniform throughout the year, as in our own country, or uniform at certain seasons, as in the Mediterranean, where nearly all the rains fall in winter. In the latter case a different type of agriculture results. The evergreen trees of Southern Europe are fitted to resist the long drought of summer. The dry autumns bring the vine and other fruits to perfection, and count as one of the climatic advantages of the region.

While the average distribution of rainfall has been worked out for the more settled parts of the world, it is liable to fluctuate from year to year. Some years are exceptionally wet, and others exceptionally dry, and these wet and dry years may occur in short or long cycles. Exceptionally wet and dry seasons are both injurious to crops, and the former may cause floods, and consequent loss of life. Of the two, drought is generally the more dangerous to life, especially in the regions where the rainfall is at no time abundant. The failure of the monsoon in the drier parts of agricultural India means famine, in which the loss of life may amount to millions. In the agricultural regions of North America, where wheat is grown for export by a relatively thin population, it results all over the wheat-importing area in the rise of the price of food, and, consequently, of the price of labour and of commodities in general. In the pastoral lands of the New World and Australia it seldom results in the loss of human life, but millions of stock may perish.

The Track of the Winds. The relation of rainfall to continental and oceanic climates has already been explained on page 300. The windward shores of islands and continents receive rain from moisture-laden winds which have crossed the ocean. These winds become drier as they pass inland, and have, therefore, less moisture to precipitate as rain. The interior of all continents is much drier than their marginal areas. A typical continental climate is dry as well as extreme. A typical oceanic climate is humid as well as equable. [See maps, page 295.]

The above results are due to the action of winds, which exercise great influence on climate. Our own islands lie in the track of the westerly winds, which blow strongly all the year round, but especially in winter. The desert of

Sahara lies in the track of the dry trade winds. On a smaller scale, great importance attaches to local winds. The daily land and sea breezes of seaside places are a familiar illustration. Many others might be found. The traveller in Italy dreads equally the tramontana from the Alps, and the sirocco from the desert. The mistral, or cold Alpine wind, of the Rhone valley prevents the cultivation of the orange and lemon, though these ripen in the neighbouring but sheltered Riviera. The chinook winds of the western prairies of North America are warm winds, before which snow disappears as if by magic, enabling the farmer to begin operations much earlier than would otherwise be possible. Similar winds in the Swiss valleys are expressively called snow-eaters. Winds of the same type blow during harvest in New Zealand, and do great damage by shaking the grain from the full ear before it is cut. A spell of such winds may mean the ruin of the harvest. The cold winds from the Mongolian Plateau make the winters of Northern China very severe, and occasionally cause frosts at Shanghai.

The Effect of Mountains. Elevation affects climate in other ways than merely by reducing the temperature. The position of the highlands helps to determine the rainfall of the regions on either side. When moisture-laden winds approach mountains they are deflected upwards, and, becoming cooled, drop part of their moisture as rain, passing on as drier winds. The windward slopes of mountains are therefore much wetter than the leeward. This difference is well illustrated in the western and eastern slopes of the Pennines of our own country. The south-west monsoon strikes the Western Ghats, which are very wet, while the Deccan peninsula above has a deficient rainfall. The same monsoon brings heavy rains to the southern slopes of the Himalayas, while the northern slopes towards Central Asia are arid. Desert areas are often found in the lee of mountains, as in the desert of Central Asia, or of Western North America.

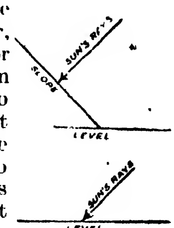
The advantages of a mountainous region, though less obvious than the disadvantages, are not less real. Mountains are the great reservoirs from which rivers are fed. This is specially important in dry regions. In the drier parts of Asia the villages are in the mountain valleys, because there only is water abundant. When mountains are high enough for the formation of snowfields and glaciers, a permanent supply of water in the hot summer months is assured. The glaciers of the Hindu Kush feed the Oxus, which brings life to the deserts of Russian Turkestan. The higher the mountain the steeper and swifter are the mountain streams, and the greater is the load of sediment they carry. Mountains are thus great soil factories, from which rivers obtain the raw materials out of which fertile lowlands are built up. The Abyssinian Highlands have furnished the raw materials of Egypt, the Alps that of the plain of the Po, the Himalayas that of the plains of Bengal. The higher the mountains the more likely is it that extensive and fertile lowlands will be formed at their base.

Rivers rising high have swift currents, which make them useful as sources of power. The sluggish rivers of the English Midlands are almost useless for this purpose, while innumerable Alpine valleys obtain cheap electric power from the torrents that rush down them. Such regions may develop flourishing industries, as in the valleys of the Jura or the Black Forest.

The Treasures of the Mountain. The wet windward slopes of mountains are usually densely forested, and the timber is easily transported by the streams. Equally valuable are the minerals in which most highlands abound. Mountains are formed by the crumpling up of the earth's strata into folds. The upper strata are then gradually worn away and deep valleys cut by the action of weather, ice, or running water, so that the inner strata are exposed. This often brings valuable minerals to the surface. In the Pennines the layers younger than the coal measures have been worn away, exposing rich coalfields on both flanks. In Southern England, where the strata have not been folded and elevated in the same way, the coal measures are buried miles deep and cannot be worked. The silver mines of the Andes, the mineral wealth of the Rockies or the Urals illustrate the importance of minerals in highland regions. One of the most widely distributed useful minerals is building stone which, as in the case of the marbles of the Apennines, or Greece, may be valuable for its beauty.

Mountains are often useful in keeping off hurtful winds. The open plains of North America, which stretch almost unbroken from the Arctic Circle to the Gulf, are often swept by icy Polar gales, and the orange groves of Florida may be ruined by frost. The French and Italian Riviera, on the other hand, are sheltered from cold north and east winds by the Alps and Apennines. Oranges and lemons ripen out of doors and the air is fragrant with flowers. To this fortunate situation is due the prosperity of the innumerable health resorts.

The Influence of Slope. Slope determines the direction of rivers and their commercial value. Those following the short slope tend to be short and swift, those of the long slope to be longer, slower, and better fitted for navigation. This is well seen in the Andes, from which no river of importance flows west into the Pacific, while the great Amazon flows east to the Atlantic. If mountains are centrally situated, great rivers may flow in many directions. From the St. Gotthard Alps the Rhine flows to the North Sea, the Rhone to the Mediterranean and the Ticino to the Adriatic.



Slope is important in another way. The diagram shows that on the slopes facing the sun the sun's rays fall more nearly vertically than on the level, and consequently have a greater heating power. This explains why, in many parts of Central Europe, southern slopes of the hills are terraced with vineyards. In the

Southern Hemisphere the northern slopes are thus planted.

The effect of slope on a large scale is seen in the contrast between valleys opening north and south. Every traveller across the St. Gotthard notes the contrast between the valleys on the Swiss and Italian slopes. In the latter the snow line and tree line are much higher, and the chestnut, mulberry, olive and vine are cultivated to a considerable height.

Finally, as we saw, highlands may be advantageous in tropical lands by lifting large areas above the unhealthy climate of the plain. This is the case in South Africa, where only the highlands above the fever line, which reaches as high as 4,000 ft., can be inhabited by Europeans. A much greater range of products can also be cultivated.

Mountains and Passes. The obstacles to communication presented by mountains are very obvious. To the physical labour of ascent, which narrow precipitous valleys, deep unfordable rivers and dangerous glaciers may render very great, are added, in the case of the higher mountains, the sufferings due to intense cold, high winds, and the difficulty of breathing the highly rarefied air. Mountains frequently form a barrier between two countries, especially when the routes across them are difficult. They hinder commercial intercourse by increasing the time and the cost of transport. The former consideration is so important that costly engineering works, such as tunnels through the Alps, ultimately pay for themselves by the economy of time effected.

The amount of resistance to communication offered by a mountain range depends on the height not of the peaks but of the passes. It matters little how high the peaks on either side rise if the pass or depression between them be low. A second important point is whether a pass can be found which enables the entire system to be crossed. Hence the importance of such Alpine passes as the St. Gotthard and the Brenner. Other things being equal a railway will tend to take a route where a single pass only need be negotiated, as in the transcontinental line from the Argentine into Chile, where the narrowing Andes can be crossed by one pass, the Cumbre or Uspallata.

The command of the passes means the control of the region. For this reason Switzerland fortifies the St. Gotthard, and Britain must retain the control of the Khaibar route from the plains of India into Afghanistan at any cost.

Hardships among the Mountains. Highland regions are, except under exceptional conditions, thinly populated. The lower temperature, and especially the longer and colder winter, are unfavourable to agriculture, and though pasturage may be good in summer the animals must generally be driven to lower, warmer valleys in winter. The heavy rainfall and the erosive force of the mountain streams rapidly denude the slopes of soil, so that for agriculture some form of terracing, always a most laborious process, is generally necessary. Every traveller in the Alps will remember the tiny terraced gardens, banked up with stones, a pathetic witness to the hardship of the mountaineer's life. The terraced olive yards of the Mediterranean represent centuries of unremitting labour. Perhaps the most striking example is seen in the high valleys opening to the upper Oxus or Indus, where bare mountains, stripped of soil, slope precipitously to raging torrents. After every flood the hill folk climb down to the confluence of the nearest side valley to gather up a basketful of soil, out of which they build up terraces of soil on the rocky hillside. In this way little villages win a hard subsistence at great heights among the bleak mountains of Central Asia. But the amount of labour expended is evidently incommensurate with the result, and, though mountain dwellers are generally strong and enduring, they remain a frugal people without those more complex needs which make for progress.

This suggests another reason for mountains acting as barriers. They are infertile and thinly peopled. The Northern Highlands of England were thus, though not high, an effective barrier between England and Scotland till population became dense on the northern coalfields.

The Influence of Rivers. Mountain and river are almost correlative terms, and in considering the influence of mountains we have incidentally considered in part that of rivers. Like that of mountains this influence is mixed, sometimes co-operating with man's efforts, and sometimes thwarting them. The importance of rivers as routes is obvious. A river is ceaselessly at work broadening and levelling its valley [see page 457] Many rivers offer a choice of routes, by water or by land. Others, though not navigable, are practicable as valley routes. Population tends to follow the river valleys, which are the natural roads. Hence, we find civilisation early developing in the river valleys of the Ganges, the Euphrates, the Nile, and so forth.

The importance of the river as a route grows with the development of means of communication. Most of the great land routes of the world follow rivers, though the line has frequently to be blasted out of the sheer sides of the valley.

Rivers, however, hinder communication as well as acilitate it. Many side valleys open to the main valley, and the streams which fill them must be bridged or otherwise crossed. Sometimes the character of the country makes this extremely difficult. The rivers may have cut deep cañons far below the surface of the country, to which descent may be almost impossible. Here a bridge is the only practicable method of communication, and costly bridges are not built till the development of a country is far advanced. In the earlier stages such cañons effectually hinder communication, as in the drier parts of the Western United States. Or, again, a river may be so swollen by floods in summer as to close a route which it opens in winter. This is the case on the great trade route from Leh to Yarkand in Central Asia. The winter route follows the Shyok Valley, but in summer the river comes down in flood, making

the valley impassable. The summer route has to go up many side valleys and across the passes which separate them.

Rivers as Constructive Agents. Rivers are ceaselessly at work making new land [see page 458]. This is sometimes advantageous to man and sometimes the reverse. It has given him some of the most fertile lands in the world, but it may undo his work, and make his task more difficult.

In every flood a river spreads beyond its banks, leaving behind it when it retires a deposit of soil. Thus it gradually levels the land on either side, forming a flood plain. The soil of the flood plain becomes deep and fertile. The flood plain of the upper Rhine, between the Vosges and Black Forest, is one of the garden spots of Europe. On a larger scale the same process builds up vast plains and deltas like those of the Rhine, the Po, or the Nile.

Broadly viewed, therefore, the constructive work of rivers benefits man by creating new lands for his occupation. But immense loss and damage may be caused in the process. The floods of the Hwang-ho constitute China's sorrow, and those of the Mississippi are almost equally destructive. Man may be forced to check the misdirected energy of such rivers by building embankments and otherwise restraining the tendency to flood. The forming of bars and the silting up of harbours are disadvantages which result from the constructive energy of rivers.

The Newer Uses of Rivers. In other ways rivers exercise an important influence on the development of civilisation. Irrigation may be necessary, and the rivers of a country may or may not be suitable for the purpose. If they are, as in the case of the Ganges, the Nile, the Euphrates, and many others, agricultural prosperity is assured. If they are not, as in the case of the Spanish rivers, which are in deep gorges, the development of a country is hindered.

Rivers may confer another advantage on a country by supplying power. The early manufactures of the Tweed or Yorkshire Ouse prospered largely because there were rapid streams to turn the mills. The discovery of electric power has made the command of water power infinitely more valuable. Niagara Falls have long been harnessed in the service of man. The largest producer and transmitter of electric power in the Old World is the Falls of Cauvery in Mysore, with 93 miles of wire to the Kolar Goldfields, and 57 miles to the electric lights of Bangalore. The command of water power may occasionally make mountain regions important industrial centres, but it is usually where the river enters the lowlands, forming falls, that industrial centres develop. This is well seen in the chain of flourishing manufacturing towns along the Appalachian "fall line."

Irrigation plays a great part in the development of many countries. Rivers are not essential, for water may be collected in cisterns and tanks in the wet season, as in Southern India, or obtained by sinking wells to water-bearing strata, as in the Sahara, the Western United States, or Australia. But for irrigation on a great scale rivers are necessary. The usual method is to dam the river, forming a head of water from which distributing canals can be fed. This method is applied with conspicuous success to the Indus, the Ganges and the Nile.

Plateaus and Plains. Plateaus have more or less of the disadvantages of all highland regions according to their elevation. Under certain circumstances they may be the most favoured part of a region. The plateaus of Switzerland, of Central Asia and the Andes are cases in point, though for a different reason. High plateaus are seldom fitted for agriculture, but their dry pastures often produce a fine quality of wool or hair. From that of the sheep and goats fed on the plateaus of Asia Minor and Persia are made Turkey and Persian carpets, the finest and most durable in the world. Plains present great uniformity over considerable areas, and offer the minimum resistance to movement and communication. They may be swampy and low lying, as in Holland, but this is met by draining and dyking. The soil is fertile for the same reason that valley soil is fertile. Throughout the world plains are centres of population, and the site of all the important cities. When they are adjacent to good harbours their prosperity is still more marked.

Soils. The character of the surface soil is important. Clay is stiff, compact and impervious to the free passage of air and water. It is therefore unsuited to agriculture. A sandy soil has the opposite defects, and is too loose and porous. Fresh lava is absolutely unfertile; but, as its surface begins to weather, vegetation appears. When thoroughly disintegrated it is extremely fertile, owing to the presence of chemical substances. Thus, though the slopes of Vesuvius are barren almost to the base, the surrounding district of Campania is extremely rich. In forest regions decaying vegetable matter enriches the soil, forming humus or vegetable mould. The virgin soil of cleared forests is therefore very fertile, as in Siberia or North America. Alluvial soils are generally fertile after they have passed through the initial swampy or waterlogged stage. We have already referred to the fertility of desert soils. The loess region of Northern China is composed of very fine soil carried by the wind from the deserts of Central Asia. An extreme case is seen in the nitrate deserts of Chile, which, though barren of vegetation, yield an invaluable fertiliser.

Certain soils are specially adapted to certain crops. The Deccan has its "cotton soil," and the Black Earth Lands of the Russian Empire grow fine cereals.

Indirectly, too, the character of the soil exercises considerable influence on the conditions of existence by its suitability or unsuitability for making hard-wearing roads. In a clay country the roads are impassable after rain, and impede communication. In the lower regions of China the roads become deeply sunk in the porous soil.

The Land near the Sea. The prosperity of a marginal area depends partly on the character of the coast, and partly on the character of the

back region, or hinderland. Good harbours are of little value where the hinderland is poor, and a rich hinderland may develop slowly owing to the absence of harbours. With good harbours and a good hinderland a marginal area possesses superior advantages to an inland region. Most of the countries of Europe and of Eastern North America are in this favoured position.

Coasts and Harbours. The different types of coasts have already been described. The presence or absence of cliffs, bays, gulfs, and estuaries opening to navigable rivers, the depth or shallowness of the seas off the coasts, the existence of sandbanks, reefs, or sunken rocks, and the presence or absence of islands, all affect the commercial development of a region.

Where mountains rise immediately from the sea good harbours are rare. In the mountainous island of Capri, near Naples, there are only two possible landing-places at any time, and in stormy weather only one. On some mountainous coasts the sea has penetrated far inland up the river valleys, forming rias, fiords, and other inlets. The coasts of such fiords are generally fringed with islands, which form a natural breakwater, as in the Skerry Guard of Norway. The fiords are natural routes to the interior, and as such valuable, but in these regions the interior, or hinderland, is apt to be rugged and barren, neutralising this advantage to a great extent. Examples of fiord coasts with poor hinderlands are Norway, the West Coast of Scotland and British Columbia and of ria coasts in North-west Spain and South-west Ireland. All along the Pacific coast of America good harbours are few. The Atlantic coast of North America, on the other hand, has many good harbours in drowned river valleys which give access to a rich hinderland. The contrast between the prosperity of the eastern and western coasts of North America is very instructive.

Low, sandy shores are also unfavourable to commerce. Such shores are frequently beaten by dangerous surf, as on the coast of West Africa, or Western India, where special surf boats are used for landing.

Seas and Oceans. The distribution of seas and oceans and their influence on climate have already been described. Europe is fortunate in possessing two inland seas, which penetrate far inland—the Baltic-North Sea in the north and the Mediterranean in the south. Both, but particularly the latter, have played a great part in the history of the world by rendering communication easy. The early growth of civilisation and commerce all round the Mediterranean is a case in point. North America has somewhat similar advantages in what we may call the St. Lawrence Sea in the north and the American Mediterranean in the south. Eastern Asia is well cut up by inland seas, but the other continents are very compact.

Trade Winds. Winds have already been described. In his struggle for existence man must take winds, currents and tides into account.

Winds exercise a great influence on navigation. A vessel leaving Southampton for Cape Town is first in the region of the west winds and may have rough weather for a day or two, especially in "the Bay." Towards 30° N. it comes into a region of calms, out of which it passes south into the north-east trades, which blow steadily till the belt of calms round the equator is reached. South of these equatorial calms it enters the region of the south-east trades, and after passing through the calms of Capricorn perhaps experiences rough weather on nearing Cape Town in the region of the southern westerlies. These, it will be remembered, blow much more fiercely in the Southern Hemisphere, giving the "roaring forties" an evil reputation, and making the voyage round Cape Horn in particular an experience to be dreaded. Ships naturally go with the wind so far as possible. A ship sailing west across the Atlantic steers a southerly course to get into the north-east trades, which originally guided Columbus to the New World. Returning eastwards to Liverpool it steers further north, to get into the track of the west winds. The summer and winter courses also differ somewhat, as the track of these winds varies with the season. A sailing vessel to Australia, similarly, finds it easiest to go by the Cape of Good Hope and return by Cape Horn.

Currents and Tides. The influence of currents on climate has already been considered. The warm surface water of the Gulf Stream Drift keeps the ports of Britain and Norway ice-free in winter; but the cold Labrador current closes the St. Lawrence ports in winter. In a less degree than winds, currents influence courses at sea. A vessel going with the equatorial current proceeds much more quickly than one going against it.

Currents play another part, which beautifully illustrates the interdependence of Nature. They often carry seeds, some of which may survive their long exposure to sea-water and germinate. In this way the coconut palm early appears on coral islands, to which its seed has been carried by ocean currents.

Tides in particular are of great assistance to shipping by carrying vessels up and down estuaries into harbour. The high tides of London, where two tidal crests meet, have contributed to its greatness as a port. Some harbours can only be entered at high tide.

Ice. The value of a sea is much lessened if it is ice-bound in winter. The ports of the Baltic and the northern Black Sea are of less importance than the ports of the North Sea and the Mediterranean, which are ice-free. The summer course of Atlantic liners is affected by the presence of icebergs, which are then drifting south from the Polar regions.

TEXTILE PRINTING

Hand, Block, and Machine Printing. The Perrotine. Cylinder Machines. Multiple Colour Printing. Finishing Processes

By W. S. MURPHY

Preparation. Cotton, wool, and silk in the order named are the fibres most frequently dealt with by the textile printer. Cotton and wool are printed not only in the piece but as yarn to produce variegated effects in cloth, and woollen slubbing is also printed. The preparatory processes do not differ greatly from those which precede dyeing, and may be studied in the Dyeing section of our course. Silk is well scoured, calico ordinarily is bleached, not only to avoid interference with the brilliance of the colours, but to give good whites when these form part of the pattern. The textile printer is contented, however, with a less perfect bleach than the "market bleach" given to goods intended to be sold in the white state. Wool is chlorinated—that is, treated with a weak solution of bleaching powder or of a hypochlorite. This greatly reduces the felting power of the wool, and makes the fibre more easily penetrable by liquid.

Block, or Hand Printing. It need hardly be said that block printing was the first method practised in this trade. The logical progress of textile printing, in fact, has been that of typography, from hand printing to machine printing on the flat, and from that to rotary printing. Block printing is still largely used for silk, and it is comparatively recently that machine printing has been adapted to the treatment of this fibre.

Blocks. The blocks are usually made of peartree wood or some other hard timber, and are of considerable thickness. On the face of the block the design is cut out in relief or formed by copper wire. When the design is a simple repetition of a pattern, it is usual to make the block large enough to contain the whole pattern. If the design be large and complicated, it may be divided into sections, each block carrying a section, and the whole making a set. Designs of two or more colours require as many blocks as there are colours, unless, as often happens, the combination of two colours produce a third. Many designs printed on heavy cloths, such as felt carpets, are vari-coloured in such a way that each colour stands out separate from its fellow. The printer's colour is a kind of paste. In old-fashioned works the paste is laid on to the block with a palette knife; but other and better means are now generally used. A woollen cloth is stretched tightly over a hoop, and upon it the colour is spread. To give the surface of the *sieve*, as it is named, more elasticity, it is floated on paste or size in a tub. On this sieve the block is pressed, and receives its coat of colour. The appliance for vari-coloured blocks to which we have referred, consists of a wooden block, hollowed out in parts the same size and position at the pattern of the printing block. Into these hollows the different colours are laid, and the woollen cloth stretched over all. Between each colour compartment pieces of thick cord are glued, to prevent one colour from running into another on the cloth. When the printer presses his block on the cloth, the different colours come into place.

The Table. A textile printer's table must be very smooth and true. The bed of the table is generally made up of slate slabs. At each end of the table strong brackets are fixed, and upon the one is slung the cloth beam, while on the other the taking-on beam is hung.

Printing. The printer draws a length of the cloth on to the table, and carefully smooths it down to the bed, till not a vestige of wrinkle remains. Having charged his block with colour, he lays it face downward on the cloth, and gives it a tap with his hand, or in the case of large patterns, with a mallet. After a moment, the block is lifted, and a clear impression of the pattern is left on the cloth. No matter what the character or length of the design may be, the printing action is the same. Block printing is merely a repetition of these simple actions in perfect register.

Machine Printing. For the present, we defer examining the further treatment of hand-printed goods, because the finishing operations of all printed cloths are the same, whether printed by machine or hand blocks. Confining ourselves to the means and methods of putting on the impressions meanwhile, we note that textile printing machines are divided into two classes. The one class is the block printing machines, and the other is the cylinder printing machines.

The Flat Press. The first step towards the introduction of machinery was an English invention that imitated copper-plate printing, calico being substituted for paper. It was practically confined to one-colour printing, and we believe that this method is no longer practised.

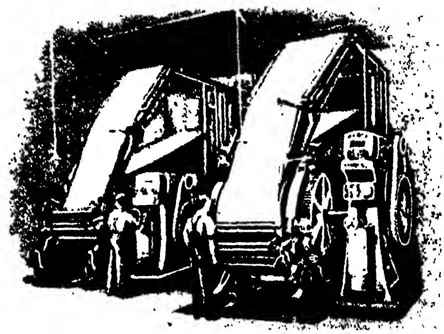
The Perrotine. A block printing machine, capable of working in three colours, was the next step. It is very largely used in Alsace and Belgium. This machine has never made much headway with British printers, though some of the highest-class houses use it alongside the cylinder machines. The perrotine is a very intricate piece of mechanism, and requires very careful and detailed study.

The machine is contained within a strong framework, semicircular in form, the fore end of the circle being continued in a curved line up, to hold the rollers which carry the blanket and cloth to be printed. The simplest perrotine prints three colours, and therefore has three blocks,

three printing tables, and three sets of colour rollers, with apparatus for colour supply. This, to begin with, suggests complexity. Our attention should first be directed to the printing blocks and their accessories. The machine has three equal arms joining at the centre, and therefore at right angles to each other. On all these arms we find a block holder into which the engraved block is fixed. Each holder is screwed on to a sliding piece keyed to a pair of beams moved alternately backward and forward by shafts supported on the main arm. The three blocks are thus given a to-and-fro motion, forward to print the cloth, and back to let it pass. Having found our blocks, we have next to find out how they are supplied with coats of colour. At the side of each arm, supported on levers, are three colour-boxes, furnished with rollers. One roller revolves in the colour-box and one runs in contact with but above its fellow, taking on a supply of colour from it. Screws regulate the relations of the rollers, bringing them into close contact when much colour is desired, and separating them if the colour supply should be light. Neither roller, however, ever touches the printing block. The medium between block and colour roller is a sieve ingeniously controlled by rods extending from a lever beam. The sieve is on the end of the rod, and the timing of its action shows fine adjustment.

We have been working from the outside into the machine, and now we are at the very centre. Here is the table upon which the block impresses the cloth. There are, of course, three tables. For the sake of simplicity we have confined attention to one set of appliances; but the tables cannot be appreciated unless the three are seen. Three iron bars of equal size are joined at right angles to each other, and on the heads of the bars sit the smooth tables. The whole three are cast as one piece, but we separate them to understand the real character of each. A table faces every block. At the four corners of the table frame sit four rollers. The tables, being flat, have no power to act on the cloth; but these rollers carry the cloth to be printed over the tables, their surfaces being covered with little teeth to hold on to the fabric. Next, above the first of the rollers we find a large roller upon which the blanket, back cloth, and pieces to be printed join together. Up above and near to the front part of the machine are sets of tension rollers and carrying blocks. Outside of all sit the beams from which come the three fabrics mentioned.

Working the Perrotine. Wound on to a suitable roller, the cloth is hung on the brackets in front of the machine. Up above, the endless blanket and the back cloth are similarly adjusted. Into the colour-boxes the printer lays his colours, adjusts the screws which regulate the supply, and puts the doctor knives over the colour rollers to clear off superfluous pigment before the sieves come into contact. The blocks are firmly screwed into the holders. On the end of the piece a few yards of rough cloth are joined and this is drawn into the machine. When everything has been put into position, the perrotine is started. Blanket, back cloth, and printing piece pass in on their separate ways, and join at the central roller above the table rollers. As the three fabrics come together the blanket is uppermost, but when going round this roller the positions become reversed, and the piece



208. BLOCK PRINTING MACHINE
(Mather & Platt, Ltd., Manchester)

cloth is uppermost when they pass on to the first table roller. Thrust in by the lever-controlled rod, the sieve has taken its coating from the colour roller and transferred it on to the block coming forward. Table and block now press in contact, with the cloths between them. The first colour has been printed. The cloths next pass round the second corner rollers, and the machine again prints. A third time the operation is performed, and then the piece cloth returns to the outer world a printed cloth, to pass on to the drying rollers.

Improvements. The original perrotine has been greatly modified and improved during the past twenty years. But the principles on which it works are unaltered, and we have purposely selected the first form of the machine because it exhibits, even more clearly than the later developments, the essential characteristics of a block printing machine. Improvements have chiefly taken the direction of adding to the number of colours which can be perfected at once on the machine. Some of the newer perrotines print twelve colours at once with great speed, and twenty colours are occasionally obtained in one printing. The English block printing machine, which is illustrated [208], gives a good idea of the size and character of that class of machines.

Cylinder Machines. The idea of devising a roller to perform the same service as a flat surface has been at the root of many of our finest mechanical inventions. Application of that principle to textile printing has gone to great lengths. Cylinder printing machines for textiles were invented by Bell, a Scotchman, in 1785.

Single Cylinder. This is a simple structure. In the middle of the machine is the

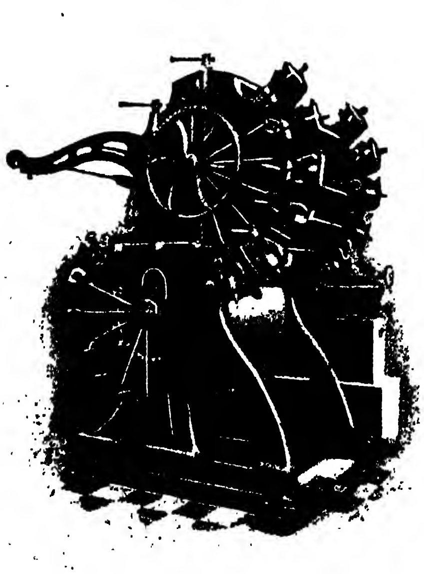
wide cylinder, called the pressure cylinder or bowl. Under it we see the pattern roller, with slanting knives at each side of it. Further below sits the colour roller in the colour trough. Note these parts a little more closely. The roller in the colour trough is clad with soft, thick woollen cloth, which enables it to take up the colour. The pattern roller runs in direct contact with the colour roller, and thus receives the necessary supply of colour. The knife at the inner side of the pattern roller is called the *colour doctor*, because it clears away all the superfluous colour; the knife at the other side is named the *lint doctor*, its function being to take away any threads which may have been deposited by the cloth on the pattern roller in passing. Made of cast iron, the large pressure cylinder is heavily clad with smooth felt to give a finely smooth and elastic surface. The cloth apparatus is equally simple. Up on the front of the machine the cloth beam is hung; adjoining hangs the blanket roller, and underneath sits the guide roller which joins them. Cloth and blanket go down round the pressure cylinder into contact with the pattern roller, and round up to the delivery rollers on the other side.

The vast saving of labour and the greatly accelerated production effected by the adoption of the cylinder principle is here worthy of note. Thousands of yards of cloth can be printed on this machine in a day.

Three-colour Machine. Progress from the single-colour machine to the three-colour printing was easy to our ingenious mechanics. We say ingenious because some difficult problems are involved. The idea of placing pattern rollers, with doctors and colour apparatus, on the sides of the pressure cylinder was obvious; but the problem of driving these appliances could hardly be described as very simple. Moreover, there remained the question of distributing the pressure on the added rollers. These difficulties have been met in various ways by different inventors. The simplest and most obvious method—namely, that of strengthening and enlarging the framing, and giving the second and third roller the same gearing as the first, has been adopted in many machines with success. In other machines the principles of the perrotine have been adopted.

Printing Many Colours. Every colour must have its own separate pattern roller, knife doctors, and colour-boxes with rollers. To group these round the pressure cylinder in proper positions has been the work of the machinist. How this has been accomplished we see most clearly in a machine designed to print four colours. The pressure cylinder is 6 ft. in circumference, and sits in the centre of the machine. The gudgeons of the cylinder rest on bushes, which can be moved up or down in slots in the side cheeks, strong screws from the top of the frame fixing them in position. Round the cylinder are grouped four mandrels, slotted, and fixed in strong bearings on slide pieces. On to these mandrils the engraved pattern rollers are forced by means of a screw press. By this arrangement the changes of pattern and colour can be effected by merely changing the pattern roller. Colour-box, roller, and doctors are contained within the slide piece, secured to the framing by means of a double screw. A pair of arms, jointed to the inner screw of the slide pieces and strengthened by bolts from the machine frame, bring forward the pattern rollers to the pressure cylinder. The mechanism of all four rollers—each with its equipment of colour-box, colour roller, doctors, and controlling levers—is practically similar. From the head of the frame two long arms curve out, and between these rests the cloth beam; while from beams more directly over the pressure cylinder come the blanket and back cloth. The cloths meet on a roller just above the cylinder, and come down into the machine. A double cylinder machine [209] prints twice the number of colours on the same principle.

Mordants and Dyestuffs. These will be considered in detail in the Dyeing section of this course. It is rather the methods of application that vary in dyeing and printing than the mordants and dyestuffs employed, although some dyes are more suitable for dyeing than printing, and vice versâ. Both soluble dyes and insoluble colours (pigments) can be used in printing. The pigments are usually coloured minerals in fine powder—ultramarine, for instance—and are mechanically fixed on the cloth with albumen. The natural colouring matters, especially logwood and indigo, are largely used, and any class of artificial dyestuff may be employed. As, however, in printing, the



209. DOUBLE CYLINDER PRINTING MACHINE (Mather & Platt, Ltd., Manchester)

fibre is not dyed so thoroughly, and as the first necessity of prints is fastness to light, the mordant colours—the alizarines, for instance—are more largely employed than the colours which require no mordant.

Styles of Work. The printer can ring an enormous number of changes in his methods of doing things, and he can combine dyeing very effectively with printing. For instance, everyone is familiar with the old pattern of indigo blue scarf with round white spots. This was produced by printing a *resist* or *reserve* paste on the cloth and then dyeing it in the indigo vat. The places covered by the resist were protected from the action of the vat and consequently remained white. Or the printer may reverse this process; he may dye the cloth first and print on a *discharge* This has the same effect of leaving a white pattern on a coloured ground, and, by adding to the discharge colouring matters not acted upon by the chemical agent that destroys the body colour of the cloth, he can produce a *colour discharge*—that is to say, for instance, red upon a blue ground. Again, as in one of the oldest *styles*, known as the *dyed* or *madder* style, he may print a mordant on to the cloth, dyeing the cloth subsequently with a colouring matter which will not go on to the fibre except in the parts impregnated with the mordant. The result is a pattern on a white ground. The term "madder style" is used because this method was employed for madder long before the introduction of the artificial colouring matters. Now madder has gone entirely out of use—in calico printing, at any rate--and alizarine reigns in its stead; but this style is still employed for alizarines and other colouring matters. Again, the printer may print the colour paste on to the mordanted cloth, or the mordant may form a part of the printing colour. As it is evident that the printer may combine these and other styles, it will be seen that he has an armoury of resources.

Padding. The large firms of indigo dyers were all printers to the extent of producing patterns on their goods by means of printed reserves in the manner we have instanced. The printer, however, is frequently content with a speedier form of dyeing known as *padding*. The fibre is not so thoroughly impregnated as in vat or beck dying, but the method is practically confined to calico, and for this material it is advantageous. It will be readily understood that the smaller amount of colour, or lesser impregnation of the fibre, allows better discharge effects to be obtained. In other words, it is easier to get good sharply outlined patterns by printing a discharge, whether white or coloured, on padded than on dyed material, and this applies even more particularly to *slop padding*, which will be touched on later.

The Padding Machine. This is a very simple apparatus. It consists essentially of a rather small vessel in which a concentrated solution of the mordant or dyestuff is contained, guide rollers within the vessel, by means of which the cloth is run through the liquor, and squeezing rollers directly over the dye bath, by which the surplus liquor is squeezed out into the dye bath. Attached to the frame of the machine are rollers to receive and deliver the cloth. The necessary concentration of the bath for this rapid form of dyeing must be noted. It emphasises the fact that in apparatus dyeing generally, where *short* baths have to be used, the dyestuff must be very soluble.

Slop Padding. When the colour is applied uniformly to one side of the cloth only, the process is termed *slop padding*. This is used principally for light, easily discharged shades. A single-colour printing machine is ordinarily employed. The printing roller is plain—that is, no pattern is engraved upon it, but the surface is grooved with fine lines in order to take up the colour. A felt-covered wooden roller, revolving in the concentrated dye bath, in touch with the printing roller, transfers the colour or mordant to this latter. Over the printing roller, and in touch with it, is a large iron roller, which brings the cloth into contact with the printing roller. The printing roller is provided with the usual colour-doctor, and in order to give an elastic print'ng surface, a thick band of felt, known as the *blanket*, revolves in an endless band between the iron roller and the cloth. As a rule, there is a *back cloth* between the cloth and the blanket to prevent the felt from being soiled.

Machine Printing. It must be noted here that although the mechanical arrangement of a machine to print a large number of colours makes it appear complicated, an eighteen-colour machine is merely a multiplication of the essential parts of the one colour machine described above. Whether it be for cotton, woollen, or silk, the actual apparatus is a copper roller engraved in lines or dots, with a pattern, one printing roller being provided for each colour. The main difficulty is to make the colours register properly —that is, to fall into their proper position in the pattern, and this, of course, increases in proportion to the number of colours in the pattern. Each roller must be in its correct position on the mandrels, and all the rollers must be correct in relation one with the other. The edge of the doctor must be perfectly level, and press evenly against the whole length of the roller. Many other difficulties crop up, but each suggests its appropriate remedy.

Printing Woollen - slubbing and Cotton Yarn. Unspun wool in the form of slubbing is printed with stripes in order to produce fancy yarns, and cotton yarns, usually in the form of warps, are printed in order to produce variegated cloths. The printing machine already described is used with a number of rollers corresponding to the required number of colours As a rule, the printing roller is simply grooved, in order to print the yarn in stripes. The doctor is arranged so that it clears off all the colour, except that in the grooves, before the printing roller comes into contact with the stuff. Especially for slubbing, the blanket must be softer than usual, in order to allow the stuff to be pressed into the groove, and so to take up the colour.

By Francesco de Feo

INTRANSITIVE VERBS

When the action or fact expressed by the verb is completed without an object (I walk, *io cammino*; I sleep, *io dormo*) the verb is intransitive. Intransitive verbs, as a rule, are conjugated with the auxiliary *èssere* (Example: *É accaduto*, it has happened); but some are conjugated with *avére* (Example: *ho viaggiato*, I have travelled), or admit both auxiliaries (Example: *sono vissuto* or *ho vissuto*, I have lived).

The only rule that can be given as to which auxiliary should be used is that the verbs expressing an action are conjugated with *avère*, and those expressing a fact with *èssere*. Exceptions to this rule are to be learnt by practice.

EXERCISE XXXV.

1. Quando sono entrato essi èrano già partiti. 2. Sono contento che siate riuscito in questo affare. 3. Lo spettàcolo è durato più di due ore. 4. Son caduto e mi son fatto male. 5. Non ho sonno; ho dormito tutto il giorno. 6. Aspetto mio fratello; doveva venire col treno delle sette, e mi maraviglio che non sia ancora arrivato. 7. Se foste venuto dieci minuti prima vi sareste incontrato col signor N. 8. Una nave da guerra è affondata nel Bàltico. 9. Una torpediniera giapponese ha affondato due navi russe. 10. Ho girato tutto il giorno senza conchiùder niente.

DEMONSTRATIVE PRONOUNS

The demonstrative pronouns are:

questi (*koo-èhstee*), this one
quegli (*koo-èh-'lee*), that one
costui (*costoò-ee*), this one (here)
costei (*costèh-ee*), this one (here)
colui (*coloò-ee*), that one (there)
colei (*colèh-ee*), that one (there)
un tale (*oon-tàhleh*), such a one
ciò (*chee-ò*), that
ne (*neh*), of it, of him, of them, etc.
ci (*chee*), in it, on it, with it, etc.

1. *Questi* and *quegli* are singular, and are only used in speaking of persons; but modern usage prefers the demonstrative adjectives *questo* and *quello* used substantively.

2. *Costui, costei* (plural *costoro*, for both genders), and *colui, colei* (plural *coloro*, for both genders) are used only in speaking of persons, and in familiar language nearly always imply a shade of contempt. Examples: *Io non mi fido di colui*, I do not trust that man (the fellow). *Non prestate danaro a costoro*, Do not lend money to these men.

3. *Colui che, colei che, coloro che, quelli che, colui il quale*, etc., are rendered in English by he who, she who, they who.

4. *Ciò* is singular and means "this thing." *Ne* and *ci* may be considered as demonstrative pronouns, as in many expressions they take the place of *ciò*. Examples: *Non ne* (*di ciò*) *capisco niente*, I understand nothing of that. *Che ne pensi?* (*che pensi di ciò?*), What do you think of that? *Non ci riesco* (*non riesco in ciò*), I do not succeed in doing that.

NOTE. The student acquainted with French should compare the use of *en* and *y*.

EXERCISE XXXVI.

1. Mettèteli da parte; ce ne serviremo quando ne avremo bisogno. 2. Ciò non sta bene. 3. Costui è tanto pieno di sè, che pare che tutto il mondo gli appartenga. 4. Questi è uno scrittore di gran mèrito, quegli un poeta genialissimo. 5. Non oso parlare apertamente, perchè temo di èssere malinteso da questi e combattuto da quelli. 6. Voi non sapete quello che dite. 7. Non so come andranno a finire le cose, per me non ci vedo chiaro in questa faccenda. 8. Ecco due bottiglie abbastanza grandi, in questa ci metteremo il vino, in quella l'acqua. 9. Non mi parlate di coloro, essi non mèritano più di èssere aiutati. 10. Ludovico mirava piuttosto a scansare i colpi e a disarmare il nemico, che ad ucciderlo, ma questo voleva la morte di lui ad ogni costo (m.). 11. Colei parla solo per invidia, è mèglio non ascoltarla. 12. Quelli che grìdano di più hanno sempre ragione a questo mondo. 13. Il prèmio sarà dato a quello che l'avrà meritato.

IRREGULAR VERBS

Second Conjugation

Verbs in **ére** (long)—continued

Dolére, to ache

Ind. Pres.-*Dolgo, duoli, duole, dogliamo, dolete, dòlgono.*

Past Def.—Dolsi, dolesti, dolse, dolemmo, doleste, dòlsero.

Future.—Dorrò, dorrai, dorrà, dorremo, etc.

Imperat.—Duoli, dolga, dogliamo, dolete, dòlgano.

Subj. Pres.—*Dolga*, etc.; *dogliamo, dogliate dòlgano.*

Condit.—*Dorrei, dorresti, dorrebbe*, etc.

Past Part.—Doluto.

Parére, to seem

Ind. Pres.—Paio, pari, pare, paiamo, parete, pàiono.

Past Def.—Parvi, paresti, parve, paremmo, pareste, pàrvero.

Future.—Parrò, parrai, parrà, etc.

Imperat.—Pari, paia, paiamo, parete, pàiano.

Subj. Pres.—Paia, etc.; *paiamo, paiate, pàiano.*

Condit.—Parrei, parresti, etc.
Past Part.—Parso.

This verb is mostly used impersonally: *mi pare, mi parve, mi è parso,* etc.

Solére, to be accustomed

Ind. Pres.—Sòglio, suoli, suole, sogliamo, solete, sògliono.
Imperf.—Solevo, solevi, etc.
Past Def.—Solei, solesti, etc.
Subj. Pres.—Soglia, etc ; *sogliamo, sogliate, sògliano.*
Subj. Imperf.—Solessi, etc.
Past Part.—Sòlito.

This verb is very little used, except in the past participle (*sòlito*), which is very common. The expression *esser sòlito* is used instead.

Avére, to have

See pages 2193, 2484.

Calére, to care for, to matter

This verb has only the 3rd persons.
Ind. Pres.—Cale.
Past Def.—Calse.
Subj. Pres.—Càglia.

Capére, to hold

This verb is obsolete; the verb *capire* is used instead. But the forms *cape* and *capa* take the place of *capisce* and *capisca.*

NOTE. Besides the verbs given above, there are only two other verbs in *ére* (long)—*viz.*, *temére,* to fear, and *godére,* to enjoy, both of which are regular.

EXERCISE XXXVII.

1. Godo di vedére che sta bene. 2. Non mi ricordo di lei, ma mi pare di averla veduta in qualche posto. 3. Ebbi il piacére di conòscerla a Roma due anni fa. 4. In campagna siamo sòliti di fare una lunga passeggiata prima di colazione. 5. Non temete di niente, penserò io al vostro avvenire. 6. Mi duole di dovervi parlare in questo modo. 7. Mi duole la testa; sarà mèglio ch'io rimanga in casa. 8. Mi era parso che avèssero suonato il campanello. 9. Finora si è fatto sempre come avete voluto voi, ora mi pare che anche voi possiate fare come vogliamo noi.

INDEFINITE PRONOUNS

The indefinite pronouns are:

altri (*àhltree*), somebody else, any other man,
altrui (*altroò-ee*), of others, to others,
niente, nulla (*nee-èhnteh, noòllah*), nothing, and the compounds of the adjective *uno* used as a substantive:
ognuno (*onee-oòno*), every one.
qualcuno, qualchedùno (*koo-àhlkoòno, koo-àhl-keh-doòno*), some one.
certuno (*chehr-toòno*), a certain person.

1. *Altri* is singular and is used of persons alone: *Làscia che altri parli di questo,* Let some-one else speak of this.

2. *Altrui* is never used as subject, and means only (1) *di altri* (other people's), as we have already seen when speaking of the possessive adjectives, and (2) *ad altri* (to other people). Example: *Non tenère per te quello che è dovuto altrui,* Do not keep for thyself what is due to others.

3. *Niente* and *nulla* are real substantives: *niente per niente,* nothing for nothing; *il nulla,* nothing.

4. We may consider such expressions as the following to be indefinite pronouns: *Dio sa che,* God knows what. *Chi sa chi,* Who knows who, etc.

NOTE. When *niente, nulla,* and the negative adjectives *nessuno, niuno,* etc., come after the verb, the verb must be preceded by the negative *non*; but when they are placed before the verb the *non* is not employed. Example: *Non c'era nessuno* or *nessuno era là,* No one was there.

EXERCISE XXXVIII.

1. Quel pover' uomo ha dovuto mèttere insieme una bella sommetta, perchè ognuno gli ha dato qualche cosa. 2. Io parlo in generale e non vorrei che altri considerasse le mie parole come dirette a lui. 3. L'iniquità si fonda spesso sulla credulità e bontà altrui. 4. Agite sempre correttamente e non vi curate di quello che altri possa pensare di voi. 5. Bussate ancòra; qualcuno dev' èssere in casa, perchè c' è lume nelle stanze disopra. 6. Certuni pare che gòdano delle sventure altrui. 7. Se non mi raccontate tutto per filo e per segno (exactly), non ne faremo nulla. 8. Dite sempre la verità se volete che altri vi stimi. 9. Coloro che non possèggono nulla sono sempre i più generosi. 10. Niente è inùtile, ogni cosa ha la sua ragion d'èssere.

Possessive Pronouns. The possessive pronouns are possessive adjectives used substantively. [See pages 2770-1.]

ESERCIZIO DI LETTURA

Lo svegliarsi la prima notte in càrcere[1] è cosa orrenda! Possìbile! possìbile! Io qui? E non è ora un sogno[2] il mio? Ieri dunque mi arrestàrono? Ieri mi fècero quel lungo interrogatòrio[3], che domani, e chi sa fin quando dovrà continuare? Ier sera, prima di addormentarmi, io piansi tanto, pensando ai miei genitori! Il riposo, il perfetto silènzio, il breve sonno che aveva ristorato le mie forze mentali, sembràvano avère centuplicato in me la potenza del dolore. In quell' assenza totale di distrazioni, l'affanno di tutti i miei cari, ed in particolare[4] del padre e della madre, mi si pingeva nella fantasia con una forza incredìbile. In quest' istante[5], mi dicevo, dòrmono ancòra tranquilli, o vègliano pensando forse con dolcezza a me, non punto presaghi del luogo dove io sono! Oh, felici, se Dio li togliesse[6] dal mondo prima che giunga loro la notìzia della mia sventura! Chi darà loro la forza di sostenère questo colpo? Una voce interna pareva rispòndermi: Colui che tutti gli afflitti invòcano ad àmano e sèntono in sè stessi. Colui che dava la forza a una madre di seguire il figlio al Golgota e di stare sotto la sua croce. L'Amico degli infelici, l'Amico dei mortali!

Quello fu il primo momento che la religione trionfò nel mio cuore; ed all' amor filiale[8] devo questo benefìzio. (Silvio Pèllico, "Le Mie Prigioni.")

NOTES. 1. Prison. 2. Dream. 3. Examination. 4. Especially. 5. At this moment. 6. To remove. 7. Cross. 8. Filial love.

CONVERSAZIONE

È venuto nessuno durante la mia assenza?

Sono venuti due signori, ma non hanno lasciato i loro nomi.

Chi ha i biglietti?

Ecco il mio e quello di mio fratello.

Quale bagàglio volete?

Quello del mio sòcio, perchè è più grande.

Son venuto per dirle addio, perchè parto stasera, e chi sa quando ci rivedremo.

L'accompagnerò alla stazione.

Spero che il mare sia calmo, perchè soffro molto quando il mare è agitato.

Vuol mangiare qualche cosa?

Sì, se c' è tempo.

Le chiedo scusa, signore, non l'avevo vista.

Va anche lei a Milano?

Tanto mèglio, faremo il viàggio insieme.

IMPERSONAL VERBS

The verbs that do not admit a personal subject are called impersonal.

1. Some relate to atmospheric phenomena, and are only used in the third person singular, in the infinitive, gerund, and past participle, as:

albèggia (*ahlbèh-dgee-ah*), it dawns
annotta (*ahnnòttah*), it becomes night
piove (*pee-òveh*), it rains
lampèggia (*lahmpèh-dgee-ah*), it lightens
tuona (*too-ònah*), it thunders
nèvica (*nèhveecah*), it snows
gràndina (*gràhndeenah*), it hails
gela (*dgèhlah*), it freezes

2. Many impersonal expressions are formed with the verbs *fare*, *èssere*, *andare*, *valére*, as:

fa caldo, it is hot
fa freddo, it is cold
c'è nèbbia, it is foggy
è mèglio, it is better
è giusto, it is correct
va bene, things go well
va male, things go badly
vale la pena, it is worth while

3. Other impersonal verbs have as subject an infinitive, with or without preposition, or a whole clause beginning with *che* (that), and with the verb in the *subjunctive*. These are verbs expressing:

a. Necessity, convenience, chance, as:

accade (*ahccàhdeh*), it happens
bisogna (*beesònee-ah*), it is necessary
conviene (*convee-èhneh*), it is suitable
importa (*eempòrtah*), it is of consequence
preme (*prèhmeh*), it is urgent
basta (*bàhstah*), it is enough
tocca a me, *a te*, etc., it is my, your turn

b. Appearance, satisfaction, and other sentiments, as:

pare (*pàhreh*), it seems
sembra (*sèhmbrah*), it appears
risulta (*reesoòl-tah*), it results
piace (*peeàh-cheh*), it pleases
rincresce (*reencrèh-sheh*), one is sorry
etc. etc.

4. Some of these verbs are also used personally, as: *Egli sembra ammalato*, He looks ill; *Sembra ch'egli sia ammalato*, It seems that he is ill.

5. Other verbs have a different meaning in the two constructions, as:

Egli importa vino, He imports wine.
Importa di studiare, It is of consequence to study.
Egli conviene con me, He agrees with me.
Conviene parlare, It is suitable to speak.

6. Other impersonal expressions are active or intransitive verbs used in the reflexive form, as:

si vede, one sees; *si è*, one is;
si vive, one lives; etc., etc.

7. Impersonal verbs are conjugated with the auxiliary *èssere*. A few, however, take *avére*. Those relating to atmospheric conditions may be conjugated with both *èssere* and *avére*: *è piovuto* and *ha piovuto*.

EXERCISE XXXIX.

1. In quel paese nèvica molto raramente, ma piove sempre. 2. Piove a dirotto; bisogna prèndere una carrozza. 3. Bisognerà partire di buon'ora, se vogliamo arrivare in tempo. 4. Ha grandinato e piovuto tutta la notte. 5. Non tuona più, ma lampèggia ancòra. 6. È meglio non uscire oggi; c' è molta nèbbia. 7. Andiamo; non vale la pena di star qui a parlare di cose inùtili. 8. Il tuo amico sembra molto contento; avrà fatto buoni affari in borsa. 9. Sembra ch'egli sia contento, ma veramente non è così. 10. La Rùssia ha importato una gran quantità di grano quest'anno. 11. Importa decìdersi sùbito, perchè non v'è tempo da pèrdere. 12. Lei ha già parlato abbastanza, ora tocca a me. 13. Rincresce il vedére dei giòvani così indolenti. 14. Si deve anche godére un poco in questa vita; si vive una volta soltanto.

KEY TO EXERCISE XXXIII.

1. Dress yourself quickly, because we must go away (from here). 2. Did you enjoy yourself at the theatre last night? 3. Do not approach too near the cage. 4. I begin to be tired; let us stop a little. 5. If you wish to wash your hands, I will give you some hot water. 6. The gentlemen of the second floor have complained about the service. 7. Wake me at half-past seven to-morrow. 8. At what time do you usually get up? 9. Get up; it is very late. 10. Do you remember that lady who was with us in the country last summer? 11. I remember her quite well. 12. One must never lose one's courage in misfortune. 13. Sit down, madam, and tell me everything; you know that you can rely on me. 14. Listen to me, sir, and may Heaven forbid that a day should come in which you will repent of not having listened to me.

KEY TO EXERCISE XXXIV.

1. This picture is worth nothing. 2. Be silent, your words are not worth listening to. 3. I will be silent at once, but it is certain that you will never persuade me to do what I do not like to do. 4. I was so sorry that you did not remain with us the other evening. 5. He fell, but he did not hurt himself. 6. Do not go so soon; stay a little longer. 7. I cannot give more; here is all I have. 8. We know how much your promises are worth. 9. I persuaded him to accept the employment which was offered to him. 10. If you do not like this room, I will give you another.

IRREGULAR VERBS—continued

Fourth Conjugation. 1. BATTRE, to beat, *battant, battu, je bats, tu bats, il bat, je battis.* The reflexive verb *se battre* means "to fight." The verbs conjugated like *battre* are *abattre*, to knock down, fell; *se battre*, to fight; *combattre*, to combat; *débattre*, to debate; *se débattre*, to struggle; *rabattre*, to pull down, to lower (the price).

2. CONCLURE, to conclude, *concluant, conclu, je conclus, tu conclus, il conclut, je conclus.*

3. CONDUIRE, to lead, *conduisant, conduit, je conduis, tu conduis, il conduit, je conduisis.*

A number of verbs in UIRE are conjugated in the same way. The most common of them are *construire*, to construct; *cuire*, to cook, bake; *instruire*, to instruct; *réduire*, to reduce; and *traduire*, to translate.

4. CONNAÎTRE, to know, to be acquainted with, *connaissant, connu, je connais, tu connais, il connaît, je connus.*

The "*i*" of the stem retains the circumflex accent wherever it is followed by "*t*." Other verbs conjugated in the same way are *paraître*, to appear, seem; *apparaître*, to appear, *comparaître*, to appear (before a tribunal, etc.), *disparaître*, to disappear; *reparaître*, to reappear; *reconnaître*, to recognise.

5. CONFIRE, to pickle, preserve, *confisant, confit, je confis, tu confis, il confit, je confis.*

6. COUDRE, to sew, *cousant, cousu, je couds, tu couds, il coud, je cousis.*

7. CROIRE, to believe, *croyant, cru, je crois, tu crois, il croit, je crus.*

8. CROÎTRE, to grow, *croissant, crû, je croîs, tu croîs, il croît, je crûs.* In this verb there is a circumflex accent not only over "*i*" when it is followed by "*t*," but over "*i*" and "*u*" in all the forms that would otherwise be identical with those of *croire*.

9. ÉCRIRE, to write, *écrivant, écrit, j'écris, tu écris, il écrit, j'écrivis.*

All derivatives are conjugated in the same manner. Those in most frequent use are *décrire*, to describe; *inscrire*, to inscribe; *proscrire*, to proscribe; *souscrire*, to subscribe; and *transcrire* to transcribe.

10. JOINDRE, to join, *joignant, joint, je joins, tu joins, il joint, je joignis.*

All verbs of which the infinitive ends in *aindre*, *eindre*, or *oindre*, are conjugated like this. The following are some of them: *contraindre*, to constrain; *ceindre*, to gird; *feindre*, to feign; *atteindre*, to reach; *teindre*, to dye; *enfreindre*, to infringe; *peindre*, to paint; *rejoindre*, to overtake; *oindre*, to anoint; and the reflexive verb *se plaindre*, to complain.

11. LIRE, to read, *lisant, lu, je lis, tu lis, il lit, je lus.*

12. METTRE, to put, put on, *mettant, mis, je mets, tu mets, il met, je mis.*

The numerous derivatives of this verb follow the same conjugation. Amongst them are: *admettre*, to admit; *commettre*, to commit; *compromettre*, to compromise; *omettre*, to omit; *permettre*, to allow; *promettre*, to promise; *soumettre*, to submit.

13. MOUDRE, to grind, *moulant, moulu, je mouds, tu mouds, il moud, je moulus.*

14. NAÎTRE, to be born, *naissant, né, je nais, tu nais, il naît, je naquis.*

This verb is conjugated with *être* in its compound tenses: *je suis né*, I was born.

15. NUIRE, to injure, *nuisant, nui, je nuis, tu nuis, il nuit* (*je nuisis*).

According to the Academy, *nuire*, and *luire*, to shine, conjugated like it, have no past definite.

16. PLAIRE, to please, *plaisant, plu, je plais, tu plais, il plaît* (with circumflex accent), *je plus.*

The derivatives *complaire*, to gratify; *déplaire*, to displease; the reflexive verb *se plaire à*, to delight in; the verb *taire*, to conceal, hush up; and the reflexive *se taire*, to be silent, are all conjugated like *plaire*.

17. PRENDRE, to take, *prenant, pris, je prends, tu prends, il prend, nous prenons, ils prennent, je pris.*

This verb doubles the "*n*" before the endings *e, es, ent.* It has numerous derivatives which are conjugated like it, and amongst which are *apprendre*, to learn; *comprendre*, to understand; *entreprendre*, to undertake; *surprendre*, to surprise.

18. REPAÎTRE, to feed, to feast, is derived from *paître*, to graze; *repaissant, repu, je repais, tu repais, il repaît, je repus.*

This verb is also used reflexively: *se repaître*, and chiefly figuratively.

19. RÉSOUDRE, to resolve, solve, *résolvant, résolu, je résous, tu résous, il résout, je résolus.*

This verb also means to dissolve from one substance into another, and then has *résous*, *résoute*, for its past participle. *Absoudre*, to absolve, and *dissoudre*, to dissolve, are conjugated in the same way; but their respective past participles are *absous*, m., *absoute*, f., and *dissous*, m., *dissoute*, f., *Absolu* and *dissolu* are adjectives meaning absolute and dissolute.

20. RIRE, to laugh, *riant, ri, je ris, tu ris, il rit, je ris.*

Sourire, to smile, follows the same conjugation.

21. SUFFIRE, to suffice, *suffisant, suffi, je suffis, tu suffis, il suffit, je suffis.*

22. SUIVRE, to follow, *suivant, suivi, je suis, tu suis, il suit, je suivis.*

23. VAINCRE, to overcome, *vainquant, vaincu, je vaincs, tu vaincs, il vainc, je vainquis.*

Convaincre, to convince, is conjugated in the same way.

24. VIVRE, to live, *vivant, vécu, je vis, tu vis, il vit, je vécus.*

This verb has two derivatives, conjugated like it, *revivre*, to revive, and *survivre*, to survive.

EXERCISE XXXII.

1. When the ancients besieged (*assiéger*) a town they battered (beat) the walls with (*à coups de*) ram(s) (*le belier*).

2. One is never beaten without being struck (*frapper*); but one may (*peut*) be struck without being beaten.

3. The muleteer (*muletier*) who served us as (*de*) guide, beat his mules in a frightful (*épouvantable*) way (*la façon*).

4. We have concluded nothing, but that is not my fault.

5. He is an author whose works (*ouvrage*, m.) have been translated into all languages (*la langue*).

6. According to a distinguished writer (*écrivain*), if you always translate, you will never be translated; and yet (*cependant*) another writer, just (*tout*) as distinguished, has said that if you wish (*voulez*) to be translated (that one translate, *subj.*) some (*un*) day, you must yourself begin by translating.

7. I have seen him only once, but I should know him amongst (a) thousand.

8. That young girl sews, sings, reads; that is all she needs to be happy.

9. Who is it that used to say that, wherever (*partout où*) the lion's skin did not suffice, the fox's (*renard*) skin was to be sewn to it—that is to say, cunning (*la ruse*) to be joined to strength (*la force*)?

10. There are people who account the rest (*le reste*) of men as (*pour*) nothing, and think (believe) they are (to be) born only for themselves.

11. An honourable (*honnête*) man who says yes and no deserves (*mériter*) to be believed; his character (*le caractère*) swears for him.

12. Any (*tout*) author whom one is obliged to read twice to understand (*entendre*) him, writes badly.

13. What is written is written means (*veut dire*) that one can change nothing in (*à*) what is written.

14. The Good Shepherd (*pasteur*) has said: "I know my sheep and my sheep know Me."

15. It is admitted by all civilised (*civiliser*) peoples that the person of an ambassador is inviolable and sacred.

16. You depict (paint) the charms (*le charme*) of country (*champêtre*) life so well to us that you make us feel inclined to (*donner l'envie de*) go (and) live (*habiter*) in a (*au*) village.

17. The Gauls (*Gaulois*) used to transmit (the) news (*les nouvelles*) to each other by (*en*) lighting fires on the heights (*la hauteur*).

18. The days lengthen (grow) from the 21st of December to the 21st of June; they draw in (*décroître*) from the 21st of June to the 21st of December.

19. Men are like the flowers which appear and disappear with an incredible (*incroyable*) rapidity (*la rapidité*).

20. On the 11th of November, 1572, a new star appeared suddenly (*tout à coup*) in the sky, where it shone (*briller*) with (*de*) the most vivid (*vif*) brilliancy (*éclat*, m.); it disappeared in the month of May, 1574, after having lasted 16 months.

21. We read in Genesis (*la Genèse*) that the ancient patriarchs (*le patriarche*) lived a very long time, and that Abraham lived 175 years.

22. We write from left to right; the Jews write from right to left (*gauche*); the Arabs (*Arabe*) write similarly (*également*) from right to left.

23. The French overcame the Austrians (*Autrichiens*) at Jemmapes and at Marengo; they were overcome by the English at Waterloo.

24. The ancients used to grind corn with little millstones (*la meule*) worked (*mues*) by hand (*à bras d'hommes*).

25. Unjust actions always injure (to) their authors.

26. Cleopatra (*Cléopâtre*) took a large pearl (*la perle*) which she threw into a cup (*la tasse*), and, when she had seen it dissolved, she swallowed (*avaler*) it.

27. You laugh, and with reason, at (of) the folly (*les sottises*) of men, at which I should do (*ferais*) well to laugh also, and at which I would laugh if my digestion were better (if I digested, *digérer*) and if I slept better.

28. What (a) passion is (*que*) envy! It follows the man of merit even to (*jusqu'à*) the brink (*le bord*) of his grave (*la tombe*).

In all verbs the endings of the Imperfect Indicative, of the Past Definite, of the Future, of the Present Conditional, and of the Imperfect Subjunctive, are regular, whatever peculiarities there may be in the stem. Consequently, only the first person singular of those tenses will be indicated. Except in special cases, the Imperative will not be given, as its first and second persons are identical with the corresponding persons of the Present Indicative, and its third persons borrowed from the Present Subjunctive.

First Conjugation

1. **Aller,** to go, *allant, allé.*

Ind Pres.—je vais, tu vas, il va, nous allons, vous allez, ils vont.

Imperf.—j'allais. *Future.—j'irai.*

Past Def.—j'allai. *Cond. Pres.—j'irais.*

Imperat.—va, qu'il aille, allons, allez, qu'ils aillent.

Subj. Pres.—que j'aille, que tu ailles, qu'il aille, que nous allions, que vous alliez, qu'ils aillent.

Imperf.—que j'allasse.

The imperative *va* takes *s* when followed by *y*: *vas-y*, go there.

The compound tenses of *aller* are conjugated with the auxiliary *être*.

Idiomatic Uses of Aller. (*a*) *Aller* is used, in connection with another verb in the Infinitive, to express a proximate future, and then means "to be going to," "to be about to," "to be on the point of": *Je vais vous le donner*, I am going to give it to you; *J'allais vous écrire*, I was going to write to you.

(*b*) *Aller* also means "to suit," "to fit." It is frequently used instead of *se porter*, with reference to the state of health: *Son habit ne lui va pas*, His coat does not fit him; *Comment allez-vous? Comment vous portez-vous?* How do you do?

(*c*) *Aller* is used in the following expressions: *aller se promener*, to go for a walk; *aller à pied*; to walk (go on foot); *aller en voiture*, to drive, *aller à cheval*, to ride; *aller en bateau*, to go for a

sail; *y aller de* (impersonal), to be at stake; *il y va de la vie*, life is at stake.

(*d*) The Imperative of *aller* is used to form interjections: *Va! Allez!* Believe me; I can tell you; Surely. *Allons!* Come! Come now! *Allons donc!* Get away! Nonsense!

2. **S'en aller,** to go away, *s'en allant, s'en étant allé.*

Ind. Pres.—je m'en vais, tu t'en vas, il s'en va, nous nous en allons, vous vous en allez, il s'en vont.

Past Indef.—je m'en suis allé, tu t'en es allé, il s'en est allé, elle s'en est allée, nous nous en sommes allés, vous vous en êtes allés, ils s'en sont allés, elles s'en sont allées.

All the other tenses are conjugated in this way, by putting *m'en, t'en, s'en, nous en, vous en, s'en* between the subject and the verb.

Imperat. (positive).—*va-t'en, qu'il s'en aille, allons-nous-en, allez-vous-en, qu'ils s'en aillent.*

Imperat. (negative). *ne t'en va pas, qu'il ne s'en aille pas, ne nous en allons pas, ne vous en allez pas, qu'ils ne s'en aillent pas.*

The following examples will show the order of the words in interrogative and negative forms:

T'en vas-tu? Are you going away? *S'en est-il allé?* Has he gone away? *Je ne m'en vais pas,* I am not going away; *Ils ne s'en seraient pas allés,* They would not have gone away; *Ne vous en irez-vous pas?* Will you not go away? *Ne s'en est-elle pas allée?* Has she not gone away?

3. **Envoyer,** to send, *envoyant, envoyé, j'envoie, j'envoyai.*

The only irregular tenses of this verb are the Future and the Conditional.

Future.—j'enverrai. Conditional.—j'enverrais.

Key to Exercise XXX.

1. La terre est échauffée par le soleil.
2. L'égoïste n'est aimé de personne.
3. Les chiffres ont été inventés par les Arabes.
4. La femme fut trompée par le serpent.
5. Les orages sont prévus et annoncés par les hirondelles.
6. L'Amérique fut découverte par Christophe Colomb en mil quatre cent quatre-vingt-douze.
7. L'imprimerie fut inventée par Gutenberg dans le quinzième siècle.
8. Le cap de Bonne-Espérance fut doublé pour la première fois par les Portugais.
9. Quand êtes-vous revenu de Paris?
10. Quel jour vos amis sont-ils partis pour Londres?
11. Depuis que la comète est apparue une foule de gens passent la nuit à la regarder.
12. Quand nous sommes arrivés à la gare le train était déjà parti.
13. Il semble que le soleil tourne autour de la terre, quand, au contraire, il est certain que c'est celle-ci qui tourne autour du soleil.
14. S'il gèle le matin, il fait souvent beau toute la journée.
15. Il faut qu'une porte soit ouverte ou fermée, dit un proverbe français.
16. Je vous ai tout dit. Que vous faut-il de plus?
17. C'est justement ce qu'il me faut; merci.
18. Ses amis sont des gens très comme il faut.
19. Il s'en est fallu de bien peu qu'il ne fût tué.
20. Pour bien parler, il faut dire ce qu'il faut, tout ce qu'il faut, rien que ce qu'il faut, et le dire comme il faut.

Key to Exercise XXXI.

1. Notre brigade assaillira l'ennemi dans ses retranchements demain matin.
2. Quelques coups de feu partent; à ce bruit Napoléon tressaille; la campagne de Russie est ouverte.
3. Tout le monde sait que c'est Christophe Colomb qui a découvert l'Amérique.
4. Il n'ouvre jamais la bouche sans dire quelque sottise.
5. Le bruit qui se faisait dans l'assemblée couvrait la voix de l'orateur.
6. Il est certain que la mer a autrefois couvert une grande partie de la terre habitée.
7. L'eau bouillirait plus vite si vous allumiez un bon feu.
8. François premier dormit sur un affût la nuit de la bataille de Marignan.
9. Nous nous endormons tous les soirs pendant qu'il nous lit le journal.
10. Lorsque nous étions jeunes nous dormions douze heures sans nous réveiller.
11. Isaac ayant demandé à son père où était la victime qui devait être immolée, Abraham répondit: "Dieu y pourvoira."
12. Charles le Téméraire périt devant Nancy, trahi par un mercénaire napolitain, et tué en fuyant après la bataille, par un gentilhomme lorrain.
13. Fuyons ensemble au fond des forêts; il vaut mieux se fier aux tigres qu'aux hommes.
14. Il y a des gens qui mentent simplement pour mentir.
15. La satire ment sur les gens de lettres pendant leur vie, et l'éloge ment après leur mort.
16. On lui a offert une place à Paris, mais il ne désire pas quitter Londres.
17. Il est utile aux superbes de tomber, parce que leur chute leur ouvre les yeux.
18. On est ordinairement moins fâché quand on part que quand on voit partir.
19. Nous aurions dû partir pour la campagne hier, mais nous ne partirons que demain.
20. Quand tu mens, la conscience ne te reproche-t-elle pas quelque chose, et ne te repens-tu pas aussitôt?
21. Le juge qui est fidèle à son devoir ne sent ni regrets ni courroux.
22. Il y a des gens qui semblent croire que le bonheur de les servir est une assez haute récompense pour ceux qui les servent.
23. Sortez quand vous voudrez, mais je vous avertis que je ne sortirai qu'après que vous serez sortis.
24. Est-ce la peine de vivre quand on souffre? Oui, car on espère toujours qu'on ne souffrira pas demain.
25. Le malheur de ces gens qui savent tout, c'est qu'ils ne prévoient jamais rien.

SPANISH Continued from page 4388 By Amalia de Alberti & H. S. Duncan

IRREGULAR VERBS—continued

Third Class

This class embraces verbs of the third conjugation with a radical *e*, which is never expanded to *ie*, but changes into *i*:

1. Throughout the present indicative, excepting the first and second persons plural.
2. Throughout the present subjunctive.
3. Throughout the imperative, excepting the second person plural.
4. Throughout the rest of the conjugation, whenever the verbal termination contains the diphthong *ie* or *io*.

Servir, to serve. Gerund, *sirviendo*. *Ind. Pres.—sirvo, sirves, sirve, servimos, servis, sirven.*

Past Def.—serví, serviste, sirvió, servimos, servisteis, sirvieron.

Imperat.—sirve, sirva, sirvamos, servid, sirvan.

Subj. Pres.—sirva, sirvas, sirva, sirvamos, sirvais, sirvan.

Subj. Imp.—sirviera, sirvieras, sirviera, sirviéramos, sirvierais, sirvieran, or *sirviese, sirvieses*, etc.

Subj. Fut.—sirviere, sirvieres, sirviere, sirviéremos, sirviéreis, sirvieren.

The imperfect and future of the indicative and the conditional are regular.

Euphonic Changes. Verbs of this class ending in *eir* change *e* into *i* as usual, but drop the *i* of the diphthong *ie* in the verbal terminations in order to avoid the double *i*.

Reir, to laugh. Gerund, *riendo*. *Subj. Imp.—riera, rieras, riera, riéramos, rierais, rieran.*

These verbs also follow the same euphonic changes as the regular verbs—*viz.*: Those ending in *gir* change *g* into *j* before *a* and *o*.

Regir, to rule. *Ind. Pres.—rijo, riges, rige, regimos, regis, rigen.*

Subj. Pres.—rija, rijas, rija, rijamos, rijais, rijan.

Those in *guir* drop the *u* before *a* and *o*.

Seguir, to follow. *Ind. Pres.—sigo, sigues, sigue, seguimos, seguis, siguen.*

Subj. Pres.—siga, sigas, siga, sigamos, sigais, sigan.

Verbs ending in *ñir* drop the *i* of the diphthongs *ie* and *io* in the verbal termination.

Ceñir, to gird. Gerund, *ciñendo*.

This change is optional with verbs whose ending is *ch*; thus the gerund of *henchir*, to fill, may be either *hinchiendo* or *hinchendo*.

List of verbs of the third class, changing the radical *e* into *i*:

ceñir, to gird
colegir, to deduce
competir, to compete
concebir, to conceive
conseguir, to obtain
constreñir, to constrain
controvertir, to controvert
derretir, to melt
desceñir, to ungirdle
despedir, to take leave
desteñir, to discolour
elegir, to elect
embestir, to attack
expedir, to despatch
freir, to fry
gemir, to lament
henchir, to fill
heñir, to knead
impedir, to prevent
investir, to invest
invertir, to invert
medir, to measure
pedir, to ask
perseguir, to persecute
proseguir, to prosecute
receñir, to re-gird
reelegir, to re-elect
rendir, to render, surrender
reñir, to quarrel
repedir, to re-demand
repetir, to repeat
reteñir, to re-dye
revestir, to dress
seguir, to follow
servir, to serve
teñir, to dye
vestir, to clothe

Fourth Class

Irregular verbs of the fourth class end in *uir* and *güir*. The peculiarity of these verbs is the insertion of a *y* before the verbal termination:

1. Throughout the present indicative, excepting the first and second persons plural.
2. Throughout the present subjunctive.
3. Throughout the imperative, excepting the second person plural.
4. Throughout the rest of the conjugation, whenever the verbal termination should contain the diphthongs *ie* or *io* a *y* is substituted for the *i*.

Verbs ending in *güir* drop the diæresis before *y*.

Huir, to flee. Gerund, *huyendo*.

Ind. Pres.—huyo, huyes, huye, huimos, huis, huyen.

Past Def.—huí, huiste, huyó, huimos, huisteis, huyeron.

Imperat.—huye, huya, huyámos; huid, huyan.

Subj. Pres.—huya, huyas, huya, huyámos, huyais, huyan.

Subj. Imp.—huyera, huyeras, huyera, huyeramos, huyerais, huyeran, or *huyese*, etc.

Subj. Fut.—huyere, huyeres, huyere, huyeremos, huyereis, huyeren.

Argüir, to argue. Gerund, *arguyendo*.

Ind. Pres.—arguyo, arguyes, arguye, argüimos, argüis, arguyen.

The imperfect, future, and conditional of the indicative are regular.

All the following verbs are conjugated according to the above rule.

atribuir, to attribute
concluir, to conclude
constituir, to constitute
construir, to construct
contribuir, to contribute
destituir, to make destitute
destruir, to destroy
diluir, to dilute
disminuir, to diminish
distribuir, to distribute
estatuir, to enact
excluir, to exclude
fluir, to flow
imbuir, to imbue
incluir, to include
instituir, to institute
obstruir, to obstruct
prostituir, to prostitute
recluir, to seclude
reconstruir, to reconstruct
redargüir, to retort
refluir, to ebb
restituir, to restore
sustituir, to substitute

Vocabulary—Vocabulario

A witch	Una bruja	An oak	Un roble
Witchcraft	Brujeria (f.)	A lemon-tree	Un limonero
A sorcerer	Un brujo	An orange-tree	Un naranjo
A compass	Una brujula	A palm-tree	Una palmera
The mist	La bruma	A fig-tree	Una higuera
A brute	Un bruto	An ash-tree	Un fresno
To nod	Cabezear	A strawberry-plant — a strawberry-bed	Un fresal
The corpse	El cadáver	A raspberry-bush	Un frambueso
The locksmith	El cerrajero	A pomegranate-tree	Un granado
The bolt	El cerrojo	The reeds, rushes	Los juncos
The brewer	El cervecero	A laurel-tree	Un laurel
The beer	La cerveza	A mulberry-tree	Un moral
The basket	El canasto	A walnut-tree	Un nogal
A gift	Una dádiva	An olive-tree	Un olivo
A dagger	Una daga	An elm	Un olmo
Delight	Deleite (m.)	A poplar	Un álamo blanco
To date	Fechar	A pine-tree	Un pino
Weak	Débil	A pear-tree	Un peral
The tree	El árbol	An apple-tree	Un manzáno
An apricot-tree	Un albericoque	A plum-tree	Un ciruelo
An acacia	Un acácia	A willow	Un sauce
An almond-tree	Un almendro	A weeping willow	Un sauce lloron
A birch-tree	Un abedul	A lime-tree	Un tilo
The heather	El brezo		
Box (shrub)	Boj		
A cedar	Un cedro		
A cherry-tree	Un cerezo		
A chestnut-tree	Un castaño		
An evergreen oak	Una encina		

Exercise XVI. (1)

Translate the following into Spanish :

1. Honours are gained in serving one's country.

2. To follow bad example is evil; let us always follow good [example].

3. In girding on his sword he cried " Long live the King!"

4. We do not compete with that firm ; its prices are ridiculously low.

5. Do not buy this cloth : the colour comes out and stains the hands.

6. We cheerfully take leave of a disagreeable and tedious guest.

7. It is difficult to choose a travelling companion, but once chosen, one must be [on good terms] (*avenirse*) with him until the end of the journey.

8. One must reflect before investing one's patrimony, as when invested one runs the risk of being unable to withdraw it.

9. Let us measure the cloth before cutting out the cloak, and cut it according to the measure.

10. They pursued the enemy until they could proceed no further.

11. To quarrel with one's friends is the action of fools.

12. Let us contribute good works for the good of our neighbours, but let the contribution be judicious.

Exercise XVI. (2)

Translate the following into English :

1. Es tan vieja y fea que parece una bruja.

2. ¡ Lastimó à ese niño, es un bruto !

3. Ese hombre es un cervecero, ha ganado su fortuna vendiendo cerveza.

4. Me enseñó una daga muy antigua, es de un trabajo hermoso.

5. El fresal de mi jardin tiene de extension media legua.

6. En el huerto hay árboles frutales muy hermosos.

7. Los higos, las peras, y las manzánas son muy deliciosos.

8. El brezo crece en los montes.

9. Los limones y naranjas que crecen en nuestros limoneros y naranjos tienen fama por lo bueno que son. Tambien nuestros fresales crian fresas de gran tamaño.

10. La flor del granado es tan bonita como su fruta.

11. Es la moda de hacer muebles de junco, son bonitos pero poco duraderos.

12. El baj de la Alcazar de Sevilla es celebrado por su antiguedad y hermosura.

13. Con almendras y avellana se hacen en España un dulce que llaman turron que es muy bueno.

14. Los olivares son tristes y melancolicos, el verde de su follaje es cási negro.

Key to Exercise XV. (1)

1. Hemos cerrado todas las puertas, y ahora cierren Vds las ventanas.

2. No vale la pena rogar que lo perdonen ; ruegen Vds si quieren.

3. El olor de esas flores es un verdadero perfume.

4. Es dificil adquirir fama, y aún mas dificil conservarla despues de adquirida.

5. Es bueno alentar á la juventud ; yo la aliento siempre.

6. Es dificil aprobar cuando un amigo nos critica con verdad ; la aprobacion de los que nos rodean es necesaria para nuestra felicidad.

7. ¡ Hay que atender á nuestros negocios !

8. Tengamos cuidado al atravesar la plaza ; yó la atravieso siempre mirando á la derecha, y á la izquierda.

9. Dice el refran que no hay peor ciego que aquél que no quiere ver. El ser ciego acerca de nuestros defectos es natural.

10. Nuestra amistad fué cimentada hace años cuando sufrimos juntos. Las tribulaciones son buenas para cimentar buenas relaciones.

11. Este cuarto necesita que se caliente, y hay que calentar tambien el almuerzo.

Key to Exercise XV. (2)

1. The political exile to which he was condemned made his fortune when his party returned to power.

2. To awaken the anger of a passionate person is dangerous ; once awakened it is difficult to appease.

3. It is more difficult to man to govern his passions than to govern a nation.

4. I absolutely deny having said such a thing, and when they confront me with him, he will not be able to deny it.

5. It is said that it is better to patch one's cloak in time than to let the patch be bigger than the cloak.

6. He who sows thorns cannot expect flowers to spring up ; it is better to sow good seed than to sow thistles.

7. The fool dreams what he will, and the wise man what he can. Dreaming cannot be commanded.

Prose Extract XIII.

From a short story by Juan Ochoa, entitled :

" Liberty."	" Libertad."
Shade, shade of green leaves, was what both sought for in their hours of love.	Sombra, sombra de hojas verdes, era lo que buscaban ambos en las horas de amor.
How they sang together that spring! What tender things they said to each other on a tree-top swayed by the breeze !	¡ Cuanto cantáron juntos aquella primaverá. ¡ Cuantas ternezas se dijeron los dos en la copa de un árbol agitado por la brisá !
If looking up at the sky she burst into ecstatic song he would listen attentively with his tiny quivering head on one side, and when the last notes died away upon the beak of his mate he would shake his feathers, draw himself up prettily, and in his turn intone the lay of ardent love. The most magnificent and long-winded of linnets ! He was large and beautifully sleek of plumage. He had suffered grave and perilous adventures in his life. One morning he fell into a snare ; he saw four children wild with glee running towards him ; then he made a supreme effort and escaped ; leaving feathers behind, he bought the liberty of his wings with blood, but he succeeded in flying to the thicket, to the dark nooks of foliage, to the leafy home of his dreams. He flew far that day, eagerly drinking in the joy of liberty, and with a blow of his beak sle spide whe he surprised, lying in ambush for a fly.	Si ella mirando al cielo se arrobaba en su canción oiala él atento, ladeando un poco la cabecita temblorosa ; y cuando morían las ultimas notas en el pico de su compañera, sacudiase las plumas, se erguia con gentileza para entonar tambien la trova del amor ardiente ¡ Gilguero de más inspiración á más fachenda ! Era grande y tenía el plumaje limpio y hermoso. Habiá pasado en la vida sus aventuras serias y graves. Una mañana cayó preso en liga ; vió correr hacia él cuatro chiquillos locos de gozo ; hizo entonces un esfuerzo supremo y escapó, dejó allí plumas, compró con sangres la libertad de sus alas, pero logró huir á la espesura, á los rincones sombrios del follaje, al hogar de hojas de sus sueños. Aquel dia voló mucho, bebió con ansia la dicha de ser libre, y á una araña que sorprendió acechando matóla de un picotazo.
What labour love laid upon him and his mate ! Luckily she turned out the most industrious and wisest bird ever seen. She was up to everything. Thread, shreds, fluff, horsehair—she carried everything home in her beak to make the nest, and while her lover twisted and wove these	¡A cuantos afanes les llevó el amor, á él y á su compañera ! Gracias que ésta salió la pájara mas hacendosa y sabihonda que se habia visto. Estaba en todo. Hilos, brignos, tamo, cerdas, todo se lo colgaba del pico, y lo tráia á casa para el nido ; y mientras su amante emarañaba y

materials, she watched him lovingly, twittering softly, and suggesting her own plans also.

Thus they raised a temple to their love, and therein were happily united, hidden in mysterious foliage, having the blue of heaven, the rays of the sun, the caresses of the breeze, and the music of leaves for their wedding present.

They had a family, four rapacious imps who were transformed into mouths as soon as they smelt food; they had to be fed—expeditions must be made in search of food; they spent the whole day at it. The warmth of their feathers, the bread out of their mouths—nothing sufficed the gluttons. What drudgery!

One day when feathers had begun to grow on the

tejía aquellos materiales, ella le contemplaba enamorada, charloteando en voz baja y dando tambien sus planes.

Asi elevárou á su amor un templo, y en el se unieron felices, escondidos en la fronda misteriosa teniendo como regalo de bodas aquel cielo, rayos de sol, caricias de la brisa, música de hojas.

Tuvieron hijos; cuatro diablejos tragones, que todos se volvian boca en cuanto olian comida; había que cebarlos había que salir y buscar alimentos. En esto se pasaban el día. El calor de sus plumas, el pan de sus bocas—todo era poco para aquellos golosos. ¡Que fatigas!

Cuando los pequeñuelos ...menzáron á echar

little ones, and the tree was enlivened by their twitter, their parents went out in search of food. They returned at nightfall—they found no nest nor birds in the tree, there were none to feed. Then came mournful love, the wailing song, the measureless lament, which lost itself in the solitude of the grove. When night drew in they kept the vigil of their sorrow together above the ruins of the nest; they never closed their eyes, and they had no song to greet the light of dawn that day.

Juan Ochoa (1864–1899), a young author and journalist whose early death was a great loss to Spanish literature. He is renowned for the delicate beauty of his short stories.

pluma y alegrában el árbol con su charla, salieron un día los padres en busca de alimento. Volvieron al obscurecer. No halláron en el árbol nido ni pájaros, no tuvieron á quien cebar. Entonces comenzó el amor triste, el cantar llorando, la queja inmensa que se perdió en la soledad de la árboleda. Cuando cerró la noche, veláron juntos su dolor, sobre las ruinas del nido; no pegáron los ojos, y á la luz del alba de aquel dia no la saludáron cantando.

Juan Ochoa (1864–1899), un joven autor y periodista cuya temprana muerte fué una gran pérdida para la literatura española. Es afamado por la delicada hermosura de sus cuentos.

ESPERANTO

By Harald Clegg, F.B.E.A.

Esperanto is an artificial language perfected in 1887 by Dr. Louis Zamenhof, an oculist and linguist of Warsaw, and is so called from his pen name, "Dr. Esperanto" (the hoping one). It is intended to serve the purpose of an auxiliary language for international use, and possesses the advantages of extreme simplicity, logical construction, flexibility, and adaptability to present and future requirements, as well as ease of oral comprehension.

The language is now taught at many continental universities, lycées and military colleges, and is rapidly gaining favour at grammar schools and colleges in this country. The London County Council has made it a subject for instruction in its schools.

The lessons appearing in this course have been carefully graduated, it being assumed, however, that the student knows already the meanings of ordinary grammatical terms. He should aim first at reading, then at writing, and finally at speaking the language with ease.

THE ALPHABET

The Esperanto alphabet has 28 letters—*viz.*:

A (*a*)	B (*bo*)	C (*co*)	Ĉ (*ĉo*)
D (*do*)	E (*e*)	F (*fo*)	G (*go*)
Ĝ (*ĝo*)	H (*ho*)	Ĥ (*ĥo*)	I (*i*)
J (*jo*)	Ĵ (*ĵo*)	K (*ko*)	L (*lo*)
M (*mo*)	N (*no*)	O (*o*)	P (*po*)
R (*ro*)	S (*so*)	Ŝ (*ŝo*)	T (*to*)
U (*u*)	Ŭ (*ŭo*)	V (*vo*)	Z (*zo*)

The consonants are pronounced exactly as in English, with the following exceptions:

c as *ts* in its
ch hurch
g ,, gun or mug
g ,, gent or *dg* in edge
h ,, hot (always aspirated)
h ,, *ch* ,, loch (or German *ch*)

This is the sound of the ordinary *h* gutturally pronounced, and with considerable aspiration. It is represented phonetically by *kh*.

j as *y* in you, yet
ĵ ,, *zh*, or like *s* in pleasure
s ,, *s* in sit or bus
ŝ ,, *sh* in show, shift
ŭ. This letter, which is a consonant and equivalent to the English *w*, can never stand alone. It is always preceded either by *e* or *a*, and pronounced approximately thus:

aŭ as *ow* in cow; eŭ as *ay-oo* in gray-ooze,

the sounds being uttered close together, with one emission of the voice, so as to produce a single syllable. It must be understood that this example (gray-ooze) is not perfect—the true sound of *eŭ* not being found in any English word.

The five vowels are pronounced as follows, all being pure sounds and of medium length:

a as *ah*.
e as *eh*.
i as *ee* in *teem*.
o as oh (very round and entirely avoiding any approach towards *ow*.)
u as *oo* in *boot*.

Every vowel, no matter where placed in a word, is always clearly pronounced.

Besides the two combinations above there are four others, *aj*, *ej*, *oj*, and *uj*. Remember that the *j* here still retains the sound of the English *y* as before stated, so that these combined letters become: *ahy* (*al y*), *ehy*, *ohy*, and *ooy*, the sounds being found in: *pie*, *play*, *boy*, and *quill*. Each of these four combinations represents, of course, but one syllable.

Every word is *pronounced as written*. There are *no silent letters*. The *tonic accent* in every word which is not a monosyllable falls on the *penultimate* (last syllable but one). Give every letter its full sound and pronounce *nacio nah-tsee'-oh*, *alia ah-lee'-ah*; not *nah'ts-yoh* and *ahl-yah*. Slightly roll the letter *r* so that no ambiguity will arise when such words as *karto* and *kato* are pronounced.

Imitated Pronunciation. Read aloud the following words, carefully observing the pronunciation printed by each:

(The stressed syllables are indicated by accents.)

buŝo (*boo'-shoh*), multaj (*mool'-tahy*), tridek (*tree'-dehk*), Novembro (*Noh-vehm'-broh*), naskita (*nahs-kee'-tah*), infanojn (*een-fah'-nohjn*), amuze (*ah-moo'-zeh*), hodiaŭ (*hoh-dee'-ow*), klerulo (*kleh-roo'-loh*), neuzi (*neh-oo'-zee*), Eŭropo (*Ehoo-roh'-poh*), monaĥo (*moh-nah'-kho*), *scienca (*stsee-ehn'-tsah*) pezilo (*peh-zee'-loh*), ĉenigi (*cheh-nee-gee*), laciĝa (*lah-tsee-*

dgah), foriru (*foh-ree'-roo*), celante (*tseh-lahn'-teh*), nenion (*neh-nee'-ohn*), ĥinujo (*khee-noo'-yoh*), ŝipanaro (*shee-pah-nah'-roh*), plenaĝulo (*pleh-nah-dgoo'-loh*), ĵurintaj (*zhoo-reen'-tahy*), ie (*ee'-eh*), maja (*mah'-yah*), revolucio (*reh-voh-loo-tsee'-oh*), tiuj (*tee'-ooy*), iliaj (*ee-lee'-ahy*).

* The exact sound of *sc* is found in the last three letters of "mists" (mi*sts*).

THE ARTICLE

There is but one article in Esperanto—*la* (the), which remains the same for all genders, cases, and numbers. The indefinite articles, *a*, *an*, are not translated. The use of the definite article in Esperanto is very much the same as in English. It is used when the noun which follows must be distinguished from others of the same species. Ex.: *I have the* (*la*) *money* (the money which has been previously mentioned or referred to), which is different in meaning from *I have money*. *I sold the* (*la*) *horse* (a horse which must be distinguished from others). Nouns of abstract quality take the article *la*, as *La fiereco* (pride); so do all the arts and sciences, as: *La zoologio* (zoology), *la kantarto* (singing). The same remark applies to nouns indicating a whole species, as: *La homaro* (humanity), *la bestaro* (the animal kingdom). Generally speaking, the sense of a phrase determines the necessity for employing the definite article, but in all cases of doubt it should be omitted.

THE NOUN

As will be seen by reference to the vocabularies, Esperanto words are built up from roots which are given a definite meaning, and to this particular attention must be paid. Some of the roots are by nature essentially substantival, others adjectival or verbal, and in adding *o* to form the substantive, *a* to form the adjective, etc., care must be taken to see that the word so constructed bears a translatable meaning. The force of this remark will appear later when the *terminations* have been fully dealt with.

Nouns are formed by adding *o* to the root, when *singular* and in the *nominative* case.

Thus: *Infan-o, dom-o, patr-o, pord-o.*

To form the *plural*, add *j* to the *o*, thus making the words *infanoj, domoj, patroj, pordoj.*

When, however, the noun (singular or plural) is in the *accusative case*—*i.e.*, when it is affected by some transitive verb of which it is the direct object—a final N is added. Ex.: I have a fine house (*domon*); He sold me two doors (*pordojn*).

In the latter phrase, *me* is the indirect object of the verb, and in Esperanto is governed by a preposition. Here it may be advisable to explain why Esperanto uses an accusative case, and thus adopts an apparent complication which other languages have abandoned as unnecessary. In English, however, we see it in the pronouns:

I (nominative), me (objective), they (nominative), them (objective), and so on, but nouns in the nominative and objective cases are alike. In a phrase such as "Father likes mother more than you" we cannot tell whether father's liking for mother excels yours, or whether father prefers mother to you. There is, moreover, another use for the Esperanto accusative which will be dealt with in a subsequent lesson. This one simple principle, while allowing freedom to the order of words in a phrase, permits a single conjugation of the verb and does away with the necessity for duplicating pronouns. As a consequence, Esperanto is more supple than any natural language, and far more precise in the meanings it has to convey. Confusion, such as the above English phrase exhibits, can never arise in Esperanto, thanks to the adoption of one general rule, which, after all, is easily grasped.

Nouns in Esperanto have no possessive case, this being rendered by *de* (of). Sometimes a possessive noun may be conveniently translated by an adjective.

Ex.: *Ŝafa felo* (sheep's skin).

THE VERB

The whole of the moods, tenses, and participles of Esperanto verbs are formed by the addition of twelve terminal particles to the roots. Their conjugation is absolutely regular.

The *infinitive mood* of the verb is formed without exception by adding *i* to the root. Ex.: *Kuri*, to run; *fermi*, to shut. The sole auxiliary verb is *esti* (to be) which entirely displaces the use of equivalents for the English auxiliaries *to have* and *to do*.

The *present tense* is formed by the addition of *as* to the root word, and this form is used for 1st, 2nd, and 3rd persons, both singular and plural. Ex.: Infants sing, are singing, do sing, *infanoj kantas*; the father sells, is selling, does sell, *la patro vendas*.

VOCABULARY

The words in each vocabulary should be thoroughly learned by uttering them aloud before proceeding with the exercise. Those which are indeclinable are distinguished by an asterisk.

aĉet', buy
admir', admire
agl', eagle
akcept', accept
bak', bake
baston', stick (cane)
best', animal
bird', bird
bov', ox
brul', burn (*v.n.*)
ĉapel', hat
ĉas', hunt (pursue)
dank', thank
dent', tooth
edz', married person (husband)
ferm', shut
fenestr', window
gazet', gazette
hav', have (possess)
**kaj*, and
kol', neck
kuz', cousin (male)
labor, work (*v.n.*)
man', hand
onkl', uncle
paper', paper
pip', pipe (tobacco)
pun', punish
ŝaf', sheep
seĝ', chair, seat
skrib', write
star', stand (*v.n.*)
tabl', table (furniture)
vost', tail
vid', see (*v.*)
vir', man

Exercise I.

Translate into Esperanto and repeat the words aloud when written:

Uncle, sheep, the stick, the windows, to write, to thank, to punish, to shear, to see. The cousin works. The husband writes. The sheep stands. Uncle punishes. The sheep run. The husband buys some[a] gazettes. Father admires the eagle. The child clips the paper. The eagle is a bird.[b] Uncle has a chair, a table, and a stick. Sheep and oxen are animals[b]. The father shuts the windows. The husband has a hat and the sheep have tails. The eagle sees the children. The child thanks the father. The man bought a table and some[a] chairs. The man accepts the hat.

a Not translated.

b When the predicative complement is identical with the subject of the sentence, it is in the nominative case.

ADAPTING EARTH TO OUR NEEDS

Man, the Trader. Utilising the Earth's Raw Materials. Transport by Land and Sea. Power and Manufacture. Canals. Rivers. Railways. Towns and Ports

Continued from page 4198

By Dr. A. J. HERBERTSON, M.A., and F. D. HERBERTSON, B.A.

THE chief barriers to communication by sea are the Isthmus of Suez, between the Mediterranean and the Red Sea, necessitating the long voyage round the Cape; and the isthmus of Central America between the Atlantic and the Pacific, entailing the rounding of Cape Horn. The first has been overcome by cutting the Suez Canal. The cutting either of the Panama or the Nicaragua Canal across the second is only a question of time. The stormy route round Denmark is avoided by the Kaiser Wilhelm Canal across the base of Jutland, and the Corinth Canal saves the long route round the Morea. A ship canal between the Forth and Clyde would give a short route from the Atlantic to the North Sea.

The natural regions of tundra, temperate forest, steppe, desert, and tropical forest have already been described. These are not arranged in parallel zones, but according to variations of configuration and climate. Each zone has its special products, the general nature of which has already been indicated.

Adapting the World to Man's Needs. Man differs from all other animals in his higher intelligence and his more complex wants. Only in the earliest stages of civilisation has he been contented to take the world as he found it, without attempting to adapt it to his needs. If we look at the lowest existing races, we see in them the germs of that ingenuity and inventiveness which has made the highest races what they are. In the course of ages man has done much to change the world he originally found. He has modified vegetation and animal life, diverted rivers, drained lakes, tunnelled mountains, and cut canals from sea to sea. In all this he has had one main end in view, the desire to obtain a fuller command of the world and its resources.

The first stage was when men lived exclusively on what they could find—dead animals, fish left by the receding tide, and the fruit, leaves, and roots of plants. It is difficult to find examples of peoples at this stage so immediately do men begin to invent devices for improving their food supply. Mere collecting of this kind is still the chief resource of the people of Tierra del Fuego, of the South African Bushmen, and of many Australian tribes.

Man, however, soon becomes a hunter, and makes weapons. Some of these—the Australian boomerang, which returns to the thrower, or the Eskimo harpoon, for example—are extremely ingenious. Civilised man has the same instinct, and invents weapons of diabolical precision and destructiveness with which to achieve his ends.

Hunters in the Old and New Worlds. Hunting is essentially a destructive occupation. It is continually reducing the food supply, and making existence more difficult. As small areas are soon cleared of game, hunting peoples require a very large range of country, and as they have to pursue their prey, they rarely have settled homes. The lowest hunting tribes build rude shelters where they may happen to want them. Similarly, the wealthy sportsman who goes far afield in search of sport carries elaborate tents and outfits. In both cases it is impossible always to return to the same spot at nightfall.

When Europeans discovered North America the prairies fed great herds of bison, which were hunted by Indian tribes. The Australian tribes hunted the kangaroo and other animals. The pygmy tribes of the tropical forest are skilled hunters. The Eskimo hunts the seal and walrus, making the sea his hunting ground. Among more advanced peoples hunting is only one among many occupations. The trapping of fur animals is important in the temperate forests of the Old and New World, but it is for exchange, and no longer for food. The Eskimo are true hunters, but the crews of whaling and sealing vessels are in a transition stage. In the long run both classes die out. Generally, it is because the game is exterminated, for this is the penalty which Nature exacts from those who destroy without renewing. Often the end is accelerated, as in the American prairies, or in Australia, by the advent of a more advanced race with superior weapons, who deliberately exterminate the game to put the land to more profitable uses. Deprived of their hunting grounds, the aboriginal people quickly perish.

Man as a Creative Agent. It is far otherwise when man begins to create. This he has done by domesticating and breeding animals, and by practising agriculture. The shepherd or the farmer is obviously a more useful type than the hunter, and one likelier to become rich. In the great grass lands of the world the pastoral peoples predominate. Agriculture of a more or less complex kind is practised wherever there is the least chance of success. Even the majority of hunting peoples have some rudimentary knowledge of agriculture, which has become the mainstay of the highest races. Both agriculture and the breeding of animals become more and more scientific as a race increases in civilisation, ensuring a larger and more certain return for the labour expended.

Man's control of Nature is thus continually increasing, though there are innumerable agencies ever liable to undo his work. Some of these are climatic; others are of plant or animal origin. Untimely frost, rain, hail, or drought

may ruin his crops and involve the loss of his livestock. Lower forms of plant life may cause blight, mildew, and other plant diseases. The animal foes range from microscopic organisms to highly organised animals. The former are the unseen causes of disease, malaria, yellow fever, etc. The ravages of the phylloxera insect have caused immense loss to nearly all vine-growing countries. The mosquito renders large districts uninhabitable by carrying the germ of malaria. The African tse-tse fly exterminates cattle over the areas it haunts. The locust, the scourge of South Africa and other dry lands, annihilates every trace of vegetation in the line of advance. The rabbit has become an equally serious plague in Australia, where it does great damage both to crops and pasture. Many other examples will doubtless suggest themselves.

Man's Utilisation of Raw Materials. A society which breeds animals or practises agriculture has a constant supply of raw materials. The shepherd peoples have immense quantities of wool and hair, out of which they make felt tents, wool carpets, leather bottles, saddlery, and so forth. The agricultural peoples have bursting barns and laden fruit trees in autumn. Fruit must either be used immediately or wasted. Thus begin such industries as the making of wine. It is needless to follow out the process in detail, or to mention the manifold ways in which the raw materials of the entire world are utilised in a complex society like our own.

Originally, all power was hand power, as it still is in many parts of the world. Labour may be so cheap that hand power is the most economical, as in China; or a region may be so remote that labour-saving devices have not penetrated to it, as in the hand grinding of cereals in many African villages, or, in exceptional cases, such as lacemaking, the hand may give a finer result. Animal power probably developed next. A common example of it is the use of animals in ploughing. Horse power remains our unit of measure, though we now employ mechanical power wherever possible.

Power — Water, Steam, and Electricity. Water power was the first mechanical power employed, and the command of it was of prime importance until the introduction of steam power in the eighteenth century. Steam power enormously increased output, and the impetus thus given to manufactures led the conveniently-situated coalfields of Europe and North America to specialise in manufactures to the almost complete exclusion of agriculture. Steam power is now being rapidly displaced by electric power, which is restoring the command of water power to its old importance. The fact that it can be cheap'y generated by water power, transmitted for long distances, and put to the most varied uses, gives it a superiority to every other form of power with which we are yet acquainted. Its increasing use is one of the great secrets of civilisation, and its increasing application in all parts of the world will almost inevitably lead in the long run to redistribution of population.

The geographical and human factors together produce great diversity of raw and manufactured products. Some system of exchange early begins, and increases in complexity as societies develop.

Exchange and Transport. For exchange two things are necessary—a surplus of some commodity and the means of putting it on the market. Without the latter the former is useless. Transport will therefore be briefly considered before commodities.

Transport is carried on either by land or water. Transport by land is carried on first by road, and much later by rail. In transport by road goods are carried by human porters or by beasts of draught or burden and recently by mechanical power. In transport by rail a locomotive is driven by mechanical power, or carriages are propelled by electricity. By water, oars, sails, steam or other mechanical powers are employed, and on inland waterways haulage—usually by horses.

Women are the oldest beasts of burden in the world, and still do most of the carrying among savage tribes. Slave labour is notoriously associated with the ivory trade, carrier and burden being sold together at the end of the journey. Slave labour is being eliminated by the progress of civilisation, but human carriage is by no means at an end. On a limited scale, it survives among ourselves. It may be the only form of transport possible under certain conditions, as, for example, in those parts of Africa ravaged by the tse-tse fly, whose bite is fatal to animals. In the tropical forests to make and keep roads open is almost impossible, and human carriage must frequently be resorted to.

Human Carriers. Human transport is slow and dear. A slave must be bought as well as fed, and as he may die on the march, a speculative risk is incurred. A free porter requires wages in addition to food, which an animal does not. Limitation is also set by human strength. A man can carry only a given load. If part of this consists of his own food, the expense becomes still more prohibitive. Always dear, human transport is only practicable in fertile regions, and then only on a very limited scale. Hence, such a region as our Colony of Nigeria develops very slowly. There is abundance of valuable produce in the interior, but it cannot be got down to the coast. The time would be prohibitive, and the cost at the present rate would work out at about £10 per ton per 100 miles.

Transport by human carriers therefore greatly hampers the rapid growth of trade, and can only be applied to goods which are not perishable, and where bulk is small in proportion to the value. Such a trade is that in brick tea across the high mountains separating China from Tibet. In no country, however, is human labour so cheap as in the rice lands of China and India, and nowhere is human carriage so common. An economy is effected when man is made into a draught animal, for he can pull larger loads than he can lift. In China wheelbarrows are largely used. Sails are sometimes attached to them, but rather to increase the load than to lessen the labour.

Animal Carriers. Animal transport is also a very ancient mode of transport, though still in daily use among ourselves. It is both quicker and cheaper than the preceding, especially if draught are substituted for pack animals. The reindeer in the tundra of the Old World, the horse in temperate Europe, the mule in southern Europe, the ox in South Africa, the camel in the hotter, drier regions, are among the draught and pack animals of the world. The yak crosses the high passes of Tibet, and the llama those of the Andes. There are, however, the same limitations as in the case of human labour. Expense is enormously increased if part of the animal's load consists of its own food. Hence the value of the camel where it can be used. This animal has fat-storing cells in its humps and water-storing cells in the coats of its stomach. Cases are recorded of camels remaining without water for two months. The average load is from 6 cwt. to 8 cwt. The cost of camel transport in Manchuria has recently been given at from 1½d. to 2d. per ton per mile, while transport by mule or pony cart comes out rather cheaper.

Before the introduction of railways, nearly all the transport of the world was done by animals. Great trade routes crossed the Old World, many of which are now followed by railways. At the present time animal transport is chiefly used to get goods to the nearest railway or waterway. It may cost the American farmer as much to haul his grain to the railway as will be paid for the rest of its transport to Europe. Hence, farming does not pay beyond a certain distance from a railway.

Transport by Rail. Transport by rail is quick, reliable, and particularly suitable for perishable commodities. Though dearer as a rule than water carriage, it is far cheaper than either of the preceding.

Three principal elements enter into the question of cost—(1) The initial cost of constructing the track; (2) the cost of the locomotive and other rolling stock; and (3) the working expenses. The examination of these in detail does not fall under the scope of geography. It may be pointed out, however, that the question of gradient and distance are of prime importance in determining working expenses. It requires more power to lift a weight up an incline than to draw it on the level. Hence, other things being equal, the route with the easiest gradient will be chosen. An example of this is seen in the case of the recently-finished Simplon Tunnel.

It was decided to pierce a long tunnel at a lower elevation rather than a much shorter tunnel at a higher elevation. The extra cost involved in hauling every ton to the higher level would in the end have more than counterbalanced the initial economy in the cost of the tunnel. Where a steep gradient is unavoidable, the rate charged is often prohibitively high. The cost of ascending Vesuvius by rail is £1 for a journey of a few miles. Here, no doubt, the element of monopoly comes in, but the working expenses on such a line are necessarily exceptionally high.

The shortening of the distance to be traversed is almost as important as the easing of gradient. A longer route means an increased consumption of fuel on every journey, as well as loss of time. Hence, to reduce distance is to reduce cost. Economy of time is rapidly becoming the only real economy, and from this point of view such costly engineering works as tunnels through the Alps and the Andes pay in the end. Tunnels are even carried below estuaries and narrow arms of the sea to avoid the time and expense of unloading and reloading.

Another element in reducing cost is the distance hauled, long hauls costing relatively less than short ones. The cost of loading and unloading is the same in both cases, so that this is another example of economy everywhere effected under modern conditions by economy of time.

Transport by Land and Water. The total mileage of the world's railways is over 500,000 miles, by far the greater part being in Europe and North America. A through line, though not on a uniform gauge, crosses Europe and Asia from the Atlantic to the Pacific. Several lines cross North America, and in South America a transcontinental line is in process of completion. A Cape to Cairo railway is projected.

Transport, like manufacture, is passing into the electric stage. Both trams and railways are now driven by electricity.

Transport is carried on by river, canal, lake, and sea. The boat or ship replaces the animal or the locomotive. It is the cheapest form of carriage—(1) Because, except in the case of canals, no roads have to be made and kept in repair; (2) because a smaller power will move a given tonnage through the water than would suffice on the most perfectly-graded railway; and (3) because it is less easy to create a monopoly, and competition tends to reduce rates. Very heavy and bulky goods can often be carried more cheaply by water than by land when both methods are available. In the case of ocean commerce, there is, of course, no alternative to water carriage, though there may be a choice between the use of wind power and steam or electric power.

The Commercial Value of Rivers. Rivers are natural roads between the sea and the interior of a country. Their upper courses are often too swift and steep for navigation, but in the lowlands they are generally navigable. Their commercial importance increases as a country develops. It would be impossible to overestimate the value of the Rhine to Germany, the Danube to Austria, the St. Lawrence to Canada, or the Yangtse to China.

Various causes lessen the value of a river as a means of transport. Its current may be too swift, as in the Hwang-ho. It may be liable to floods, as the Loire. It may be too shallow, as the Elbe, which is not navigable in its upper course in dry summers. Its bed may be broken by falls or rapids, as at the Iron Gates of the Danube, now made navigable by blasting away some obstructions, and making a canal to avoid others. All the African rivers suffer in this respect. Africa is a high plateau, falling by steep terraces to the sea. Over these the rivers

fall to the coastal plains, forming falls. They are navigable above and below these, but they are not natural routes from the sea to the interior.

Another drawback is the tendency of rivers to form bars at their mouths. This is well seen in the case of the Rhone. It has a large delta, and bars are formed at the mouth of all its distributaries. Aigues Mortes, once a flourishing port, is now inland, and the port of the Rhone valley, Marseilles, is east of the delta.

Thirdly, a river is of little use for transport if the approaches to it are not good. This is illustrated by the Danube. The Rumanian bank is low and marshy, while the Bulgarian bank is high and above flood level. Hence, Rumania makes much less use of the Danube for transport than does Bulgaria.

Again, it is a disadvantage if a river be icebound in winter, as transport must cease. When the St. Lawrence is frozen much trade is diverted from Canadian to American ports. Most of the rivers of Eastern Europe, including the Danube, are icebound in winter. Siberia is handicapped in the same way, and the Amur, the other great river of Asiatic Russia, is closed to navigation from November to April.

Transporting Timber. A very primitive mode of river transport may still be seen on the Rhine, and on most of the rivers of Europe which flow from forested regions. The timber is made up into great rafts, which are towed or floated down stream. This mode of transporting timber is practised all over the world—in Canada, where the Ottawa is the busiest timber river; in Brazil, where mahogany is floated down stream; on the rivers of Burma, which carry teak; on the Amur, where timber is floated down from the forests of Manchuria; and on the Yangtse, from the dense forests between China and Burma. On the last named river logs are floated down in January, and take about six months to travel 600 miles.

Few goods, however, would stand such rough handling, and the usual method of transport is by boats, which assume innumerable forms in different parts of the world. In the chief commercial countries river transport is carried on by steamers of suitable draught. The estuaries of many rivers admit ocean-going steamers far into the interior. The Seine is navigable for ocean liners to Rouen, and to coasting steamers even to Paris, the Rhine to Cöln, and to coasting steamers to Mannheim. Compare this with the Rhone, which is inaccessible to ocean-going vessels.

Lakes. Lakes are of all sizes, the largest assuming the dimensions of inland seas. When of any size they are generally utilised for transport, which may be chiefly passenger traffic, as on Loch Lomond, or may include freight. Whether freight can be profitably carried depends on various considerations, one of which is tran hipment. Where lakes do not communicate with the sea the traffic is necessarily local. In a country where roads are few the navigation on lakes may be of great importance. Consequently we find steamers plying on Lakes Nyasa and Tanganyika in the heart of Africa. Where lakes are connected with the sea by a navigable river, the advantage for transport is obviously greater. No better example can be found than the Great Lakes of the St. Lawrence.

The Commercial Use of Canals. Canals are artificial waterways. They include inland canals for river traffic and ship canals for ocean traffic.

Inland canals are made to improve existing rivers, to connect navigable rivers with each other, or to avoid obstructions. The rivers of England and the Continent have been extensively canalised, and connected with each other by canals. Sometimes the canalisation and deepening of a river bed calls a new port into existence. The deepening of the Clyde and the rise of Glasgow is a case in point. At the end of the eighteenth century there were only 15 inches of water at Glasgow at high tide. To-day it is a port for the largest liners afloat. Similarly Montreal has been artificially made into an ocean port.

Canals are frequently made to avoid obstructions to navigation. The navigation of the St. Lawrence above Montreal is obstructed by the Lachine Rapids, three miles long, now avoided by the Lachine Canal, from Montreal to Lachine. This is nine miles long, and rises 45 ft. by means of five locks. There are altogether 42 miles of canals between Montreal and Lake Ontario. Other canals avoid the obstruction between lake and lake. The Welland Canal, between Lakes Erie and Ontario, avoids the Niagara Falls.

Canals versus Railways. At the present time the canal question is exciting much interest. In this country the canals have suffered from railway competition. Very primitive methods of canal transport are used, chiefly barges towed by horse power, and so small that goods cannot be handled in bulk, a factor in reducing expenses. The rate is very slow, and can be profitably applied as a rule only to bulky goods not of a perishable kind, such as coal, or building stone. In view of the often repeated axiom that time saved is money saved, canal transport must be accelerated if it is to pay. A possible change of method is illustrated by a short canal just opened in Prussia.

The Teltov Canal, which is about 24 miles long, passes through the forests and lakes to the south and south-west of Berlin, and connects the upper Spree with the Havel near Potsdam. It shortens the distance for barges passing from east to west by the canals connecting the Elbe and Oder, and relieves the congestion of the river traffic through Berlin. The special feature of this canal, which is all but unique in Europe, is the mode of traction. Electric locomotives, supplied with power from overhead wires, run along the banks, and tow the boats in either direction. Each can tow 1,500 tons at the rate of three miles an hour. [See 4, page 2275.] The rates at present charged for towing are high, one penny per ton per kilometre ($\frac{5}{8}$th mile). The result of this new experiment in canal transport remains to be seen.

Canals have declined owing to the competition of railways. For this geographical causes are to some extent responsible. A region suited for the construction of a canal is also well adapted for the construction of a line of easy gradient, which is inexpensive both in construction and working. Before the development of railways many hundreds of miles of canals were made along the valleys of eastern Pennsylvania to carry coal down to the markets. None of them are now important, for the whole route being on the down grade, the railways can carry it very cheaply, as well as more quickly, and in greater bulk.

Ship canals are made either to shorten routes, as in the Suez Canal, or to bring inland towns into direct communication with the sea. The Manchester Ship Canal was constructed at a cost of £15,000,000 to make Manchester a port and to avoid transhipment at Liverpool.

Transport by Sea. Transport by sea is of unknown antiquity. At the dawn of history we find the Phœnicians on the Syrian coast possessed of a great navy, and trading with all parts of the known world. Their ships were propelled by rowers, and sails were used only as an auxiliary means of power. Up to the beginning of the nineteenth century the world's ocean commerce was carried on entirely by sailing vessels. The first steamer crossed the Atlantic in 1819, and ever since there has been a steady increase in the ratio of steam to sailing vessels.

Steam transport is initially costly. In addition to the cost of the vessel, which is much more than a sailing vessel, there is the fact that machinery wears out rapidly or becomes out of date, so that the life of a steamer is shorter than that of a sailing vessel. Further, there is the permanent charge for fuel. The fastest liners consume nearly 400 tons of coal a day. This expense has not to be met by sailing vessels. To counterbalance the heavier working expenses it must be remembered that a steamer can carry far more per annum, which makes for economy. As in the case of locomotives, improvements in the construction of engines have resulted in a great economy of fuel, thus lowering rates. In some cases these are only half what they were 25 years ago.

Where Steamers Beat Sailing Vessels. In addition to their greater carrying power, steamships possess another great advantage over sailing vessels. The latter are dependent on winds, and must often shape a longer course to get a favourable wind. The steamer is practically independent of wind, and can choose the shortest route. Nowhere is this better illustrated than in the case of ships on their way from the Indian Ocean to the Atlantic. The rates for towing in the Suez Canal are so high that most sailing vessels take the route round the Cape, though it is 3,000 miles longer. A steamer, of course, does not require towage. The acceleration in delivery makes steam carriage the most economical for all perishable commodities.

The introduction of steam transport has caused a certain oscillation in the situation of ports. Originally, when all vessels were sailing craft of limited size, the ports tended to be at the head of tidal navigation. As steam came into use and vessels increased in size they were no longer always able to reach the inland port, and ports nearer the mouth of the river rose in importance. The advantage of penetrating as far as possible into th interior was, however, of such great commercial importance that the more important rivers of Europe were deepened and dredged to make them accessible to ocean-going steamers for the longest possible distance. Thus commerce flowed back again to the port nearest to the interior, which rose at the expense of its former rival at the mouth of the river.

The Beginning of Towns. The earliest settlements of man were determined by ease of access to certain commodities, without which life is impossible. The two most fundamental are water and food. Next to these comes the presence of some material for making weapons. In our own country primitive man made his weapons of flint, and traces of early settlement are found all over the chalk counties of Britain. A second important consideration was ease of defence. This led to the forming of settlements on hills (Edinburgh), or on islands in a river (Paris), or on firm ground surrounded by marshes (Ely). So long as each settlement was small and relatively self-sufficient, these two considerations were probably all important. Some simple form of exchange early developed, and along with it there was an irresistible tendency for settlements to grow up at certain points of vantage. Broadly speaking, these were concerned with the control of routes. A good example is the growth of a village at a point where a river could be forded (Oxford), or bridged (Cambridge). The nucleus of what has become the greatest city in the world was the ford of the Thames at Westminster, and the bridge across the river a mile or so below it. Another obviously good site is the confluence of two rivers. Duisberg, Coblenz, and Mainz are all confluence towns on the Rhine. At Nizhni Novgorod, at the junction of the Volga and the Oka, an annual fair is held, at which the business of two continents is transacted. Where a river changes its direction an important town frequently grows up, owing to the convergence and divergence of routes in different directions. Such a town is Basel, where the Rhine turns north across the Upper Rhine Plain.

The command of land routes is equally important. London had not merely its ford and bridge, but it was at the end of the only practicable routes across the otherwise impassable marshes. Towns naturally arise at the mouths of valleys (Heidelberg), especially when these lead to important passes (Turin, Milan, Verona). Towns also grow up at the mouth of gaps or depressions across mountain ranges (Salisbury, Winchester). Basel is at the end of the important route by the Burgundian Gate, so that two distinct causes have promoted its growth.

The Beginning of Ports. Another series of towns is associated with the change from one form of transport to another. The most obvious

illustration is the ordinary seaport, where land and water routes meet. A large and important town almost inevitably grows up at the head of navigation for large vessels, where freight must be transhipped from or to smaller steamers, or to the rail. This explains the rapid growth of Mannheim. There will also, for a similar reason, be a considerable port at the head of tidal navigation, the limit for any smaller vessels. If the river be interrupted by rapids, transhipment may be necessary, and consequently a town will grow up (St. Paul in Minnesota, Detroit, Montreal). Even under more primitive conditions the same law holds good. Ta-chien-lu, the centre of the tea trade between China and Tibet, owes much of its importance to the fact that here the tea is transferred to yaks, the beasts of burden on the high passes of Central Asia.

The Position of Manufacturing Towns. The position of manufacturing towns is due to a different set of conditions. Anciently they tended to grow up where raw material and control of water power were both available, as in the woollen towns of the Tweed valley, Yorkshire, the Cotswold, the Ardennes and Saxony. The existence of some other favourable circumstances might be the determining cause. Thus many of the Flemish rivers have special bleaching properties, and towns engaged in the linen manufacture grew up along the Lys and other rivers. The most striking case is the rise of manufacturing towns on the coalfields of Britain, Europe, and the United States after the discovery of steam power. The cotton towns of Lancashire possess three advantages of position. Two of them are obvious—proximity to coal and to the cotton-shipping ports of the United States. The third is climatic. The humid atmosphere enables a fine thread to be spun, and gives a better result than the artificial dampening of the air in drier districts.

Where several of these advantages are present the prosperity of a town is more likely to be permanent than where there is only a single one. Space forbids an analysis of the advantages of position possessed by the chief cities of the world, but in almost every case it would show that these are very numerous.

The Advantages of Seaports. Unless the hinderland be poor, the balance of advantage lies with seaports. A large population finds employment in handling the merchandise brought in and out. Every grade of labour is represented, from the merely manual tasks of loading and unloading, through the various agencies of distribution to the highest forms of administrative ability, which shape the destiny of whole communities by regulating the amount of capital engaged and the mode of its employment. As raw material and coal can be cheaply obtained by sea, manufactures tend to develop, causing a further increase of wealth and population. This again reacts on the agencies engaged in collecting raw material and distributing the finished product Thus the seaport city tends to acquire an ever increasing momentum. New lines of railway are built to it, new lines of steamers make it a port of call, steadily increasing the prosperity which originally attracted them.

One more aspect of the interesting question of position may be noted. The greatest towns may have their vicissitudes, and unforeseen causes may for a time neutralise their indisputable advantages of position. A famous case is that of Genoa and Venice, which, in the early Middle Ages, were on the great highway between Asia and Northern Europe. The Turkish conquests in the fifteenth century interrupted this trade, and struck a deadly blow at their prosperity. The discovery of the Cape route transferred the advantage of position to the Atlantic ports, and Lisbon, Antwerp, Rotterdam, and the British ports successively secured the greater part of the world's trade. The cutting of the Suez Canal again made the Mediterranean the highway, and led to the rapid growth of Marseilles, Genoa, and in a lesser degree of Venice. There are those who maintain that its opening has been prejudicial to the interests of British ports, but this cannot be taken yet as proved.

The Drawing of Maps. The illustration on page 4514 shows three different maps of the world on which the British Empire is indicated by shading.

1. The Mercator projection is that most familiar. It has this advantage, that a straight line drawn between any two places on it represents the correct direction between them. It has many disadvantages. The size of countries is greatly distorted. Compare Australia, nearly 3,000,000 square miles, with Greenland, some 700,000 square miles.

2. To get rid of this distortion the oval-shaped map above it has been drawn. Australia and Greenland are shown in proper proportions. On it we may compare the size of different parts of the British Empire. Notice that the distance between the meridians at the equator is equal. The meridians of 90° W. and 90° E. of Greenwich form the circumference of a circle. One diameter of this represents the equator; the diameter at right angles, the meridian of Greenwich. The parallels are now drawn so that the area between two parallels is proportional in the scale of the map to the area between these two parallels on the earth. The equator and each parallel is divided into eighteen equal parts, nine west and nine east of the meridian of Greenwich, each representing 10° and numbered 0° to 90° W., and 0° to 90° E. Then the equator and each parallel is prolonged east and west until the distance beyond the circle is equal to that from the meridian of 0° to the circumference. Each part beyond the circle is divided into nine equal parts, numbered from 90° to 180° W., and from 90° to 180° E. The curves are now drawn through all points with the same numbers, and the network is complete. This equal-area, or equivalent projection, is called Mollweide's, and was invented in 1805.

3. The western and eastern hemispheres are not equal area projections, but the distortions are not nearly so great as in the Mercator projection.

DRAWING FOR SHEET-METAL WORKERS

Envelopes of Bodies. Plane Figures. Non-plane Figures. Projections. Pyramids—Right Figures. Pyramids—Oblique Figures

By JOSEPH G. HORNER

THIS course does not deal with problems in practical geometry, which are treated earlier. It only embraces the actual development of the envelopes of solid bodies. Although the problems involved in this subject are those of marking out with compasses, rules, and scales, more than this is required in order to translate these into practice. Joints of many forms occur continually, and suitable allowances have to be made for these beyond the edges obtained by the geometrical outlines. Then, again, allowances have to be made for some other matters which do not admit of exact calculation, and which have not been and cannot be formulated, but which can only come by experience in the shops. These include the influences of *bending, flanging, raising*, and allied operations in which sheet-metal undergoes coercion, so that its fibres move one over the other some being compressed, others extended. In very thin sheets the influences of these may be nearly neglected, but as sheets increase in thickness, as in the plates of the boilermaker, the results sometimes become puzzling to the workman. For actual metalwork is not like making a drawing that you may rub out and redraw. An error means a waste of valuable material, as well as of time.

Envelopes of Bodies. We will preface this article with remarks on the subject mentioned above as being a fundamental one—namely, the envelopes of solid bodies. That is the same thing as the envelopes of hollow bodies, with which all sheet metal workers are concerned. In other words, solids are enclosed by envelopes, the forms of which can be produced on plane sheets and wrapped around the solids, or enclose hollow spaces identical in form and dimensions with the solids.

We can here lay down two leading statements: (1) The shapes of the envelopes of bodies or of geometrical solids can in all cases be arrived at by the application of geometrical problems, combined with the principles of projection; (2) all these envelopes, of whatever form, can be obtained by the preparation and union of sheet-metal or alloy originally in plane forms, as sheet tin, copper, brass, zinc, iron, and steel, as used by tin and coppersmiths, zinc workers, and boilermakers. This is obvious in the case of *cubical* bodies, but the difficulties, real or apparent, exist when bodies are of *conical, spherical*, or *flaring* outlines, and when combinations of these occur, and junctions of various figures with each other. Frequently, when work such as hammering has to be done on sheets to cause them to assume other than plane surfaces, the number of joints has to be increased in thick plates more than is necessary in thinner sheets.

Joints. Next, with regard to the allowances for joints. The general rule is, first, to have as few joints as possible; next, to adopt the simplest joint that is consistent with efficiency. Within this range we have many kinds, from the simple union by soft solder to the treble-riveted, double-butted joints of the largest steam boilers.

The question of allowance for joints is not usually difficult, but it must not be overlooked. Generally, it involves a simple addition to the developed pattern of so much for overlap, or for wiring in some cases. In others, something more has to be considered, as when flanges have to be turned with more or less of radius, and when flanging has to be done in two directions on the same plate, as in the firebox sheets of locomotive boilers. Sometimes no allowance is made, as in thinned corners for boiler plates, or but little, as in the thinned edges of cramped joints. In butt joints, again, no extra is required. So that all through the work the craftsman who marks out must also keep in mind the methods of jointing as well as the allowances for puckering and drawing in concave objects.

Machine versus Hand Work. At the present time much of the work of the tinsmith and coppersmith has been appropriated by machinery, in which articles of steel are stamped at one operation or more, instead of being tediously marked out and shaped by hand hammering. But for all, except comparatively simple articles, the service of the worker in sheet-metals are still in request, and to all such a knowledge of drawing lies at the basis of the craft.

To those who are not familiar with this work it must sometimes be a matter for surprise how sheet-metal work is produced in such an infinity of forms. Neither is it all simple to the craftsman. But when difficulties arise, they are seldom those due to marking out the geometrical patterns, but they generally lie in the making of suitable allowances for raising by hammering processes. Generally, patterns, however elaborate in appearance, are composed of simple elementary forms in repetition, or in combination. It is, therefore, essential to grasp the elementary problems before attempting those examples which include combinations of the same.

Plane Figures. Considering in brief the forms of the envelopes of solid bodies, we see that large numbers of them have plane faces. These give us the first object lesson in our course.

Take any polygonal solid, and you see that by separating each side the figure really develops itself. As many sides as the figure possesses, so many individual planes will there be. Any

square [1] or oblong body would have six planes [2] for its envelope; top, bottom, and four sides. This may be made by cutting from a single sheet, as in 2, then turning up the four sides, and turning over the top; or each piece may be cut separately. A hexagonal body [3] would have eight planes [4]; top and bottom, octagonal in plan, and six sides, each of rectangular outline. This can be developed either as in 4, or as in 5, the relations of each of which to the body are obvious. The can with tapering sides, a prismoidal figure [6] is enveloped as in 7. The complete envelope [8] of an octagonal pyramid is a simple form. The envelopes of the sides have their lengths, A, equal to the *slant* height of the pyramid, and the widths, B, at the base are equal to the length of a side of the base. In obtaining the shapes of the envelopes in 1 to 8, the important point to be sure of is the dimensions of length and width, and correct angles—right and octagonal, and so forth. It is just a case of plain measurement with rule or compass.

The development of a truncated pyramid is shown in 9. The pyramid is first completed as indicated by the dotted lines, and then a length is marked off equal in length to the slant height required. The top and bottom octagonal sheets are exactly the same as those of a truncated pyramid in plan view. The construction in 9 would completely envelop the body.

In working out these, every face is a plane face, and the outlines are those of the faces looked at in a direction *perpendicular* thereto.

Slant Height. This manner of looking at a figure is of cardinal importance, as we shall see subsequently. It will occur continually in speaking of the *slant height* of an object - that is, the dimension taken along the plane of its face, instead of along the axis of the body. The two only coincide in figures having their sides parallel, as in rectangular and cylindrical bodies, and not at all in pyramidal and conical figures and those derived therefrom.

In working out many developments it is essential to bear in mind this difference in dimensions in the perpendicular and in the slant, or sloping portions of figures of which 6, 7, 8, 9, 10, and 11 are typical. Taking a pyramid for example, it hardly needs demonstration to show that the perpendicular height is different from the slant height. The perpendicular height is shorter, the slant height of the edge is longer, and the slant height of the faces is different from that of the edges. In obtaining the development of the envelopes of such figures, the perpendicular height has no permanent place. It is only used as an element in the work of development, but both of the slant heights are required for the cutting of the actual sheet of metal. The relations of these will differ considerably with the proportions of figures.

Non-plane Figures. Looking now at the envelopes of figures that are not plane, we see that bending has to be done. For a cone [10], the envelopes are a sector of a circle, and a circular base. For a conic frustum [11] they are a segment of a circle, and two circles for base and top respectively. For a cylinder [12] the envelope is one rectangular sheet bent to form the cylindrical body, and two plane ends, which are circles.

The envelope of a globe is a complete sphere also. But such bodies are formed by taking two circular discs and beating or pressing them to hemispherical shapes, or by preparing small pieces called *gores*, and bending and uniting them.

Methods of Bending and Hollowing. The question of bending and hollowing affects different trades in different ways. While a coppersmith easily hammers a sheet into a spherical form, the engineer has to bring powerful hydraulic machinery to do such work on steel plates. In the absence of such aids he increases the number of joints, and so lessens the amount of *dishing* required on a single sheet.

It might seem as though it would be easy to hollow a sheet of metal to any extent if the work be done at a high temperature. But such is not the case. In all work where metal or alloy is subjected to severe treatment, with much extension of its fibres, frequent annealings are necessary. To this rule there is no exception, either in thin sheets or in thick plates. Extreme examples are cartridge cases used for ammunition. These are drawn from solid sheets, but the work is spread over several stages with alternate annealings. It is in such work, of which this is an extreme though common illustration, that the shape and dimensions of the sheet cannot be obtained correctly by simple draughtsmanship, but previous experience of similar work is essential.

Projections. The drawing of the worker in sheets and plates is essentially that of projection, superadded to plane geometry. It is so, too, in engineers' drawing in general, but with this difference—the projections of the engineer are largely those of plans, elevations, and sections in directions perpendicular to each other. But those of the worker in sheets as often take place in planes perpendicular to sections taken at various angles with main axes. And what appears to the beginner to complicate matters is that many of the patterns of the tinman and coppersmith, zinc worker, and engineers' plater, are not symmetrical, or right figures, but are unsymmetrical, oblique, or slant figures, and these again have their projections of sections taken at various angles. And then, further, many objects of manufacture combine right with oblique figures, and portions of the envelopes of different groups of solids. If the separate sheets be not marked correctly they will neither joint correctly as separate pieces nor connect up to each other.

Once more, many cases arise in which, though it is known that an edge must be an arc of a circle, and though one could see how to strike it with compass or trammel, yet the radius is far too large to permit of this method. Then other devices are available, those of intersecting lines or of triangulation, by which accurate curves can be obtained step by step by constructive methods. And once the leading principles of development and projection are grasped, new problems are readily solved by a little thought.

Examples of Projection. Some elementary illustrations of the principles of projection, as they apply to the envelopes of bodies, will be of value before beginning practical problems. They are simpler in some respects than those which deal with projection as a whole, in which *thicknesses* are constantly occurring, because sheet-metal may be considered from this point of view to have no thickness, and therefore one surface—an exterior one—only has to be considered.

The sphere is the only object which appears the same from all points of view and in all sections. The same remark applies to the cube looked at perpendicularly to either face. In all other figures the projections are different.

A cylinder [**13**] has two external developments, that of the body [**12**] and that of the ends, circles. But if cut obliquely [**13**] its development is an ellipse. A square figure [**14**] shows plane faces if viewed perpendicularly to its sides, but angular faces if projected from the angles. An oblique conic frustum [**15**] has two projections, that of its circular base, and that of a smaller circle corresponding with the plane of truncation, besides the foreshortened plan view. An oblique cone [**16**] projected has the appearance shown; here, as in **15**, we see at a glance that the projected plans, being foreshortened, do not give actual lengths of the envelopes, which must be obtained on slant heights. A conic frustum [**17**] projected gives two concentric circles corresponding with base and top, and the slant in plan view. A hexagonal prism [**18**] has its true form projected parallel with the axis, but the equal-sided proportions do not appear if a projection be made perpendicular to a diagonal section. A cone has the conical form in elevation, the circle in plan, and the ellipse if cut diagonally across [**19**], besides the parabola and hyperbola if cut in other directions. The truncated octagonal pyramid [**20**] gives octagonal figures in plan, as shown, and tapering sides. The development of this was shown in **9**. An octagonal pyramid cut in oblique section [**21**] develops an irregular octagon.

The point to be noted in these figures is the alteration in form which the projections at different planes indicate. With every increase in angle there results an elongation of form, and when joints have to be made to fit at certain angles the importance of exact methods of development on the projected planes is obvious.

Simple Examples. We will now begin work on some of the simpler examples that arise. However varied are the shapes in which sheet-metal and plated work occur, they are reducible to a few elementary forms and combinations of the same. These are *parallelopipeds, prisms, pyramids, cylinders, cones, polygons, and spheres.* The prisms, pyramids, cylinders and cones may be right or oblique figures.

Pyramids—Right Figures. We may dispose summarily of parallelopipeds and prisms because the dimensions as well as the forms of their envelopes are obvious [**1** to **5**]. Right pyramidal forms are also simple, but some explanations are necessary here. A pyramid may be defined as a solid bounded by three or more triangles which meet at a point, and by the base, which is of polygonal form, having any number of sides. The height of the triangles must be taken on the slant lines, and a comparison of the two figures [**22** and **23**] shows how essential is the amount of slant in determining the forms of the triangular envelopes. If the pyramids be cut across the planes *aa*, we have truncated figures, and then the dimensions are required in the plane of truncation, and these are given by the projections in plan. In these figures each triangle, or wedge-shaped piece around the pyramids is like the rest, because the apex is situated perpendicularly over the centre of the base. But if located elsewhere, the pyramid is an oblique one [**24**], and the triangles are of unequal lengths, excepting those that correspond on opposite sides of the figure taken in the plane of the paper. The methods of marking out, therefore, differ in the case of right, and oblique pyramids, and, of course, of complete, and truncated pyramids, **8** and **9** respectively.

Truncated Pyramids. Complete pyramidal figures are seldom wanted, but truncated pyramids, or pyramidal frusta, and portions of the same, occur constantly, alone or in combination with other figures. Thus, taking one example by way of illustration, the pattern for a common octagonal tray with tapering sides is related to the truncated pyramid. Fig. **25** illustrates such a tray in plan and elevation, to be made in one piece, and though of polygonal outline, having small angular corners only. The centre lines, *ab* and *cd*, divide it at right angles; *e* is the vertical height of the tray. Lay out one half the *base* [**26**] to the same dimensions as in **25**, and draw through its centre, *c*, centre lines *ab* and *cd*. Draw centre lines, *hi*, *hi*, through the corners, corresponding with *hi*, *hi* in **25**. Now take the slant length *fg* [**25**] and transfer it to **26**, to *ag*, *bg*, and *dg*. Draw the lines, *aj*, *bj*, *dj*, *dj*, perpendicular to the main centre lines. Next take the lengths *aj*, *bj*, *dj* in **25**, and transfer them to *aj*, *bj*, *dj*, *dj* in **26**, which gives the lengths of the top edges of the tray sides.

To obtain the lengths of the corner pieces, project the vertical height, *e* [**25**], to the small diagram on the right; measure off the horizontal, or plan length, *ih*, in the upper figure and transfer to *ih*. Then the length of the slant line, *fh*, transferred to *hi*, *hi* in **26** will give the actual lengths of the corner pieces. Through *hi* the lines *jj*, *jj*, drawn at right angles with the centre lines *hi*, *hi*, will give the top edges of the corners. To get their length, measure off in **25**, *hj*, *hj*, and transfer it to *hj* in **26**, and draw the lines shown to the corresponding lines that give the bottom of the tray.

Pyramids—Oblique Figures. Taking now a few oblique examples, we must extend some of the fundamental facts already noticed as to the difference in perpendicular and slant heights of faces and edges.

Fig. **27** shows a square oblique pyramid, the development of which is shown in **28**. The

real lengths are not *ab*, *ac*, but the dotted lengths *ab′*, *ac′*, obtained by taking off the slant lengths in plan, *a′b* and *a′c* respectively, and transferring them to the upper figure from *a″*.

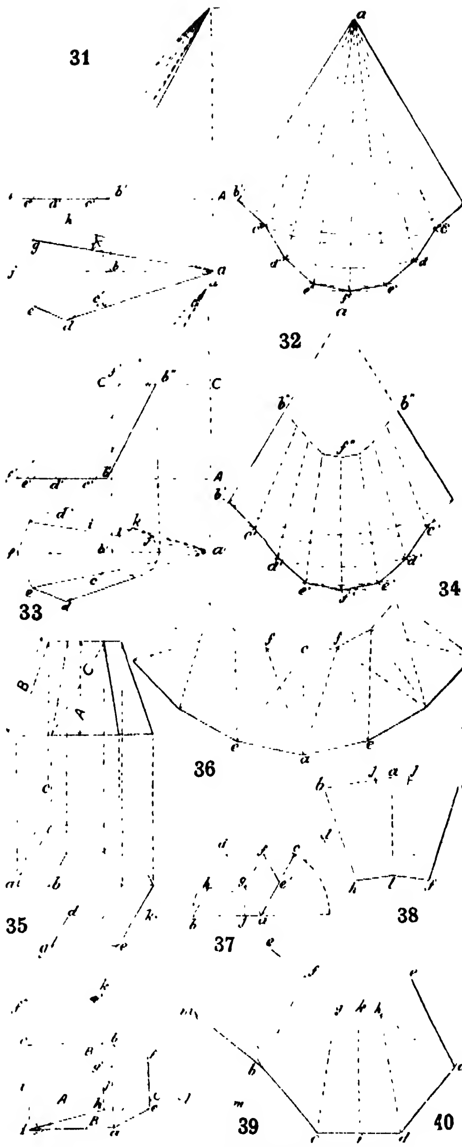
The development shown in **28** is obtained as follows: As the corners, A and B [**27**], have different lengths, measured from the apex, *a*, two radii are taken for these—the projected ones, *ab′*, *ac′*, and struck from *a* in **28**. Take the length of one side, *bc*, or *ce* [**27**], and set it off four times [**28**], cutting the radii just struck, starting from *ed*, thence from *db*, *bc*, and *ce*. Joining these intersections with lines, and also *ae*, and *e* at the extreme right and left, will complete the outline of the figure, while the lines dotted joining *ad*, *bc* correspond with the three angular corners of the figure, where the sheet-metal is bent from the solid. The seams will be added down the sides *ae*, *ae*.

Oblique Truncated Pyramids. The envelope of an oblique truncated pyramid [**30**] with square base is illustrated in **29**. The essential construction, so far as the base and the slanting corners are concerned, is exactly like that in **27** and **28**, and the same reference letters are retained, so that recapitulation is unnecessary. The top of the figure is determined by the cutting of the pyramid by the plane CC at a definite height, that of truncation.

Clearly, now, nothing more is necessary, having the complete pyramid already produced, than to take off a set of measurements on the plane CC, in addition to those on the base line. The set corresponding with the base of the pyramid is obtained first as in **28**, to which the same reference letters apply. The development of the top edge can be got either by taking lengths from *ab″*, *ac″* [**30**], or by measuring up from *b′b″* and *c′c″* [**30**]. With these remarks the construction in **29** is clear. The seams are added from *e″e* [**29**].

Oblique Pyramids. The oblique pyramid with octagonal base [**31**] resembles **27** in the manner of its development. It is necessary to have the base outlined correctly in plan, as in the lower portion of the figure. The real lengths of the slant angles of the corners of the figure are not the full lines in the elevation (upper figure), but the longer dotted ones adjacent, obtained by measurement from the plan view (lower figure), thus: *a′e*, transferred to A*e′*, *a′d* to A*d′*, and *a′c* to A*c′*, and the same lines, of course, answer for the length from *a′g*, *h*, and *i* respectively. The lengths A*b′* and A*f′* are the same as *a′b* and *a′f* below, because obviously these do not slant *away* from the observer, but only in one direction, that in the perpendicular plane.

To obtain the development in **32**, take the successive radii [**31**]—namely, *ab′*, *ac′*, *ad′*, *ae′*, and *af′*, and strike these radii in the manner shown in **32**; the seam in this case has to be added on the inner angle *ab′* of the pyramid, though not shown. Then take the length of any side of the octagon, as *bc* [**31**], and step that round six times between successive arcs, as shown in **32**, *b′c′*, *c′d′*, etc. Unite the points of intersection with straight lines, which, with the lines *ab′*, complete the boundaries of the enveloping sheet. The dotted lines from *a* to the points of intersection are the seamless angles where bending is done.



DEVELOPMENTS OF PYRAMIDAL BODIES

31. Octagonal oblique pyramid **32.** Development of san **33.** Truncated oblique pyramid **34.** Development of san **35.** Truncated pyramid to be developed by triangulatic **36.** Development of same **37, 38.** An alternative methc **39.** Oblique truncated pyramid to be developed by triangulation **40.** Development of same

The truncated oblique pyramid with octagonal base [**33**] requires little explanation, following the previous examples, which include the essential features in its development. The base of **33** is developed in **34**, as that of **32** is from **31**, the same reference letters being retained. The truncated portion is treated like that in **29** and **30** modified only by the difference in the rect-

angular and octagonal forms. A comparison of the reference letters in **29** and **30** with the instructions already given will render the construction of the developed outline in **34** clear, without repetition of details.

Pyramidal Figures, with Apex Inaccessible—Right Figures. Many cases arise in which the taper is so slight that the apex is, for practical purposes, inaccessible. We now, therefore, give attention to other methods adopted, by obtaining certain points in triangular figures, which can be best explained by a concrete example.

The method of triangulation is based upon the fact that the perpendicular height of A, and the slant height B [**35**], and the diagonal C, are mutually related, so that one can be obtained from the other. In this case, as in **25**, the slant height can be obtained by direct measurement. But if there were no elevation it can be got from the plan, thus:

The slant edge, *ab*, seen in plan, the real length of which corresponds with B in elevation, is taken as a base line. On this the perpendicular *bc* is raised, and upon this the vertical height *bc*, equal to the vertical height of *ab*. To obtain the length of the diagonal, C, draw the diagonal *de* on the plan view. On it raise the perpendicular *df*, and measure on that *df*, equal to the vertical height A of the pyramid, and draw the diagonal *ef*, which will give the true, or slant length of *de*; or C in the elevation. These lengths, *ac* and *ef*, are now employed to develop the envelope of the truncated cone thus: In **36**, *a* is a starting point in which the compass is set to mark the length of the slant height *ac*, taken from *ac* in **35**, and the length also of a side of the base *ae*, *ae*, equal to the length *ge* in **35**. The length *fe* of the diagonal face [**35**] is taken, and set off from *ce* and *e* in **36**. The lines *ae*, *ae*, will be drawn to intersect the distances *ae* with *ce*. From *e* and *e*, set off arcs *ff* equal in radius to *ac*, equal to B, the slant height of the figure **35**. Take the length *bd* of a side of the upper face [**35**], and set that off from *cf*, *f*. Draw lines, *cf*, *cf*, through the points of intersection. The remainder of the envelope is obtained by repeating these operations.

An Alternative Method. Another method, in which the essential development by triangulation is similar, is illustrated in **37** and **38**. In **37** a line, *ab*, is drawn equal in length to the base length of a side of the pyramid, and prolonged to right and left. From *a* as centre, and radius *ab*, describe a semicircle and divide it into half as many equal parts, by *c*, *d*, as there are faces to the pyramid—three for a hexagon, four for an octagon, etc. Draw the line *ac* through one of these points of division; *ab*, *ac* now represent the lengths of two base lines and *cab* is the angle which they make. The length of the bounding lines on the upper or smaller end of the frustum of the pyramid is obtained by setting off the length of a side from *ae*, and drawing a line *ef* parallel with *ad*. From *f* the line *fg* is drawn parallel with *ae*, and *fg* is the length of a side on the smaller end; *gh* being drawn parallel with *ab*, and equal in length to *gf*, gives the length of the side adjacent. The figure *bacfgh* is a plan view of two sizes of the figure required, but it does not as yet give the slant height of the sides and edges. These are obtained by the triangulations of the previous figures.

To obtain the slant height of the faces, let fall a perpendicular from *gj*, set off *jk* equal in length to the perpendicular height of the frustum of the pyramid. Then the length *kg* will give the slant height of the face, indicated in plan by *gj*. To obtain the slant height of the edges, draw *gl* perpendicular to *ag*, and equal in length to the perpendicular height *jk*. Then *al* joined will be the slant height of the edge *ag*.

The developed pattern [**38**] is obtained thus: Draw the line *al* equal in length to the line *al* in **37**. Then from *a* as centre, and radius *aj*, set off the arcs *j*, *j* in **38**. With *l* as centre, and radius equal to *kg* [**37**], draw arcs intersecting *jj*, at *jj*, and draw lines from *a* through these points, prolonging them to *b* and *c*. Measure the length *ab*, *ac*, equal to the lengths *ab*, *ac*, and *lf*, *lh*, equal in length to *gh*, *gf*, in **37**, completing the development of two sides of the required frustum.

Pyramids—Oblique Figures. If, for any reason, a truncated oblique pyramid cannot conveniently be developed to the apex, as in **39** and **40**, triangulation is available which we have just applied to right figures. Fig. **39** illustrates, we will suppose, such a pyramid in plan, and of which we know the height of the figure. A line *ij* is drawn on the front slant, and on it another, *jk*, is raised, equal in height to the height of the figure. The diagonal, *ik*, then equals the slant height of the frustum on the outer face A. For the slant height of the faces B, draw the diagonal *bg*, on it raise the perpendicular *gl*, also equal in height to *jk*. The diagonal *bl* then equals the slant height of the faces B and B. To obtain the slant height of the face C—that is, the face bounded by the corners, *a*, *b*, *e*, *f*—draw the diagonal *af*, on it raise the perpendicular *fm* equal in height to *jk*, and the diagonal *am* will equal in length that of the slant face C.

The development is shown in **40**. Draw a line *ik* equal in length to *ik* in **39**, and draw two lines at its terminations at right angles with it. On these lines set off the lengths *cd* and *gh*, corresponding with those in **39**. Take the diagonal *bl* in **39**, and strike radii with it from *gh* [**40**] to *ab*. Measure the length of the sides, *ad* and *cb*, and strike radii with these, cutting those just struck at *ab*. Join *ad* and *cb*. Draw *eh* parallel with *ad*, and *gf* parallel with *cb* and equal in length to *gf* and *he* in **39**. Take the diagonal *am* in **39**, and strike an arc from *fm* [**40**]. Draw *bm* of length *cd* to intersect, and draw *fe* parallel with *bm*. The lines *me*, *ae*, will complete the boundary of the pattern outlines, and the dotted lines *bf*, *cg*, and *dh* are the angles for bending.

Continued

THE NATURAL MAN

The Three Aspects of Man. Perfect Health. The Effect of Occupation. The Great Gain of Life in our Generation. Town Life and the Death Rate.

By Dr. A. T. SCHOFIELD

THE normal man, like "the average man," is a being often heard of but seldom seen, because he rarely exists. Like pure air or pure water, he is supposed to be a commonplace, whereas in reality he is a great rarity.

There seem to be sound psycho-physiological and even anatomical grounds for the tripartite division of man into spirit, soul, and body. The brain itself has naturally a threefold division anatomically, as pointed out by Dr. Hughlings Jackson. There is the cortex or surface of the brain in hemispheres, the mid-brain, composed mainly of two great masses respectively concerned in motion and sensation, and then there is the third and lowest—the medulla and upper part of the spinal cord. That these three regions are broadly connected with three parts of man is shown by experiments on frogs and pigeons. It is found that a pigeon from which the cortex, or seat of the intelligence, or spirit, has been removed can still perform all the functions of animal life and physical existence, but it has lost the directing, guiding intelligence. It flies, but cannot direct its flight, and acts more or less like an automaton. If the mid-brain be removed, the animal life goes, and bare existence remains. The bird can no longer fly or seek food, but if fed, can exist.

The Three Parts of Man. We may thus anatomically and physiologically and psychologically say that with the cortex we *live* (spirit life), with the mid-brain we *move* (animal life), and with the medulla we *exist* (body life), or, in the words of the great Christian apologist on Mars Hill, "In Him we *live* and *move* and have our *being*." A man, therefore, must be regarded as a tripartite being. While mainly concerned with physical health, we seek to give due weight to intellectual and moral health, and, taking a broad view, deem no man in health whose spirit or soul is sick, though the body may be sound.

"In good health," says one well-known hygienist, broad enough to survey man as man, "there must be the capacity and desire for every kind of prolonged physical exertion with skill, ease, and pleasure. But this is not enough. There must be the capacity and desire for every kind of prolonged intellectual exertion with skill, ease, and pleasure. But this is not enough. There must be the capacity and desire for every kind of prolonged spiritual activity with skill, ease, and pleasure, and there must be evidence that all three divisions are in health."

Not that the three divisions are equal. Mr Eustace Miles has graphically shown their true relations somewhat after this manner:

In health, spirit controls the soul, which controls the body.

In ill-health, body controls the soul, which controls the spirit.

In other words, a strong body obeys the mind, a weak one rules it.

The Healthy Man. In full health a man lives as simply and cheaply as he can. There is self-control and purity, patience, candour, altruism, contentment, and happiness. He is healthy in all circumstances, and, even if the balance be upset by bad environment, the healthy man soon unconsciously compensates, and the balance is restored with ease.

Health, it has been well said, is a constant equilibration rather than a constant equilibrium—that is to say, there are daily variations, and constant oscillations, and not a fixed condition. Health is like a block of wood with many sides; so that whichever way it is pushed over, it stands equally well. The healthy man controls his circumstances, and is not controlled by them. Ideal health is largely independent of conditions. The athlete is not a healthy man, nor the student, nor the saint. Each one has a tendency to develop one part of himself at the expense of the other two. The recent development of colour photography is a good illustration of this. There are three colours in nature, as there are three parts in man, and any scene that has to be photographed in colours has to have three exposures, each one made by cutting off two-thirds of the light, which, of course, is itself made up of all three colours. These exposures are then printed in red, yellow, and blue, and when one is shown on a screen we get the landscape in shades of red, when the yellow is superimposed we get the orange and yellow tints added, but all is glaringly unlike Nature. But the moment the third part, the blue, is added, all falls into perfect harmony, and we get the browns and greys, and all the subdued half tints of Nature herself. So with man: it is not until we get the three parts—spirit, soul, and body—superimposed, and all in healthy development, that we can see and know what is a true man.

The Physical Man. What, then, is a human being physically? If a man, he is, in the perfection of civilised life in this twentieth century, an individual six feet high, weighing thirteen stone. In certain manufacturing districts he is only five feet one and a half inches, and averages seven and a half stone in weight. All averages, however, are being now constantly exceeded, and must soon be raised. At birth, if a man, he will now expect to live only for 45 years, if a woman, for 47 years, although it is believed that his full span of life should be 105, or five times the period of his growth. He is essentially a unity, and yet a unity in diversity.

A Unity in Diversity. It will, of course, occur to all that he is a trinity in unity, a compound of body, soul, spirit, and yet but one man, one personality. A collection of divers machines of complex structure, and constructed of heterogeneous materials, all crumbling away at different rates, he yet moves, and acts as an independent unit, governed as regards the life of his body by the one unifying factor, the unconscious mind; as regards its actions by his conscious mind, the two forming but one mind, one character, one ego, and the whole, with the body, forming one person—man.

This man, if he survives the first two or three years of his life, will probably live to 75 instead of to 45; and his life would then be divided into three stages of about 25 years each, the first being *growth*, the second *maturity*, and the third *decay*.

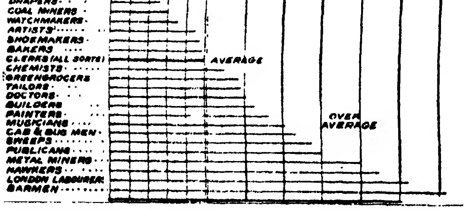
The height and minimum weight of those men who do not reach the high standard of six feet and 13 stone, if in perfect health, are as follows:

5 ft. 6 in.	= 10¼ stone.	5 ft. 9 in.	= 11½ stone.
5 ft. 7 in.	= 10½ „	5 ft. 10 in.	12 „
5 ft. 8 in.	= 11 „	5 ft. 11 in.	= 12½ „

The points to look for in man are height in relation to weight, perfection of movement, and sensation.

The Slaughter of Life. As to physique, it must be remembered that the measurements we have given are far in excess of those of ancient times, for the race is supposed to increase, as we have already said, in stature in civilised countries at the rate of 1¼ in. in every 1,000 years. Not only so, but, low as the average of 45 years out of a possible 105 may appear, it is really a very great advance over that of 36 in the early part of the nineteenth, or 20 in the eighteenth century, and is mainly due to the increase of private and public hygiene everywhere. It is probably an understatement to say that hygiene saves now some 120,000 lives every year. And yet to-day the needless mortality amongst infants (some 50,000) is terrible and shameful, for the low average of 45 years is mainly due to the enormous infant mortality that persists. When all babies under six months old drink nothing but clean milk infant mortality will at once be reduced by one-half.

Occupation has a bearing upon the health and longevity of the man, as this table shows:



It will be seen that clerks of all sorts are the only people who live the right time according to the present average: that is, that they die at the rate of 100 per cent., and at 45 years of age.

Why People Die. The clergy head the list and live nearly twice as long as the average. They come of a good stock, are temperate in habits, and have a small but assured income. Free Church ministers die a little faster. Farmers live long, but would show up better if they spent less money in drink. The agricultural labourer's favourable lot in life (only three-fourths of the average death-rate) is all the more striking when contrasted with that of the town labourer (the lowest but one), who dies just twice as fast as he should. Grocers owe their higher death-rate to the spirits they consume. Lawyers are well off, but it is found that after 45 they die off more quickly than they used to do, probably from increased strain of life.

Drapers die mainly from consumption, owing to the amount of dust in their trade, which makes it less healthy than that of a grocer. The health of coal miners, which is surprising, is probably due to the fact that only strong men enter the colliery, and to the harmlessness of coal dust. Artists owe their higher mortality to the fact that with them are included engravers and sculptors, among whom the death-rate is high. Bakers die usually from drink and suicide. Clerks occupy the average, as we have seen, and their death-rate is much lower than it used to be, owing probably to better ventilation of offices and increased exercise.

The table ranges from the clergyman, with a mortality of 55 per 100, to the pot-boy, with 220—a difference that needs no words to show the value of hygienic influence. Nevertheless, as a whole, this table, composed in 1885, shows an improvement over previous ones that is equivalent to an addition of 2,000,000 years of life annually to the nation. Since then the improvement has continued steadily.

The Perfect Man. A man "in order" is, then, as a whole, one free from disease, functional or organic, whose weight bears a certain relation to his height and general physique; who leads a healthy life, and pursues, if needed, some healthy calling; who is temperate in all things, avoiding intoxication, physical, mental, or moral; who gives due balance of work to both physical and psychic natures; to whom every morning is a resurrection, and whose life is one of perfect personal ease and action both in mind and body. All his three natures are in perfect harmony, so that internal discord is unknown; and lastly, but above all the rest, he is "in tune with the Infinite."

The personal appearance of this man will be the mean between fat and thin; his shoulders will be broad; his hips lean; his chest well developed; his hair probably brown in this country—for, comparing the proportion of the different shades of hair, there are about eight brown to every six either light or dark brown, or four fair, or two either black or flaxen, or one red. He will have a clear, bright eye; a frank, noble, pure expression; a clear, soft, unwrinkled skin; elastic arteries, with good heart, lungs, and liver, good digestion, and perfect sight and hearing.

Manhood in its perfection may be said to extend from 25 to 55 years of age, the whole of which time should be a period of perfect health, equally free from the dangers and diseases attending youth and growth on the one hand, and those attending old age and degeneration on the other. Absolute perfection may be said to be attained about 40.

Marriage and Health. The best time for marriage is—for woman, from 21 to 28, the limits being 20 to 35; for a man, 28 to 35, the limits being 24 to 40. For a happy marriage there should be some contrast between the pair, but not too great a difference in tastes, position, temperament, age, size, and race. Neither should be seriously diseased, and if healthy up to the age of marriage, the fact of being the offspring of diseased parent or parents is not a sufficient bar to union. The marriage of healthy cousins is sometimes detrimental in one generation, but, if persisted in for several, results in a dwarfed and deteriorated race. A town dweller of three generations should certainly marry into a country stock. The health of the parents is of the utmost value to the offspring. Hence nerves should be kept in order in married life, not only for selfish, but for altruistic reasons. All ex-excesses of body, soul, or spirit should be carefully avoided, and moderation and temperance in all things should be practised. When the food is scanty and poor, boys are likely to preponderate; where plentiful and generous, girls are most numerous.

Marriages are not so fruitful if the man is younger than the woman, or more than 16 years older. The boy and girl unions amongst the less educated are the great cause of the infant mortality. A woman reaches her perfection at thirty-five years of age, a man at forty. At this period of life many of the rules of hygiene have to be radically changed. As long as the body was growing one could hardly eat too much food, but now abstinence is the rule, and the weight once fixed should be by no means exceeded.

The table on this page gives the approximate weight of men, women and children at different ages (clothes average 7 lb., or 6 lb., without shoes).

With regard to food, the majority of us eat too much. A man should be most strict not to exceed his settled weight as shown by the scales.

What we Should Eat. It is well to eat a good breakfast, a good luncheon, and a plain and somewhat scanty dinner. Both the digestion and assimilation get weaker as the day goes on. The French breakfast at twelve or one o'clock is too late for English habits, and the early roll and coffee is not enough by itself to do a morning's work on. It has been found that on the coffee and roll a French workman does only some 250 to 300 foot-tons of work as compared with the Englishman's 500 on a better breakfast.

But it is not only the habit of eating too much that has to be resisted at this age: there is the question of drinking. Strict moderation is increasingly imperative in the wear and tear of modern life, and a very careful watch should be kept against the growth of any habits at this period; for it needs but one or two evil ones to wreck fatally the most promising life.

All Classes.				Boys. Upper Classes only.			Girls. All Classes.

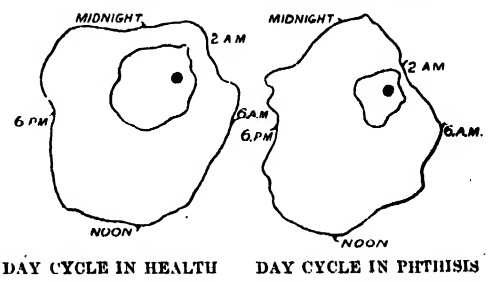
As to dress, a flannel belt is of value, and is a protection in many ways. It must be remembered that fat does not lessen the risk of taking cold but rather increases it.

Bathing in ice-cold water is not advisable after 35 or 40, but the coldest water is always safe when standing in hot. The hair should not be constantly wetted, as this tends to baldness; but the whole body should be bathed every day, and washed with soap once a week.

The bodily powers, as measured by the force of respiration and circulation, vary very much in the twenty-four hours, and there can be no doubt that two o'clock in the morning is the weakest time of the twenty-four. It is the hour of most births and most deaths.

These diagrams show the varying force of respiration and circulation through the day:



DAY CYCLE IN HEALTH   DAY CYCLE IN PHTHISIS

In these diagrams the dot represents death or the stoppage of life; the inner line is that of respiratory force, the outer the circulatory.

The life should be conducted so that there is neither gain nor loss, but an even weight for

30 years at least. A long journey every day by train is certainly bad, and a great strain on the nervous system. For sedentary occupations it is of great value to be able to walk to and from business. If there is difficulty about going to sleep at night a good plan is to rise half an hour earlier each day until you go to sleep as soon as you go to bed.

The Three Dangerous Ages. Avoid all irregularities and excesses, strains on the heart, worry, loss of sleep and obesity. There are said to be three periods when one is prone to sickness—at 36, when the lean tend to get fat, and the fat lean; from 45 to 50 the climacteric; and at 61 another crisis occurs, when the powers of life may suddenly fail.

In spite of the rush of people from country to town, in spite of the enormous size of London and the growth of all our cities, every generation at the present day lives in the aggregate millions more years than in the "good old times."

The difference between the present time and fifty years ago may be well shown. Out of a million men born 62,000 are alive at 20 years of age who would then have been dead; at 50 the same number; while even at 70 we have over 15,000 to the good. Surely this shows the solid value of health laws in adult life!

It may be said that in this country, at the age of 20, over 2,500,000 people are living now who, 50 years ago, out of a similar number of the same age, would have been dead; and when we know that each person on an average is said to be worth £156, this represents an addition of nearly £400,000,000 to the assets of the nation. So that hygiene pays its way

We are constantly being warned of the ill effects of the present rush of life. Diseases of the nervous system are increasing, and diseases of heart and lungs and liver are rife; but zymotic diseases are much fewer, so that we die now more from wearing out some part of the body than by a premature poisoning by germs.

Town Life and Health. On the whole, life was never so safe from fatalities as at present. At any single year up to 79 there are more survivors out of any given number than formerly; but, curiously enough, over this there are fewer, and this is said to be mainly due to the modern preference for town life. The increase of mortality due to this cause is amazing If a labourer comes to town he takes, on an average, 20 years off his life. At 65 years of age, out of 100,000 persons born, nearly 20,000 more are alive in the country generally than in a large town.

As hygiene lengthens our days, we cut them short by our town lives; and it would be greatly to be regretted if mere length of life represented the greatest desideratum. But this is far from being the case, and, doubtless, a large number of those who spend their years in town can show how much they and others have benefited in other ways even if they have lost somewhat in length of days. There is, however, a far better prospect for healthy manhood than there ever was before; for not only are the years longer, but they are much more healthy and more enjoyable. There can be no doubt that the modern appliances for saving time and wear and tear have greatly lessened the evils produced by the greater rush of life.

Care of Old Age. Now, as to the care of old age, the chief points are moderate and digestible food, sufficient warmth, and an even and quiet life. The chief of the three is the food, or fuel for the lamp of life. While all fixed dieting is bad where it can possibly be avoided, a few hints can be given that may prove of value. The older a person is after 50, the less food he requires. Luigi Cornaro, who lived to 100, though of a feeble constitution, took 12 ounces of solid food and 14 ounces of fluid daily during the latter part of his life; and his most severe illness was caused by his increasing his allowance, through the continual entreaties of his friends. Very little proteid or animal food is required, and though in many respects false teeth are a great boon to the aged, they may lead to too great a consumption of animal food. It is not the amount of coals we put in a grate that warms the room, *but the amount that can be burnt;* and the great point is to avoid choking the digestive and excretory organs with excess of food. The food of the nursery is the best in old age. Bread-and-milk and honey is a capital diet. Milk agrees with nearly all. Hot milk with a little Mellin's Food forms an admirable drink at night, and can be kept warm in a hot water jug covered with a cosy. Fruit is wholesome if ripe or well cooked. Fat, as cream or fresh butter, is good. Warm food is very suitable. Soup enriched with cream or marrow is light and nourishing. All meals should be regular, and all excesses avoided. If weight is being gained the diet should be decreased. In addition to the after-dinner nap, as years creep on, a doze after breakfast and before dinner is often helpful.

Clothing and Warmth. Clothing should be both warm and light. The underclothing should be of wool. Fur is an admirable material. A sealskin waistcoat is useful, and the feet and hands should be well and warmly clothed. An eider-down quilt on the bed, which should be warmed in winter, is a good covering. No aged person should be suffered to get cold in bed. The warmth of the bed is of great importance in old age. A warm bath should be taken every day, and a warmer bath, with plenty of a pure mild soap to keep the skin supple and soft, should be used twice a week. It is better for old people who have the opportunity to winter in the South of Europe, if possible. If not, the aged should shut themselves up in a well warmed house at this season.

The rooms should be at a temperature of 65° to 70°. The habits of old people should not be lightly altered. Whatever excites exhaustion should be forbidden; early rising is, therefore, bad. Hard drinking-water is not good, as it tends to hasten the calcareous changes in the body. A fixed diet should not be rigidly adhered to: variety is often essential.

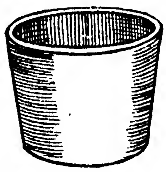
GLASS AND GLASS-MAKING

Nature and Properties of Glass. Manufacture of Glass Pots. The Furnaces. A Series of Recipes. Annealing and Hardening. Crown and Sheet Glass

IT is not within the scope of this article to trace the history of the manufacture of glass. It will suffice to note that the first window glass was made in England at Crutched Friars, London, in 1557, and fine articles of flint glass soon afterwards at Savoy House. The first sheets of blown glass for looking-glass and coach windows were made in 1673, at Lambeth, by Venetian workmen. The abolition of the Excise duties on glass, in 1845, may be considered the starting-point of the modern glass industry in England, which at once expanded into an enormous trade.

What is Glass? Glass may be defined as a non-crystalline, transparent, solid substance produced by melting at a high temperature *silica*, or a similar body, with an *alkali*. In place of silica *borates* and *phosphates* have been used, and the term *alkali* must be taken in its most elastic sense to include alkaline earths such as lime and baryta.

It is usual to regard glass as insoluble in water, although it is not so, strictly speaking, infinitesimal amounts being soluble. Alkaline solutions have a slightly greater solvent power on glass than water, but acids act but little on glass with the exception of hydrofluoric acid.

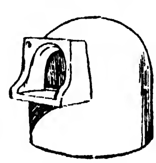


1. OPEN POT FOR PLATE AND SHEET GLASS

Age and Weather Affect Glass. The weathering of ancient glass in cathedral windows is due to the decomposing action of atmospheric moisture, and a special "disease" of old glass has been traced to a fungoid growth. The iridescence of old glass is due to exposure to moist air or damp earth for long periods. Sir William Crooks has traced a curious lavender coloration of glass to the action of ozone in the air. The brittleness of glass will occur to the reader as one of its most characteristic features; but curiously enough, glass drawn out into fine threads is quite flexible, and a mixture of glass and silk has been used to make a fabric of exquisite sheen. When hot glass is rapidly cooled it often breaks, because it is a bad conductor of heat. The exterior surface of the glass cools more rapidly than the inner portions, unequal contraction and usually fracture resulting. The thinner a glass vessel is the less liable it is to break. It is quite usual for chemists to put boiling water into thin blown vessels without any untoward results; but as soon as thick-walled vessels are submitted to similar treatment trouble begins. When newly-made glass is allowed to cool quickly great tension is put upon the various strata of glass so that if such a vessel be scratched it flies to pieces. This effect of tension is overcome by cooling glass slowly, the whole process being known as *annealing*. Glass is impervious to gases and is a bad conductor of electricity.

Glass Pots. The crucibles in which the glass materials for making pots are melted are made of fireclay and require the greatest care in the manufacture, as imperfections lead to fracture of the pot and consequent waste of glass. In Great Britain the most famous fireclays are those from Stourbridge and Glenboig, near Glasgow. Other famous fireclays are obtained from Forges-les-Eaux in France, Namur in Belgium, Sargenau in Switzerland, and Schwarzenfel in Bavaria. In the United States the Missouri plastic clays are chiefly used. The composition of fireclay is mainly silica and alumina combined with a small percentage of water, which last-named, being expelled in the drying and annealing process causes a considerable amount of shrinking in the pot.

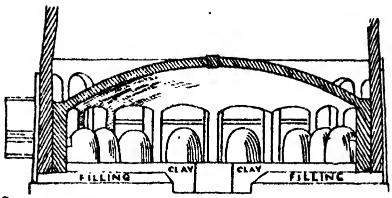
Preparing Fireclay. The virgin fireclay is carefully picked over to remove impurities, dried, ground, and sifted. To counteract the shrinking of the pots a proportion of old glass pot or ground burnt clay is always mixed with the raw fireclay. A mixture such as the following is used: Ground pot scrap, 3 parts; ground burnt clay, 4 parts; ground raw clay, 6 parts. These ingredients are carefully mixed and sifted and measured into a lead or zinc-lined trough. The mass is then damped with water, allowed to stand for two days and kneaded. This kneading is accomplished by workmen trampling in the clay from side to side of the tank, the warmth and elasticity of the naked feet being considered better for developing the plasticity of the clay than the pug mill sometimes employed. The treading is repeated at intervals, some months being allowed for the material to mature. There results finally a dense plastic clay from which the pots are fashioned. The workman makes the clay into rolls, taking care that no air cavities are left, and begins modelling the pot on a board or stone covered with granulated pot scrap or burnt clay. The roll of clay is laid in a spiral manner, the edges being scored to promote adhesion of the separate layers, the bottom and sides of the pot being in this way gradually built up. The two kinds of pots are illustrated in 1 and 2, the former being the open pot used for plate and sheet glass, the covered pot being the kind used for flint glass-making. The drying of the pots is very carefully regulated, the process occupying from four to 21 months. The final process consists in annealing the pots by heating them for a few days gradually



2. CLOSED POT FOR FLINT GLASS

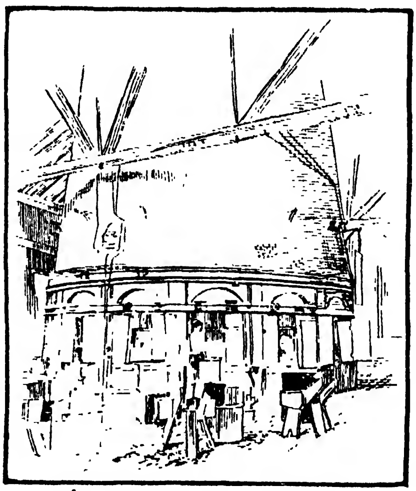
to red heat and glazing. The interior of the pot is glazed by throwing in a quantity of broken glass just before use. The coating thus given protects the clay from the action of the alkali used in meltings.

Melting Glass. Glass is melted in a modified form of reverberatory furnace, gaseous fuel being employed. The furnaces are constructed upon the general principles of obtaining the most intense heat possible, regularity in maintaining this heat, and economy of fuel. Silica bricks, which are quite infusible if kept free from alkali, are used for the most exposed parts of the furnace, but fireclay bricks of the most refractory kind are the general material of which the furnace is built. The fireclay is mixed with ground flint before being made into bricks, and the bricks are used without previous drying. The bricks are bound together with iron. After building, the furnace is left to dry for some months, and then the drying is completed by firing. A furnace lasts from two to five years.



3. SECTION OF GLASS-MAKING FURNACE SHOWING MELTING-POTS

The Furnace. The older dome-shaped type of furnace [4] consists of two parts the combustion chamber and the *cave* or draught chamber beneath. Between the two, in the centre, is the grate, which is sunk a few feet below the *siege,* or bench upon which the glass melting-pots are placed [3]. From 4 to 18 pots are accommodated on the siege, and they are reached for working or charging by a small arched opening situated directly over each pot. In the case of the covered pots used for flint glass the mouth of the pot is exposed on the outside of the furnace walls. The combustion chamber is surmounted by a low flattened arch for the purpose of reverberating the flame. The products of combustion are led by means of short flues situated beside each of the pots into the large chimney surmounting the furnace. A double-arched roof is arranged in some kinds of furnace. The draught needed to promote combustion of the small coal is obtained by means of the cave, which is frequently arranged in two passages at right angles, so that advantage can be taken of the direction of the wind. As a good deal depends on the regularity with which the fuel is supplied, mechanical feeders are employed. The Boetius furnace is an improved type of this furnace, in which heated air is introduced with the gas obtained by heating coal. These furnaces are also constructed in connection with a Siemens regenerator, the air and gas entering through the bench of the furnace within the circle of pots.



4. GLASS-MAKING FURNACE

The Siemens Furnace. In 1861, C. W. Siemens and F. Siemens obtained a patent for a glass furnace in which regenerators are applied to receive the waste heat of the products of combustion and conduct it to the air needed for supporting combustion. The solid fuel is decomposed or gasified in a separate apparatus, and heated to a high temperature before it enters the glass furnace. Since then, notably in 1870 and 1872, further improvements have been patented.

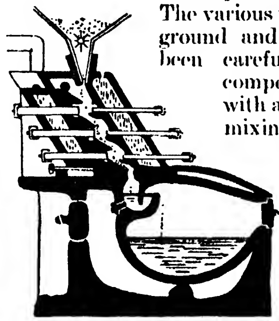
The Siemens type of furnace is now very general, but has been altered in many ways since its first introduction. The gas producer, for instance, is now made as part of the furnace, and the expense is lessened, because the regenerator is omitted.

In the newer furnaces the ordinary glass melting-pots are replaced by tanks, and as the melting is generally continuous, great economy of fuel is effected over the older kind. There is also an intermittent type of tank furnace which is necessary for some kinds of work. In the continuous tank furnace a capacity of 12 to 20 tons each 24 hours is usual, such a furnace being worked with two shifts of men. A furnace of this description, having a capacity of 12 tons, uses about 8 tons of bituminous gas coal each 24 hours, the 12 ton production being the net product over and above all waste and breakage. The furnaces are more durable than the old furnaces, because in keeping up the heat the firebricks are not so strained by being subjected to grêat changes of temperature.

Electric Furnaces. Many attempts have been made to use the heat of an electric arc for melting glass materials, two of the most promising electric furnaces being figured in 5 and 6. In the Voelker furnace [5] the hopper feeds the material, which passes in succession between carbon arcs. Direct current generated by a 360-ampère dynamo with a voltage of 120 is passed through the carbons. The intense heat of the first arc melts the raw material and causes it to trickle downwards, bringing it under the influence of the second arc, and then of the third arc. The melted glass collects in the cup beneath and thence into the large reservoir free from gases and impurities. It is claimed that with this

furnace bottles can be blown within half an hour of charging the hopper. Referring to the illustration of the Becker furnace [6], the three small circles represent the carbons, the passage of the raw material being indicated by the dotted lines. From the left-hand tank the melted glass passes over a bridge into the right-hand side and is free from bubbles of gas and ready for use.

Glassmakers' Recipes. The following standard recipes for making various kinds of glass are intended to give a general idea of the proportions of materials employed. In practice the number of recipes is very great, different makers preferring certain mixtures of ingredients.



5. VOELKER'S ELECTRIC FURNACE

Crown Glass. 1. Silica (sand) 600 parts; chalk, 65 parts; sodium carbonate, 400 parts; cullet (broken glass), 500 parts. 2. Silica, 400 parts; quicklime, 64 parts; sodium sulphate, 200 parts; charcoal, 16 parts.

Window Glass. 1. Silica, 120 parts; potassium carbonate, 60 parts; arsenic, 1 part; borax, 2 parts. 2. Silica, 100 parts; chalk 25 parts; sodium sulphate, 35 parts; cullet, 100 parts; arsenic, 1 part; charcoal, $1\frac{1}{2}$ parts; manganese oxide, $\frac{3}{8}$ part.

Plate Glass. 1. Silica, 400 parts sodium carbonate, 250 parts, chalk, 30 parts. 2. Silica, 100 parts; quicklime, 12 parts; potassium carbonate, 6 parts; sodium carbonate, 33 [illegible] cullet, 100 parts; manganese oxide, [illegible] part; pota[illegible]m nitrate (nitre), 2 parts.

Lead, Flint, or Crystal Glass. 1. Silica 336 parts; potassium carbonate, 112 parts; red lead, 224 parts; manganese oxide, $\frac{1}{2}$ part potassium nitrate, 20 parts. 2. Silica, 300 parts; chalk, 60 parts potassium carbonate, 105 parts; red lead, 160 parts; cullet, 100 parts; manganese oxide, $1\frac{1}{2}$ parts.

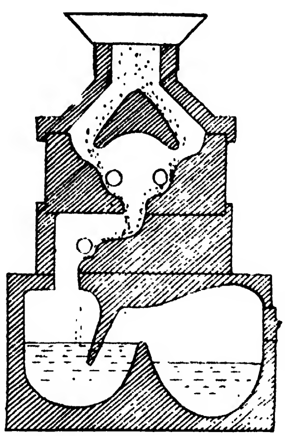
Baryta Glass. Silica, 350 parts; sodium carbonate, 100 parts; barium carbonate, 300 parts; lead oxide, 230 parts.

Lime Flint Glass. Silica, 400 parts; chalk, 35 parts; sodium carbonate, 155 parts; potassium nitrate, 20 parts; arsenic, 2 parts; manganese oxide, 2 parts.

Bottle Glass. Silica, 100 parts; chalk, 5 parts; potassium carbonate, 20 parts; sodium sulphate (Glauber's Salts), 15 parts.

Amber Bottle Glass. Silica, 100 parts; chalk, 28 parts; sodium sulphate, 40 parts; cannel coal, 14 parts; charcoal, 8 parts.

Opal Glass. Silica, 100 parts; potassium carbonate, 30 parts; red lead, 120 parts; arsenic, 4 parts; borax, 4 parts; calcium phosphate, 14 parts.



6. BECKER'S ELECTRIC FURNACE

White Enamel Glass. Silica, 240 parts; sodium nitrate, 64 parts; manganese oxide, 1 part; red lead 256 parts; arsenic, 23 parts; antimony oxide, 1 part.

Alabaster Glass. Silica, 100 parts; potassium carbonate, 40 parts; borax, 5 parts; French chalk, 5 parts.

Red Glass. Silica, 128 parts; potassium nitrate, 64 parts; manganese oxide, $\frac{1}{4}$ part; red lead 144 parts; antimony oxide, $\frac{1}{4}$ part; dissolved gold, $\frac{1}{4}$ part.

Blue Glass. Silica, 100 parts; chalk, 25 parts; potassium nitrate, 6 parts; sodium carbonate, 36 parts; red lead, 10 parts; cullet, 200 parts; cobalt oxide, $\frac{2}{5}$ part; copper oxide, 7 parts.

Green Glass. Silica, 100 parts; chalk, 20 parts; sodium carbonate, 33 parts; iron oxide, 3 parts; copper oxide, 5 parts; potassium bichromate, $1\frac{2}{3}$ parts; potassium nitrate, 5 parts.

Yellow Glass. Silica, 125 parts; potassium carbonate, 37 parts; red lead, 52 parts; potassium nitrate, 7 parts; uranium oxide, 2 parts.

Preparing and Melting the Batch. The various ingredients for the batch of glass are ground and sifted, each of the materials having been carefully weighed to ensure an uniform composition. The mixing is done either with a shovel or more often now in a special mixing machine. Formerly a calcining process called *fritting* was employed before filling the "melt" into the glass pots, but the superior purity of the ingredients now employed has rendered this operation unnecessary. The material is charged into the pots, which are already strongly heated in the furnace, and as the ingredients sink with fusion more material is introduced until the pot is full, each of the additions being allowed to melt completely before the fresh introduction of material. This first part of the process—the melting—takes from 10 to 12 hours. Gases are given off from the mass as it melts, these answering the purpose of stirring the semi-fluid mass and also helping the fusion. A potato, apple, or stick of green wood is sometimes introduced to generate additional gas during this stage. When melting is complete a scum rises to the surface, which is known as *sandiver* or *glass gall.* This scum is removed by means of a ladle. The temperature meanwhile has been increased to make the glass more fluid and facilitate the refining or *plaining.* The exact stage of refining is ascertained by taking samples of the glass and noting whether the glass is homogeneous and free from colour. When the glass is found to be quite *plain,* the temperature is reduced so as to make the glass more viscous and ready for use by the glass-blower. This is known as *cold stoking* or *standing off,* and is brought about by the introduction of a cold-air blast, so that the temperature of the furnace is continued for the benefit of other pots. The temperature is reduced gradually so that the impurities can rise to the surface.

In the case of tank furnaces only the space inside the floating fireclay rings is cleared of scum. The various temperatures are judged by the workmen, but accurate work in this direction is done by means of porcelain cones, which soften at known temperatures. The temperature of the glass furnace is variously estimated at from 1200° F. to 3600° F. The refining process takes from four to six hours.

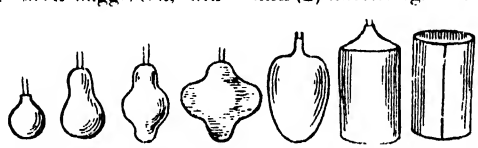
Annealing. The process of *annealing* is necessary to impart strength and durability to glass. The method simply consists of heating the glass and cooling it gradually, so as to make the glass nearly or quite homogeneous. The furnaces in which the annealing is done are called *leers* or *lehrs,* and vary in construction according to the purpose for which they are used. For sheet glass the ordinary leer consists of an arched tunnel kept heated from one end by suitable furnaces, and through which the sheets of glass to be annealed are caused to travel with an intermittent motion. For annealing small glass articles, such as tumblers and jugs, a train of trucks is caused to travel slowly along a leer, which is about 30 ft. long. The heat becomes less and less as the leer is traversed, the rate of travel being arranged so that the annealing is finished by the time the articles reach the far end.

Hardening Glass. Many attempts have been made to render glass less fragile, and so to increase its usefulness. In 1874, a French engineer, Bastie, discovered that by plunging glass vessels heated to their softening point into melted fat or heated oil, the glass was rendered so tough that a diamond would not scratch the surface. The glass so treated is, however, liable to explode or fly to pieces. Other processes, modifications of Bastie's method, have been suggested, and the Siemens method of rapid cooling between metal plates is used with some success. A modern development, the result of investigations by Schott, consists in flashing a glass of smaller coefficient of expansion upon a glass of a known coefficient, thus reducing the tension resulting from the sudden application of heat and cold. This glass is known as *compound glass* or *verbundglas.*

Crown Glass. Crown glass is the oldest kind of window glass, but is now almost replaced by sheet glass. This kind of glass is produced from melted glass by blowing it into the form of a globe, and then the globes are thrown open into flat circular plates called *tables,* by means of the operation called *flashing.* The workman takes a metal pipe 6 to 7 ft. long, and, dipping it several times into the melted glass, gathers from 16 to 20 lb. of glass upon the end. By swinging the pipe or holding it in a perpendicular position the glass is collected in a lump beyond the end of the rod. The operator then rolls the metal on an iron plate called a *marver* until it assumes a tapering cylindrical shape, the end opposite the pipe being known as the *bullion point.* He then blows through the tube to produce the shape shown in the third figure of the diagram, the glass being rotated in the meantime [7]. The glass is reheated, and an iron rod, called a *pontil* or *punty rod,* is applied to the bullion point, and the blowing tube detached by touching it with cold water at its juncture with the glass. A hole is left at the point where the blowing tube was attached, and this, by rotation and heating, is enlarged until finally, by centrifugal force, the edges flap outwards and form a perfectly flat plate of uniform thickness except in the centre where the iron rod was attached, the lump of glass being known as the *bullion* or *bull's-eye.* When cooled sufficiently the plate of glass is cut free from the punty rod by shears and then lifted by means of an iron fork into the annealing furnace. There the temperature is gradually lowered for from 24 to 48 hours, and the plates taken out and cut up for sale. Owing to the bull's-eye in the centre, squares of glass of the size of 38 by 24 in. or 35 by 25 in. only can be cut, and it is this limitation that has tended to displace crown glass by other processes by which larger sheets are obtained.

7. STAGES IN THE MANUFACTURE OF CROWN GLASS

Sheet Glass. Sheet glass is another form of window glass, and is made by blowing a cylinder and flattening out the cylinder into a sheet. A larger piece of glass can be obtained by this process than from *crown glass,* as there is no loss of glass due to the bull's-eye. The manufacture may be divided into two chief operations: (1) blowing the cylinder and (2) flattening. The workman gathers a lump of glass as in the process of making crown glass, and by rotating on the marver, reheating, swinging, and blowing, forms the cylinder, the stages being shown in 8. The end of the cylinder is opened by applying a piece of hot glass to soften the end and then blowing. The burst edges are trimmed off with a pair of shears, and the gathering rod is cracked off by applying a cold iron. The top part of the cylinder is broken off by putting a hot thread of molten glass round, and then applying a cold iron, or by first touching the part with a semicircular piece of hot iron, and following this by a drop of water, when the fracture takes the line where the heated iron was applied. The cylinder is then, while still hot, cut from end to end with a diamond cutter. The cylinder is then transferred to the flattening furnace, where it is softened by the heat, opened out flat, and passed on to the annealing chamber. An instrument called a *flattener* or *polissoir* is used for smoothing the cylinder when it has opened. The annealing process lasts three or four days. In this process a sheet of glass of the ordinary size of 50 by 36 in. is made, but larger sheets are made. The standard weights of sheet glass range from 15 oz. to 42 oz. per foot.



8. STAGES IN THE MANUFACTURE OF SHEET GLASS

When sheet glass is subsequently polished it is known as *patent plate* glass.

THE IDEAL MARRIAGE

Amateur Critics of Marriage. False Systems. The Oldest Human Institution. Its Triumph and its Supreme Importance to the World. The Family

By Dr. C. W. SALEEBY

IT has, unfortunately, become a recent fashion for novelists, writers of plays, and other men who earn their living by more or less imaginative literature, to invade the realms of sociology, to pose as authorities upon it, and to lay down propositions which the public is expected to accept. Nothing could be better than that the vital questions of society and human life should engage the attention of serious people by means of illustrations in fiction and on the stage. But grave disaster is liable to ensue when men who are unequipped for the study of sociology, whether by reading or by mental training or by temperament, permit themselves to advise the public upon matters of the most serious moment. The quack doctor of the individual body is an evil; the quack doctor of the body politic is a far worse evil.

A Pestilent Propaganda. Now, it is no less a social institution than marriage that has lately furnished material for copy to a number of contemporary writers. Thus, we have the problem play and the problem novel. It would be easy to exaggerate the harm that these do, for, after all, we do not take the theatre or even our fiction very seriously—and in this we show a rare degree of wisdom. But serious harm must ensue when men like Mr. Bernard Shaw, Mr. H. G. Wells, and even Mr. George Meredith, who have gained popularity, or even the homage of the wise, as imaginative writers, use the influence thus obtained for the purpose of propagating views upon social questions which can be described only as puerile, superficial, and pestilent. This, of course, is strong language. It is, indeed, our intention to make this protest against the wholly amateur and irresponsible contributions of these writers to the subject as strong as we can conveniently make it. In certain grave social subjects we plainly must be prepared with scientific warrant for the doctrines which serious and responsible sociologists have formulated and the truth of which they have proved.

The Only Authority is Truth. We must enter upon our study with no prepossessions in any direction. We may be on the side of established religion—and established religion is an upholder of marriage. That ground is not sufficient for our upholding of marriage. We cannot accept any social doctrine upon authority. In science there is no authority but Truth, and each man must find her for himself. On the other hand, we may be antagonistic to established religion, as are, in general, the writers who are now criticising marriage. This, however, is no adequate reason for any prejudice of ours against marriage. We must rid ourselves equally of theological and anti-theological bias. There is some excuse for both in the study of this question, according as we look at it from one side or another; but there is no adequate excuse for bias in the search for truth, and if there were it would not redeem the search from failure.

Marriage is Older than the Human Race. Our only scientific method, evidently, is the historical method. What is the origin of marriage; what are its forms in different places and different ages; what are the social phenomena with which any particular form is constantly found associated; and what, if any, are the social phenomena which the various forms of marriage actually cause?

In this country we are familiar with marriage as a civil institution and as a religious institution; it is regarded here as a civil contract, and there as a divinely ordained sacrament. Now, the first fact which we have clearly to recognise is that no Church, living or dead, is or was the inventor or originator of the institution of marriage. This institution is definitely older than any existing Church or any historical Church; i is definitely older than even the most primitive of all primitive religions; nay, more, it is older than the human race itself.

This is a fact worth noting on every ground. There is some humour in it, too, for it at once makes absurd the opposition of many persons to marriage, and exposes their ignorance. A vast deal of contemporary opposition to marriage in this country, and more especially on the Continent of Europe, is really engendered by opposition to established religion. It is thought that any blow struck at marriage is a blow struck at the Church, and it is quite definitely supposed that, practically, marriage is a product of the Church, and cannot very well exist without it.

Marriage is Not an Institution of the Church. Now, for this absurd error there is considerable excuse. It is the case that the Church, which long ago recognised the importance of marriage, took this ancient institution under its own protecting wing. It is true that the Church has sometimes taken upon itself to deny the validity and even the reality and decency of any marriage that has been made under the control of any other body than the Church itself. Here, however, we must gain a clear and final recognition of the historical fact that marriage is older than any Church, present or past. How far back, then, must we go before we come to

the origin of an institution which, however old it be, must certainly have had a beginning somehow and somewhere? We have no record, alas! of the ways and doings of man when first he made his undistinguished appearance upon the earth. The most we can do in the way of actual observation is to study the lowest types of man that are now to be found. This vastly interesting and important study is now being pursued on a comparatively large scale—and only just in time; for the contact of these rude tribes with higher civilisation—that is to say, with whisky—very soon exterminates them. However, we find that marriage is practised by man everywhere, even amongst the very lowest races that are now passing their last years on the earth.

The Beginnings of Human Progress. Now, one of the most important generalisations that have emerged from the modern study of the lowest races constitutes a denial of the old view that such races very fairly represent for our own eyes the earliest remote stages of human history. We now believe that the lowest race of which any record has been or is now being made is very far removed indeed from anything like the beginning of human progress. The most primitive of primitive races that we know has really no claims whatever to primitiveness. These races are primitive and low compared to ourselves, certainly. But the more we come to know them—their customs and traditions and languages, their gestures and their magic, and their social institutions in general—the more clearly we recognise the all but obliterated traces of a long and eventful past at which we can now only guess.

If this be so, then, we may still conceive of early stages in the history of humanity—stages earlier than any represented or hinted at by any contemporary savages—when marriage was unknown. Let us, then, outline as briefly as possible the orderly—too orderly—history of marriage which the knowledge of his time sufficed for Spencer to write. We shall not strictly adhere to Spencer's words or opinions, but shall merely state what might be supposed to be the history of marriage and what is, indeed, very commonly supposed to be its history.

Forms of Marriage. It used to be thought, then, that in the beginning there prevailed a state of what is technically called *promiscuity*. The modern term for this is "free love"—the worst debasement of two noble words with which the present writer has any acquaintance. Then, after a time, a certain amount of order would begin to display itself. There might, for instance, be, as indeed there certainly were, some more or less severe restrictions upon this freedom or promiscuity. Then, in certain societies where for some reason there was a scarcity of women, there might possibly be instituted the form of primitive matrimonial institution which is called *polyandry*—literally, the existence of many husbands. Polyandry has certainly been a fact in various parts of the world at certain times. Perhaps the commonest form it has taken is where one woman is possessed by two or more brothers in common.

Much more frequent and important is another ancient matrimonial form, known as *polygamy*, and familiar to most of us in consequence of its revival by the Mormons. It is true of polygamy, however, as of all other marriage forms except one, that it has played a very much smaller part in human life than used to be supposed. It may be said that polygamy has never been the rule anywhere. It may have been permitted, which is a very different thing. Generally speaking, among peoples where polygamy has been permitted it has been practised only by the wealthy few.

A Theory that Ignores Human Nature. In our imaginary history of marriage, then, we may suppose that, in course of time, the forms we have named, and many others, were all superseded among progressive peoples by the form which is known as *monogamy*—the union of one husband with one wife. During the historic period this is the form of marriage that has generally obtained the approval of established religion, and during the Christian era it has, of course, been the only form of legal marriage.

Now, the modern view is that this supposed imaginary history of marriage needs very considerable revision—and a revision all in one direction. It is every day being more clearly recognised by serious students that the norm, or normal type, of marriage is none other than monogamy, and that all the other forms of marital relation must be regarded as mere local and relatively unimportant deviations or aberrations from the normal type. It is, further, most positively and warrantably believed that in the course of the history of man, whether under the tropical sun or amid the Polar snows, there never was any stage of promiscuity. The writers who believed in a primitive promiscuity not only had no positive evidence in their favour, but were running right in the teeth of human nature. The key to all human institutions is human nature, and the theory of promiscuity ignored the facts of human nature—facts so deeply rooted in it that they are shared by sub-human nature—that is to say, by the lower animals. The mere mention of the word jealousy is sufficient to make anyone a sceptic so far as this theory of promiscuity is concerned.

The Triumph of the Only True Marriage. And as regards the other forms of marital relation, we find that their importance has been greatly exaggerated. The truth, indeed, is that in all times and in all places the dominant tendency has been towards monogamy, and it is monogamy that has played the great part for which the word marriage stands in the development of humanity.

We are not concerned for the moment to assert any superiority of monogamy, but merely to state the historical fact that, superior or inferior, natural or unnatural, ecclesiastical or civil in origin, monogamy has been the dominant form of sex relation in the history of mankind. It may be permitted, however, to inquire into the causes

of this general dominance of monogamy at such various times, in such various places, among such various peoples. There are certain familiar facts which might be expected to militate, and do indeed militate, against the dominance of monogamy. Of these the most important is the known character of the amatory passions in man. Thus it is undoubtedly a half-truth, but no more, that the human male is naturally a polygamous animal. Now, certainly, man, rather than woman, in virtue of his superior physical strength and endurance, has determined the form that marriage has taken ; and thus it might almost be supposed that polygamy would have become the dominant form of marriage everywhere, and certainly so wherever the number of women considerably exceeded the number of men. Now, it is true that the practice of polygamy is found to have been most extensive among purely military peoples of a low order of civilisation—as, of course, a purely military people must necessarily be. In consequence of perpetual war, the number of men in such communities is disproportionately small, and thus is established a state of affairs especially advantageous to the practice of polygamy.

The Secret of the Triumph. But the survival of any social institution is not to be explained, and is not determined, by the wills of individual men. It is determined by the needs of the race. Many forms of matrimonial or semi-matrimonial institutions may be named, besides polygamy, which offer marked attractions —some to men of one type, some to men of another type. But these institutions have played no part of any note in the history of mankind, because they did not make for the survival, but instead made for the death, of the peoples who accepted them. The writer believes that the true cause of the dominance and triumph of monogamy, as opposed to other marriage forms, is to be expressed in terms of the *children*.

The current theories of the success of monogamy will not hold water. There is, for instance, the theory that monogamy is a creation of the Church, which substituted it for pagan forms of sex relation. The valid answer to this theory is that monogamy flourished and succeeded long prior to any Church. Another theory states that the success of monogamy has been determined by Nature, which ordains that the numbers of boy babies and girl babies are approximately equal at all times and places, there thus being one member of each sex for each member of the other sex. But this theory is not valid, for, in the first place, the fact of the average numerical equality between men and women might just as well be used as an argument in favour of promiscuity; and, in the second place, man everywhere dominates his fellow-man, so that polygamy, among those who have power, is always possible. Doubtless the natural fact of numerical equality between the sexes may be admitted as a condition that is admirably consonant with the institution of monogamy ; but this fact does not begin to be an adequate explanation of the triumph of monogamy as against, for instance, promiscuity.

Marriage and Character. The theory of the present writer, to which he will return, is that monogamy has triumphed because it provides the best conditions for the children, produces the best children, who grow up to be the best men and women, and who survive in the struggle for existence as compared with their neighbours who practise polygamy—let alone polyandry or promiscuity. On superficial examination it might be thought that in the course of the struggle for existence between two neighbouring peoples, one practising polygamy and another practising monogamy, the polygamous peoples would tend to outlive their neighbours because of their presumably higher birth-rate. Now, doubtless polygamy does make for a high birth-rate, but it also makes for an infantile mortality compared with which our infantile mortality, disgraceful though it be, seems almost decent. In this instance we see illustrated the general proposition of the writer that it is in terms of the life and health and character of the children that we must express the condition which leads to the triumph of monogamy over its rivals.

The Heresy of Mr. George Meredith. The reason, therefore, why we find so scanty a record of forms of marriage other than monogamy in human history is that these forms have handicapped the races which adopted them as against the monogamous races. On the other hand, we hear much of monogamy *because it is the monogamous races that have made human history.*

Some special contemporary interest attaches to a particular form of matrimonial relation which is very expressively termed *leasehold marriage.* Its interest for us depends upon the fact that one of the greatest living men of letters, Mr. George Meredith, lately gave definite form in the pages of the "Daily Mail" (Sept. 24th, 1904) to the views which, as readers of his novels will know, he has long held. Said Mr. Meredith: "Certainly, however, one day these present conditions of marriage will be changed. Marriage will be allowed for a certain period—say, ten years." This statement of opinion naturally attracted a very great deal of attention on both sides of the Atlantic, and also on the Continent of Europe. Indeed, it has been intimately discussed all over the world during the past two years ; and it has found favour in many quarters, though it need hardly be said that no one with the smallest pretensions to be regarded as a sociologist has been found to express anything but richly deserved contempt for Mr. Meredith's opinions.

Mr. Meredith's Experiment is Condemned by History. We saw in an earlier part of our course that there is one point of view from which history may be conceived as a series of vast and varied sociological experiments, conducted by our forefathers for our benefit. We also saw that, if history be read aright, certain definite conclusions may be reached, these conclusions being strictly scientific generalisations derived by a rigid inductive process of reasoning from the experiments of history.

Here is a case in point. There is no need to try Mr. Meredith's proposed experiment, though it must lamentably be admitted that the experiment is being tried, or something very nearly equivalent to it, under the conditions in the United States which permit of divorce at the pleasure of the contracting parties. But apart from this contemporary and disgraceful experiment, which is alarming the most thoughtful and least prejudiced of observers, we can fall back upon the experiments of ages long past; we can point to the condition of tribes which in modern times practise leasehold marriage —degraded, degenerate, worthless, and rapidly disappearing. But it is not even necessary to condemn leasehold marriage by pointing to facts of observation and experiment. The *a priori* method of reasoning is quite adequate alone to serve for its utter condemnation. The sociologist has a criterion by which he is enabled to judge of marriage methods. What, he asks, will be the consequences for the coming race?

Marriage and Society. The fundamental character of the sociological point of view is that it looks ahead. To the sociologist the individual is nothing as an individual, though we must discuss this from another point of view in a subsequent chapter; he is concerned with the life of society, which outlives many generations of individuals. This it is which endows marriage with its supreme importance for him. He leaves it to the psychologist to inquire as to the comparative worth of marriage and other forms of sex relation to the individual; but *he* must inquire as to its influence upon the future life of the society in which it occurs. Marriage vindicates itself in his eyes because it furnishes the one perfect condition for the young generation whose business it is to continue the life of society.

Thus the sociologist looks with entirely distinct interests upon the two kinds of marriages. The childless marriage is doubtless of interest to the psychologist—the student of character; but it matters scarcely anything at all to the sociologist, for it signifies nothing for the future. True, it is a social relation, but, so far as he is concerned, it amounts to nothing more than that two persons, who happen to be of opposite sexes, live in the same house and arrange their finances jointly. It is the appearance of a baby that vitally interests the sociologist, for now he has to consider not merely a marriage, but a marriage leading to the *family*. In this respect he is like Nature. She, also, is "careless of the single life," and for those who are not parents, whether they be married or unmarried, she cares little or nothing. "Her supreme interest," as the present writer has said elsewhere, "is with those chosen individuals upon whose characters and behaviour, as upon no other factor in the universe, the whole future of the race depends."

The True Test of Marriage is the Family. The fertile marriage is of supreme importance to the sociologist because it leads to the establishment of the family. The type of the family, historically considered, has varied in dependence upon the type of marriage, and we may lay down the proposition, as sociologists, that the value of any form of marriage may be judged by the quality of the type of family which it tends to produce. It is this fact, in the present writer's opinion, which explains the observed preponderance of monogamy in the history of man. Monogamy produces the best type of family; the best type of family produces the best type of society; and thus the races which have used other forms of sex relation in preference to monogamy have played no part of moment in history, and have left scarcely any records at all behind them.

As the arrangement of this and the allied courses indicates, we are attempting to base sociology upon "the solid ground of Nature." We can have no more certain warrant for any social institution than that we find it sanctioned by the facts of biology. Now, it is an extremely noteworthy fact that the biological sanctions for marriage are actually older than the human race itself. In many of the lower animals we find that institution called the family—a family produced by a monogamic union of less or greater permanence. This fact of *animal marriage* is of the utmost interest to the sociologist, who builds upon biology. It furnishes him with yet another of the many instances where institutions supposed to have been invented by man, by the law, or by the Church, are found to have played their part in the evolution of life even before the emergence of man.

The Ideal Family. The ideal family is that produced by monogamy. Not very far behind it, perhaps, is the type of family produced by a qualified polygamy, such, for instance, as we observe in the patriarchs of the Bible. Relatively to these, and especially to the former, all other kinds of marriage stand condemned; and this constitutes the ultimate warrant for monogamy. Contemporary practice and experience may be quoted in proof of the assertion that the monogamic family constitutes the best condition of environment for the rising generation. The best kinds of family of this type constitute the realisation of the ideal. We are incapable of conceiving anything better. Those who advocate "leasehold marriage, with State care of the children," or those who advocate the "nationalisation of the children," as a general principle, may be counselled to consider the experience of those whose duty it is to make provision for pauper orphans or other children who are necessarily thrown upon the State even under present arrangements. Many different plans have been tried for dealing with such children. These range from the most unnatural to the most natural. The first description surely applies to the herding together in large institutions of children all of one sex, and, as far as possible, all of one age. This plan is as remote as possible from Nature's indications, having nothing but (false) economy to recommend it. At the other extreme is the boarding out of these children under conditions as nearly as possible approaching those of the normal family.

The Supreme Value of True Marriage to the Race. In general it may be said that "the nearer our provision goes towards the establishment for those children of conditions simulating those of the family, the better are the results. . . . . Indeed, what sane person will dispute that the best prospect for an orphan is afforded when it is adopted by some parental-hearted pair who will treat it as if it were one of their own children ?" No one who has paid the smallest attention to these facts can hesitate to admit that the proposals for leasehold marriage and nationalisation of the children touch the ultimate bottom for ignorance and short-sighted stupidity. The more we study the family, and substitutes for the family, the more clearly we see that the institution of monogamic marriage has the final warrant of Nature. Monogamy has survived, not because of the injunctions of any Church, but because it has supreme "survival value." This it has "partly because it implies a due control of male passion and a due limitation of female endurance; partly because it promotes the development of the higher sentiments and represses the lower; *but pre-eminently because it provides for the coming race a peerless environment.*"

Why Other Systems Fail. Communal, or collective marriage, group marriage, leasehold marriage, and "pooling the children," have all been the subjects of experiment by man in the past. They have all failed, and all for the same reason, because they did not work. "They had no survival value, and the societies which adopted them are no more. They had no survival value because they prevented the formation of the family, upon which alone must be founded any human society that is to endure."

Now, it is true that oaks survive and multiply, and flourish without the aid of the family. It is true also that there are some sub-human societies, such as those of the social insects, which flourish without any institution that really corresponds to our family. It is true also that among birds the family lasts for only a short period, and birds still flourish, even though monogamy, as practised by them, may be an extremely brief affair. If leasehold marriage, so to speak, be an efficient social institution among birds, why not also amongst men ?

The Key Fact of Marriage. The answer is that there is a fundamental difference between the early stages of the life-history of man and those of the life-history of any other animal, not to say plant. If the young acorn falls upon good soil, it is quite independent of any care on the part of the oak which bore it. The young insect may need much care for a short period, but very soon it is able to find its own living. The young bird must be fed at first by its parents, but only a short time need elapse before it is able to fly away, and depend for life upon its own activities. But the young of the human species are different; they pass through an extremely prolonged stage of dependence in youth. Not only is this longer than in the case of any lower animal, but the degree of dependence is much greater. It is perhaps the most remarkable paradox in the whole of living nature that of all young beings the young of the dominant animal, the "lord of creation," should be the most helpless, and the longest helpless. This fact undoubtedly has a great meaning, even a greater than the meaning on account of which we have here referred to it, which is that the family and the due exercise of parentage, more or less important in most of the lower animals, are of supreme importance for man. So long as man retains this character—that at birth he is utterly helpless, and that for many years afterwards he is incapable of fighting his own battles—so long will the survival value of marriage be supreme, and so long will the empire of the earth be given to those societies which avail themselves of that value.

Marriage will Survive all Criticism. We may speak indignantly of amateur critics of marriage at the present day, and our indignation is warranted, but if we were able to take a quite impartial view, caring nothing for any one society rather than another, we should have no need to concern ourselves. No institution that makes for life is really in danger or in need of our assistance. There is a natural automatic process which has been at work since the beginning, and which will continue working to the end: it is the process which Darwin called "natural selection," and Spencer "the survival of the fittest," and it ensures that whatever individual character or social institution makes for life will survive. Marriage, as we have demonstrated, is such an institution, and it will be practised upon the earth a hundred thousand years hence. Here and there a society may try something else, forgetful of the fact that it is not worth while to repeat any of the old experiments which have already been made; but the society which abandons marriage will simply go under before the society which does not. Thus fell the "glory that was Rome," and the same cause—a decline in this fundamental morality—would assuredly tend to the destruction of an empire greater still. It is at the heart that empires rot.

The two chief works upon marriage in the English language are—excepting, of course, that part of Herbert Spencer's "Principle of Sociology," which deals with the subject—Professor Westermarck's "History of Human Marriage," carrying the investigation onwards from the stage where Spencer left it; and, secondly, the "History of Matrimonial Institutions," by Professor G. E. Howard, of the University of Chicago (Fisher Unwin 1904).

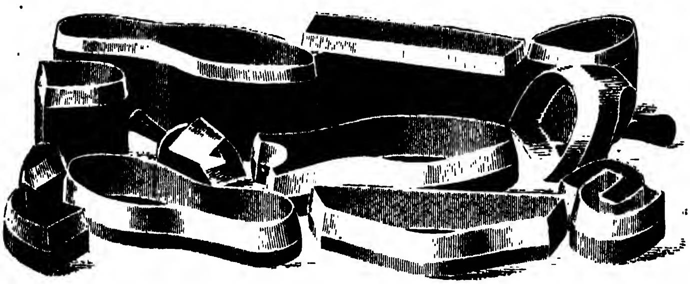
BOTTOMING & HEELING BOOTS

Cutting Dies and their Use. Lasting, Attaching Soles, Cementing, Channelling, Stitching, Heeling, and Finishing

By W. S. MURPHY

Cutting the Stuff. Cutting bottom stuff for the boot factory is a trade by itself, at which a man may find useful employment for both head and hands. When the leather comes from the stores into this department, the hides are ranged, trimmed, and rolled. No doubt, the man who puts the butts and side pieces together thought he had done his work pretty thoroughly, and so far as leather classing goes, he may have done the best possible; but we have something more to ask from the leather. The cutters need pieces of such shape and size as they can put them into the machines in batches. All the leather to be cut has, therefore, to be sorted. Sorting is not merely a case of putting hides of the same size together, or getting them trimmed or shaved to requisite dimensions. Before starting on that job you had better make yourself well acquainted with the various tannages and classes of leathers. Verbal directions in this matter are useless. That is to say, you have to learn the trade by practical experience, step by step. Having put the hides of each class together, we range them on the cutting machines, which may be either guillotine or horizontal, according to the class of leather with which we are dealing.



50. KNIVES FOR CUTTING BOTTOM STUFF (B. U. Shoe Machine Co., Leicester)

Rolling. When the hides and pieces come from the ranger, they are square-sided. But we do not hand them over to the cutters yet. Leather, as it comes from the tanner, is not of the close fibre we need for boot-making. To stiffen and close it, we pass the leather, after wetting, through a pair of heavy rollers. From the pressure of the rolls the stuff comes out clear and firm.

Cutting Soles. The different kinds of leather are now distributed among the various cutters. Light flank pieces go to the cutters of stiffenings, shoulders to the insole cutters, butts of graded sorts to the sole cutters, and scraps of heavy leathers to the heel lift makers. Now we see the benefit of the ranging. For every size of boot we have a special set of cutting dies [50] and presses ranging in size and power from the foot-driven press that cuts lifts or side pieces to the heavier presses that stamp out the strongest soles. Revolution presses do not demand that the leather be ranged; but it can be cut up in whole sides or butts [51]. If we are to get the best results from these mechanical cutters, the leather must be of such uniformity as will enable us to go ahead without stopping to adjust and alter to suit variations in size and grade of leather. The edge of each knife blade is exactly the shape of the piece of leather to be made. Look along the edges of a sole knife, and you see that the shape is a sole, and so with all the others. Fix the leather under the press, lay on the knife, and put the driving belt into action. In a moment there is a crunch, and the soles are cut.

In principle all the die-cutting machines are the same; after having learned to work one, it is easy to take up the others. One thing must be constantly borne in mind—those machines need the assistance of the operator; they are not automatic, and to work them a man must give his whole attention to what he is doing. A leather-cutter is a skilled workman, though not always rewarded as such.

Insoles and Welts. An insole comes from the cutting-room a plain piece of leather shaped to the sole of the last; but it could hardly be sewn in that form, even by hand. The edge of the insole which lies under the top is pared away, leaving a corner into which the sewing holds: this is technically called the *lip*. Forming a lip is a delicate operation; but our mechanics have got over it. One of the best is the "Goodyear" channelling machine, the cutting parts of which are a slanting circular blade working on a flat disc. Lay the insole on the disc, and the knife cuts round, forming a clean lip in a very short time.

Cutting Welts. Welts in the factory are long continuous strips of split leather. The short strips of leather have been cut from the hides, and now we run them through the welt-splitter, which levels them neatly with wedge-shaped sides. The ends of the parts are neatly spliced and joined with cement to form a continuous ribbon of the length required for the machines. They are also cut with an ingenious tool called a *welt-stripper* from shoulders dressed specially for the purpose.

Lasting. Our materials are now shaped, and we assemble them, to begin making up

The uppers, the lasts, the insoles, are here, and now begins that arduous and difficult operation, the lasting. Up till the end of the nineteenth century, hand lasting [53] was carried on in the best equipped factories; it made a gap in the mechanical organisation of the factory; the hand laster could paralyse the greatest factory in the world.

Machine Lasting. Between about 1898 and 1903 no fewer than six efficient machines were placed on the market, and improvements have been constantly going on since. The method of the best of these machines [52] is an imitation of the hand lasting action. Last and insole are inserted into the upper, so as to hold easy, and then put into the mechanical laster. Presented to the machine in a slanting position, with the insole uppermost, so that we can see exactly what is being done, the top is gripped by a pair of power-worked pincers that pull it upwards, drawing it tightly on to the last. The pincers are adjustable, so as to work upon any size of upper. Wipers now come into operation and lay the upper close to the insole, and five tacks are driven in simultaneously to make the work secure. This operation of *pulling-over*, as we name it, is begun and completed in fifteen seconds.

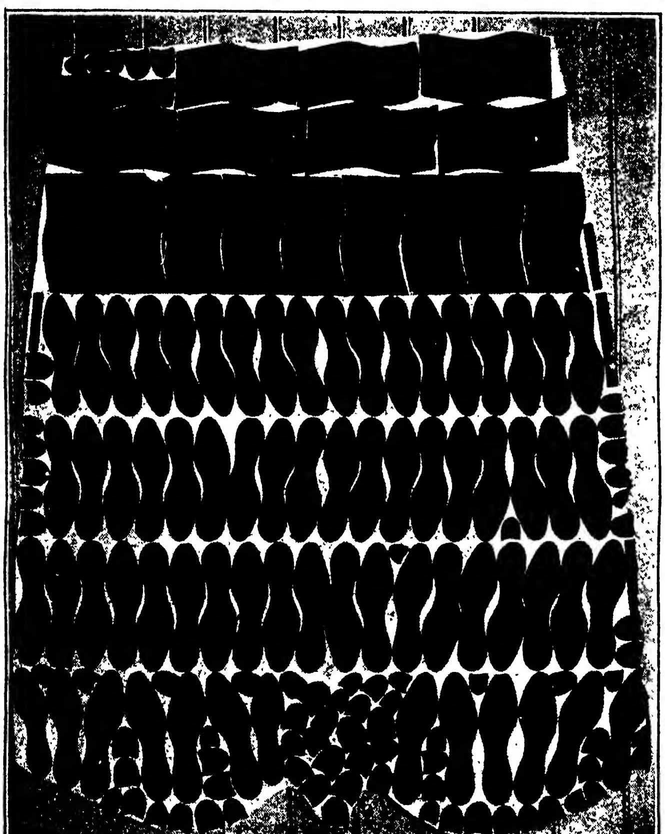
Series of Lasters. Among the other lasting machines there is a series with which the worker should be acquainted, the set grading in degrees of complexity. Taking the common laster first, we find it to be a rather complex mechanism, though not difficult to work, the parts being strong and automatic. Our second machine [52] has a twist motion that brings the top on all sides close up to the feather of the insole, and a slanted tack-driving arrangement that drives in the tack and fastens the upper.

Joining Insole, Welt, and Top. We are ready to begin what has been described as the "impossible" mechanical operations of the boot factory. Handicraft bootmakers used to ask, How was it possible for a machine to put a thread through welt, upper, and insole all at once?—convinced that it could not be done. But the machinists of the boot factory offer us a choice of machines for the purpose, each one advertised as capable of doing perfect work. One thing helps another, as Arkwright is reported to have said when he organised the cotton factory. The mechanical lasters are designed to make the work of the sewing machines easy. The springs and levers of even the least complex of these machines are so numerous as to render description unintelligible even to the worker. Yet the action is perfectly harmonious. Set the boot in place, and see how the work goes on. Through welt and upper and insole the stitches are made by the cunningly-devised mechanism, [54], and as each stitch is made the boot moves forward the length of the stitch [27].

On this machine is a ball of white thread, and at the side is a coil of welt. When the boot is placed on the flange under the needle, the thread comes through a bath of wax kept constantly at melting point by the steam heater, and at the same time the welt uncoils to the boot. Both are manipulated by the needle, which draws the thread through welt, insole, and upper, and firmly binds them together.

Preparing for the Outsole. As we have taken it from the welt-sewing machine, the boot would hardly make a good foundation for the outsole. The seams are rough, and between the surrounding welt and the insole there is a hollow space.

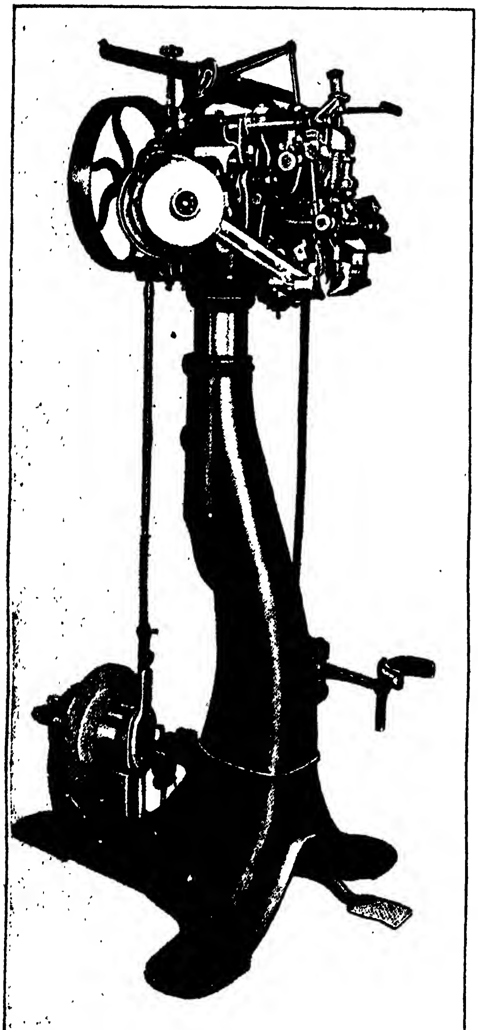
Filling. Very light boots are packed with felt soles thinly covered with cement; but for strong boots the packing is scraps of fine leather, graded to the thickness of the



51. SOLE LEATHER CUTTING
showing how a hide is cut up with little waste

welt. For this purpose we have a small shaving machine, in which a boy puts bits of leather, and brings them out neat packing pieces. At his side is a small self-heating vessel full of melted rubber solution, and with the brush attached he sticks the insoles and puts in the pieces of packing.

Levelling. When the solution is dry, we take the boots to the inseam leveller, which trims the welt and lays the seams at the same time. Like the rest of our machines, the seam trimmer is very complex in the mechanism and very simple in operation. All we need to do is to hold the boot in the jaw of the machine and let it throb round the seams, smoothing each stitch down as it goes along.



52. CONSOLIDATED HAND-METHOD LASTING MACHINE (B. U. Shoe Machine Co., Leicester)

Soling. The boot soles are passed on to the blocking press. Pair by pair the pieces of hard leather are fed in on the top of the foot-moulding blocks, and over them comes down the matrix, to lift again, and let out a pair of finely-modelled soles.

Cementing. Sole-laying is our next important work; but before that can be done we have a choice to make. The question now is whether the soles are to be pegged on for sewing or cemented. The best and most satisfactory is the cementing, and for this we have a fine machine. Within a jacketed pan, heated according to the general system of the factory, rubber solution is kept soft, and within the pan revolves a round brush. Over this brush the soles are fed, and it smears the flesh or inner side with the solution.

Sole-laying. We have to be smart now, for the rubber cement dries quickly. At the side is the turret sole layer. There are several, but we can work only one. Fixed on a revolving platform, this little tower of mechanism holds six iron soles lined with pads of soft rubber, and on the platform under each movable holders that let in the lasted boots and hold them tight. With one hand take the clasping levers, and with the other set in the boot with the sole on it. Now fix the grips on toe and last, and the top pads of rubber come down to make the whole fast in a firm grip. The turret moves round, and offers another station for your boot; you repeat the operation. When the six stations have been filled, the boot first fixed comes round ready to be taken off, and its place is filled with another boot. You can lay a thousand soles per day with this machine. There are other sole-laying machines equally serviceable. Another interesting model has a vertically revolving motion, with four stations. As the machine slowly goes round, the station at the top automatically relaxes, the action of turning clamping the laying press down on the newly inserted boot. The variety of sole-laying machines is considerable, and the effort of machinists is to render them as gentle and firm and automatic as possible. The maximum capacity, so far as we have seen, of the best of these machines is about 1,200 per day of actual working.

Sole Rounding and Channelling. Sewn soles are channelled to hide and protect the stitching. Channellers are called upon to work any variety of machines. Some are merely little knives held in the grip of a motor, with a stand for the boot; others are more complex and aim at rounding the sole while making the channel; but none is difficult to understand. The chief thing to watch in these machines is the adjustment. A thin sole will not stand the depth of channel that a heavy sole requires.

Stitching. The soles are now stitched to the welt by a machine which is called the "rapid stitcher" [55], the boot being laid to the machine without removing from the last.

Blake Sewers. Boots are often made without a welt by sewing with a "Blake," already described. This machine is still in general use. No boot factory sewer can afford to be in ignorance of the working of this machine. On the head of a tall standard the complicated mechanism is set, while from the platform in front

OPERATIONS IN BOOTMAKING

53. Lasting by hand 54. Sewing in a welt on the Goodyear welting machine 55. Working the Goodyear rapid stitcher 56. Bottoming, or levelling the sole to shape of the last 57. Attaching the heel by heeling machine 58. Trimming the sole edge by machine

protrudes a horn. Over this horn the sewer puts the boot, and needle and thread make stitch after stitch, piercing through sole and insole, making a fine seam in a channel cut in the sole by a sole-channelling machine as though it were only thin cloth that was being sewn.

Pegging. The sewn boot is still the favourite; but, curiously enough, the first machine-made boots were pegged in the soles. It may be admitted that the early bootmakers by machinery did not understand the British climate, and introduced a kind of pegging suited only to a dry and equable climate, or a population that never walked in the wet without indiarubber overshoes. By pegging we mean that the soles are secured to the uppers by small pegs. Stitches may seem to grip firmer, but threads cannot last as long as wood or brass. Nothing daunted by their first failure, the inventors of the pegging machines have worked away, and now have produced many contrivances which make really good work. We hardly think the pegged sole will ever displace the sewn one in this country; but a trade of some dimensions has sprung up. The idea which revolutionised the pegged trade was the substitution of a screw rivet for the ordinary peg. The pegging machine most familiar to us resembles in general appearance a kind of "Blake" sewing machine. On the horn in front the boot is set, but instead of the needle a screwing punch containing a screw-tapped wire comes down and drives the peg through welt and sole, automatically cutting off and riveting what is practically a wood nail in the boot. Swift and effective, the action is repeated automatically. Spacing between the pegs is done by the machine, and the intervals may be made as small or as wide as the operator desires.

59. FOREPART CUTTERS

Heeling. Hand-working bootmakers build the heel on the boot, lift by lift; but in the factory the heel-builder is a specialist. The wide variety of heels we are called upon to make has rendered this inevitable. Square heels, round heels, peg-top heels, low and high, broad and narrow, the variations run through the whole range of sizes and classes. If any speed were to be attained in this department, some method of simplification was bound to come. The end was gained by making the heels first, and then fastening them to the boot. We admit that these heels have not the spring of the hand-built heels; but the difference is small and cannot be helped. For the highest class of boots we make split lifts, and produce a heel equal in every respect to the best hand-made; the consumer, therefore, has it in his own hands—he can get the article if he will pay the price.

Building the Heel. The bottom course, or foundation of the heel, is called the *seat*. This is made level with the sole and usually comes off the same hide. Next is the bottom lift, also solid. The two lifts above may be split with inside packing, in the approved hand-made way. The lifts are cemented together by a solution of rubber or other paste, and built on ingenious machines, the most common models of which resemble miniature hydraulic presses in construction and principle.

Putting on the Heel. Heels are attached to boots by various machines [57], the greater number by merely riveting presses, which clench the wire nails left protruding from the heel-seat into the sole and insole. A machine much favoured by manufacturers of heavy boots works on a peculiar plan. Into a disc the nails are fed head downwards; heel and boot are placed together in position; the press comes down and the hammer comes up, driving the nails into the boot and heel. The top pieces of the heel are nailed by a special machine [61] that drives the "nails" regularly and at a very rapid rate.

Sole-levelling. When we get the boot from the making-up department, the channelling of the sewn seams gapes and the sole may not lie quite flat. Obviously, if you can pass a roller firmly enough, and yet yielding to the proper shape of the boot, over the sole, it will be levelled. On this idea the best levelling machines [56] are constructed. The rollers are hung on spring attachments; alternatively, the stand of the boot is spring-seated, and the rollers move firmly over the soles.

60. "SMITH" HEEL-TRIMMING MACHINE
(B. U. Shoe Machine Co., Leicester)

Finishing the Boot. Heeled and soled, the boot has been built together; but it must not yet pass out of our hands, for it is a rough production. Most factories do not class the departments as we do; they make some of those workers whom we consider finishers work in the soling and heeling departments. This matters little; but a more rigid method of division, such

as we propose, would help all parties. When the sole-sewers and heel-fixers have put the boot together, the work of that department of the factory is done. The rest belongs to the finishers. It seems ridiculous that sole-levelling should be included in soling while edge-trimming belongs to the finishing division.

Heel-trimming. Though finely cut to shape when laid on the boot, the heel has margins which can be dispensed with only after it has been seated on the boot [60]. The front, or breast, of the heel has been left rough for shaping to the level of the shank. Breasting is very hard work, and needs a sharp, strong knife. Over a dozen kinds of breasting machines are regularly employed, but the best are very simple. A knife the shape of the breast required is fixed on the head of a press; the boot is set in the stand, and the knife shears down, cutting a clean breast.

To give our heel a solid appearance, we take it to the scouring machine, and on flat sand-paper, running on spindles, the heel is smoothed to a fine level.

Edge-trimming. Like the heel, the sole has been left with rough edges, and for trimming these we have the machine cutters. Here the special character of bootmaking machinery comes out strongly. The edge-trimming machines are nothing more than mechanically-driven knives [59], shaped to suit. Instead of the flat blades we use by hand, the cutters are grooved blocks of steel, cast in a wheel and fixed on a spindle. Against the revolving cutters the boot is held [58], and a fine edge is the result.

Buffing. In most trades, buffing implies polishing; but with us the meaning is the opposite. The object of buffing is to take off the old surface of the leather of sole and heel, and prepare it for receiving a new surface. But we use buffing wheels, like other workers, the difference being that, while wood and steel are smoothed by the rough surface, the leather is made rough. On the rims of the wheels bands of coarse emery are fixed. By applying the sole and heel to the running wheel [62], we scour off the surface of the leather in a regular manner. One thing has to be specially watched, and that is the work of the emery on the sides of the soles, or the edges so carefully cut will be ground down. Simple as it looks, buffing can not be learned in a moment. Nothing can obliterate the streaking and scudding of defective buffing. Dust flies from the buffing wheel at a great rate. To keep the air of the workshop clean and preserve the health of the operator, the wheels are hooded over with covers, through which attached fans suck the leather dust into closed receptacles.

62. BUFFING, OR SANDPAPERING

61. NAILING ON THE TOP PIECE

Sandpapering. Similar in construction, the sandpapering machines begin to build smoothness on the rough work of the emery buffing wheels. The rollers are made to resemble in feel and elasticity the human fingers, being composed of felted material under the sandpaper.

Blacking, Edge-setting, and Polishing. In this division the skill of the workman counts for more than the speed and structure of the machines. So long as the present fashion of boots maintains its hold on the popular taste, no other system, it seems to us, is possible. The routine of the hand-working bootmaker is preserved. First,

the hot irons are run over the edges of the sole [63], the back of the heel, and the skiving of the waist or shank; next, the blacking or ink is brushed on; next, the heated setting irons run round and over, making the dark places shine like mirrors; and then, with grease and blacking, brushes and cloths, the whole boot is made beautiful.

We work with machine tools in the factory; that is the sole difference between the ancient and the modern practice. Where the bootmaker heats his irons at a gas jet, we have the gas stove, or patent ring; we fix the irons in a machine and hold up the work, instead of grasping the handle of the irons in our hands and leaning down to give pressure on the polisher. For the little ink-brush we have the patent circular brush, and for the cleaning cloth a pneumatic felt pad. One great and important difference remains, and it explains why machinery has been adopted for hand labour in this, the delicate touching-up of our work. In ten minutes, without stress, we can turn out as much work as a bootmaker, working hard, could do in two hours.

64. TREEING THE BOOT

Tying. When finished, the boots pass in pairs on to the tying machine, which, with one stitch in each, links them together. Then they pass into the treeing department [64]. By the treeing device we have been enabled to dispense with the last during the finishing processes. Formed of several pieces, the tree goes into the boot, and is screwed up to the size of the last, shaping the boot again, and fixing it in the proper form.

62. SETTING THE EDGE

The boot has been made ready for the wearer; who that may be cannot be guessed, but we have done our best to give a good boot.

Technical Trade Teaching. With all its limitations, the bootmaking machine factory produces good work, and handicraft can never again obtain a strong hold on the boot market. It is satisfactory, therefore, to find our technical schools in London, Leicester, Leeds and Glasgow teaching machine bootmaking instead of confining their efforts to imparting a craft which has sunk into a subsidiary though artistic branch of the industry. Handicraft bootmaking is the foundation of the trade, and, as such, should be taught, but knowledge of machinery is indispensable to the workman of the present day.

Many of the photographic illustrations in these articles were taken in the factories of the Trueform Boot Company of Northampton and London.

SEWAGE DISPOSAL

Sewage Outfalls. River Pollution and Purification. Utilisation of Sewage. Different Systems of Treatment

Continued from page 4463

By Professor HENRY ROBINSON

WE now consider the question of the disposal of the sewage from a town. This must be effected without causing a nuisance by polluting the air, the water of a river, or the sea.

If the town be situated near the sea or a tidal river, there is a natural tendency to assume that the sewage can be got rid of by discharging it there. Before this can be safely done, it is essential to take careful float observations [see page 1016], to ascertain whether, under every condition of tide, the sewage will be carried away without causing a nuisance by polluting the foreshore, either near the outfall or elsewhere.

In determining what standard of effluent should be required at any sewage outfall, each case must be considered with reference to its own special conditions. To insist on a *perfectly* pure effluent would, in most cases, be unreasonable. In past years it was unattainable, but is now possible, as was the case at Maidenhead, by *electrozone*, a sterilising fluid produced by passing a current of electricity through saline solutions.

Management of Outfalls. Another matter deserves mention, and that is in reference to the management of sewage outfalls. Even supposing the most suitable system has been carried out, the anticipated results may not be attained owing to the want of care or intelligence in managing the outfall.

In some places where it has been found necessary to discharge the sewage only at certain tides, to ensure fluid filth being carried away at ebb tides and not returned at the following flood tides, storage chambers have been made at the outfall to retain the sewage until the proper time for its discharge has arrived, when, by raising a sluice, either by hand or automatically, the stored sewage is let out from the chamber. This arrangement is liable to failure in the event of heavy rainfall following a period of dry weather, when the sewers are flushed and the quantity arriving at the outfall is more than can be retained there until the right time for its discharge into the sea or estuary. In cases where such an outfall sewer receives storm water the storage chamber may be a very costly work. An alternative method of dealing with this temporary excess is to lift it by centrifugal pumps the few feet necessary to discharge it above the top of the tide when there is a coincidence of a high tide and a heavy rainfall. Such an arrangement, however, requires to be worked almost automatically, as the coincidence may happen only once a year, and then in the middle of the night. Anyone desiring to follow this matter further can study two recent cases of pollution which were decided in the Courts. One is " Lord Gifford *v.* Chichester Corporation," where the action was based on the pollution of the air and foreshore in an estuary. The other is " Foster *v.* the Warblington Urban District Council," where the plaintiff's oyster-beds were polluted by the discharge of sewage near them and his oyster trade interfered with. Both the cases were decided against the authorities responsible for the sewage outfalls, and they will serve as a precedent for future reference.

River Pollution. The Rivers Pollution Prevention Act, 1876, was passed to meet the well-founded demand for such legislation as would prevent the injury and pollution of rivers by the discharge into them of refuse, putrid solid matter, or other waste or noxious or polluting liquid or solid sewage matter. The Act deals with the evils under three heads: (1) solid matters; (2) sewage pollution; (3) manufacturing and mining pollution. The prohibition as to putting solid matters into rivers is absolute. The prohibition as to the discharge of sewage or poisonous noxious polluting liquids from manufactories or mines into rivers is accompanied by the proviso that no offence shall be deemed to have been committed where the fluid is conveyed by a channel used, constructed, or in process of construction at the passing of the Act, if the best practicable and available (or reasonably available) means has been used to render harmless the sewage matter or polluting liquids. In 1893 the following important amendment was enacted in explanation of Section 3 of the Act:

> "Where any sewage matter falls or flows or is carried into any stream after passing through or along a channel which is vested in a sanitary authority, the sanitary authority shall, for the purposes of Section 3 of the Rivers Pollution Prevention Act, 1876, be deemed knowingly to permit the sewage matter so to fall, flow, or be carried."

The result of legislation to protect our rivers is not very satisfactory.

Self-purification of Rivers. While referring to the avoidance of river pollution by discharging foul matters into it, we may mention that there may be cases where slight pollution may be tolerated owing to the amount of matter discharged and the point where it reaches the river, together with the relation between the volumes of both, preventing appreciable injury. It was once thought that "a river once polluted remained always polluted." Those who have to advise about sewage disposal recognise that a river can be self-cleansing within certain limits. The number of minute organisms and plants which are found in a river are instrumental in destroying organic impurities and afford under the microscope a means of determining the character of the water. These organisms are found to multiply and thrive in a sewage-polluted stream to an extent enormously greater than they would in the same

stream if unpolluted, although they exist in fresh water. They may be said to act as scavengers; but, if the amount of impurity be too great, the organisms are, it is thought, less able to exert this beneficial action. Minute plants also help, by giving off oxygen when exposed to the light, and thus assist to oxygenate the water.

Liquid Refuse from Manufactories. The admission of liquid manufacturing refuse into sewers has often increased the difficulties attending the treatment of sewage at outfalls, but it is to be anticipated that these facilities will be very much curtailed. The local authority may refuse to allow trade effluents to enter sewers on any of the following grounds: (1) that they would injure the sewer; (2) that they would prejudicially affect the disposal of the sewage; (3) that their volume is too great for the capacity of the sewers; and (4) that their admission to the sewer would interfere with some order of a Court of competent jurisdiction.

The admission of trade wastes to sewers in large quantities causes difficulty in treating the sewage at the outfall, especially when the waste is not admitted at regular intervals coinciding with the varying volumes of sewage, and when undesirable solids are not removed. If the conditions as to the admission of the waste be observed, there is no trouble in dealing with it, when it is associated with sewage in reasonable quantities, as the sewage sets up the necessary putrefactive change if the waste is either acid or alkaline, unless in excess, when it should be neutralised before admission to the sewer. The Sewage Commission are of opinion "that the law should be altered so as to make it the duty of the local authority to provide such sewers as are necessary to carry trade effluents as well as domestic sewage, and that the manufacturer should be given the right, subject to the observance of certain safeguards, to discharge trade effluents into the sewers of the local authority, 'if he wishes to do so.'"

Tidal Waters. The requirements of the Public Health Act with reference to the purification of foul fluids before their discharge into rivers, etc., has not been considered as applying to tidal waters, and the Rivers Pollution Act has only very rarely been put into force. Inasmuch as it is illegal under the common law to pollute the air, or the rainfall after it reaches the earth, it is equally illegal to cause a nuisance by polluting the tidal water of an estuary, or the foreshores adjoining, as the Courts have held in the cases to which we have referred.

Compulsory Provisions. The further powers now conferred on county councils, joint committees, and river boards will lead to a closer scrutiny of rivers and streams, and to the detection and abatement of pollutions.

In arranging sewage disposal works it must be borne in mind that the Local Government Board at the present time require provision to be made for dealing with the dry weather flow, and a further five volumes, or six volumes altogether. If the town be drained on the *combined system,* three volumes must be treated as sewage proper, and the further three volumes has to be disposed of on specially-prepared filters or on land. If the town be drained on the *separate system,* two volumes must be treated as sewage proper, and the further four volumes has to be disposed of on filters or land.

Quality of Sewage. The quantity of sewage delivered to an outfall has been regarded too much as the governing factor, without reference to the quality. The facts which are now available with respect to the results of treating sewage by bacterial action will no doubt be productive of elasticity in the Local Government Board's requirements, and will entail a more intelligent consideration, based upon detailed expert information of the condition of the sewage of the town in question. At present too little attention has been devoted to this, resulting in the enforcement or adoption of unnecessarily costly works at sewage outfalls. After the sewage arrives at the outfall it is passed through a chamber in which is arrested floating substances such as corks, paper, and the like, which must not be allowed to pass to disposal works of any kind.

Irrigation. If suitable land be available near a town, and the sewage can be conveyed to it without any engineering difficulties, its utilisation for agricultural purposes is possible.

Sewage farming has too frequently been regarded only from an agricultural point of view, whereas it must be treated as a combination of both sanitary and agricultural interests. These two, however, can be successfully combined only where a sufficient area of suitable land is acquired to enable the crops cultivated on it to receive the sewage only when they want it, at the same time that the sewage is purified on other areas when it is not wanted by crops. When this cannot be accomplished, the agricultural part of the matter must be disregarded, and the filtration and purification of the sewage as a sanitary necessity should be alone kept in view.

It is now clearly established that the changes that have to take place in sewage to effect purification, or that are necessary to enable the manurial ingredients in it to be best adapted to the requirements of plant life, are due to the nitrifying action of micro-organisms. Where the land under treatment is open and pervious, the most solid part of sewage, as well as the dissolved and finely suspended organic matters, admit of being liquefied in the interstices of the soil, and of being converted into the harmless nitrates and nitrites which are so beneficial to plant life. Where the land is impervious this can be only partially effected, and in such cases the liquefaction of the solids by bacteriological influences has to be brought about by methods that are described elsewhere, so that the fluid that is applied to the land is both free from what would clog the pores, and is at the same time highly charged with the nitrates and nitrites which are available for vegetation. If they are not required by the crops they are in a form that can pass away without causing pollution or nuisance.

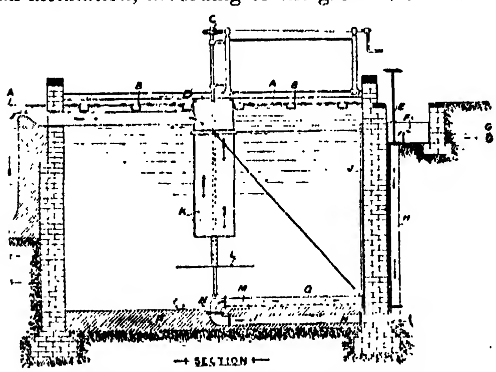
Land for Sewage Purification. The most unsuitable soils for sewage purification are stiff, tenacious clays, peaty or boggy land, and certain conditions of coarse, gravelly soils, which contain hard conglomerate layers often very dense and impervious. Clay lands can be rendered more fitted for filtration by preparing specially the surface to some depth by ploughing or digging in ashes or other materials.

The land must be prepared so that it will absorb the sewage uniformly over its surface, without flooding or overflowing. This can be done by laying out the area in slopes according to the contour of the surface, and according to the nature of the soil.

After the sewage is delivered on to the land at the outfall it is distributed by main carriers, either of earthenware or concrete, or of bricks in cement. These are placed in contour, and are regulated by sluices and stops so as to command the area to be irrigated, the sewage being distributed over the surface by carriers made in the ground. Any pipe carriers underground which convey the sewage from one point to another should be kept low enough to prevent disturbance when the surface is being manipulated either with the plough or otherwise.

Systems of Sewage Distribution. There are several methods for distributing sewage over the surface of land.

In the *ridge and furrow* system the land is prepared in beds with ridges about 40 ft. apart, having slopes of about 20 ft. on each side with an inclination, according to the ground, of from 1 in 50 to 1 in 150, or even more if the ground be very impervious. The ridges have distributing channels formed so that the sewage flows over them down the slope of the plot or field to the furrow in a uniform layer or film, and any which is not absorbed passes to a lower plot.



36. CANDY'S TANK ARRANGEMENT

A. Water level B. Overflow channel C. Worm gear E. Screw-down valve F. Sludge sight-box G. Sludge pipe to well or lagoon H. Sludge exit pipe J. Squeegee for cleaning wall K. Centre sewage inlet L. Patent adjustable spreader M. Perforated revolving sludge pipe with hood and scraper N. Pivot O. Hood P. Concrete

The *catchwater* system is used more for very sidelong and irregular ground. A carrier is laid to command the area to be treated, and the sewage overflows from it at any part by temporarily stopping up the carrier. It then passes to a lower level, where a catchwater gutter, made to the contour of the land, passes it over a still lower part of the area. Main carriers vary in size, but are generally about 1 ft. to 2 ft. wide, and about 6 in. to 10 in. deep. The fall should be about 1 in 500 or 1 in 600.

Crops for Sewage. Italian rye-grass is one of the best crops for sewage, as its capacity for absorption is enormous, and it occupies the soil so as to choke down weeds, which are a source of trouble and expense on sewaged land. Osiers are very useful plants to absorb the organic impurities in sewage.

There are other plants which are capable of absorbing organic impurities, such as duckweed, sedges, common reed, flowering rush, white and yellow lilies, frogbit, water ranunculus, liverwort, sunflower, and watercress.

Precipitation. Where land cannot be obtained for the disposal of sewage by broad irrigation, one way of dealing with it is by chemical precipitation, that is, by adding to the sewage chemicals which have a deodorising and precipitating effect, so that on a small area of land the foul fluid from the outfall sewer can be converted into an inodorous effluent. Many years ago this was thought to be the solution of the sewage difficulty, but the bacterial treatment of sewage (which will be referred to later) has afforded an alternative method.

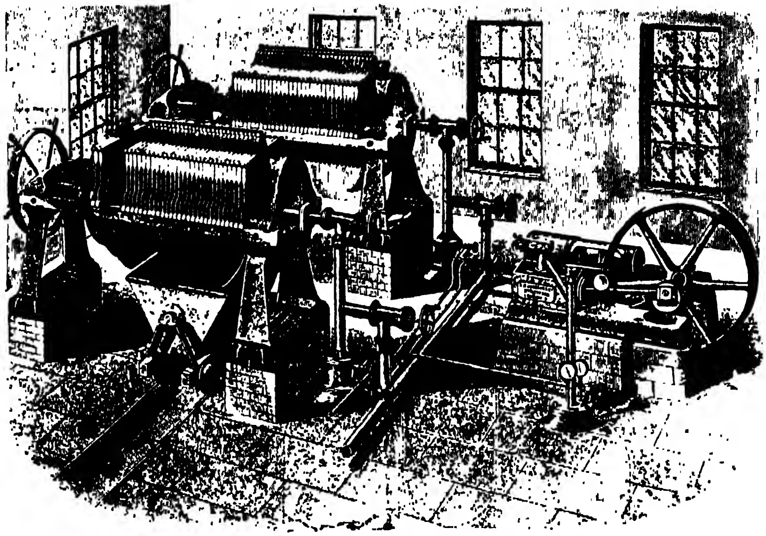
Where a considerable part of the rainfall is received into the sewerage system, provision should be made for a tank capacity of at least 50 per cent. of the average daily dry weather flow, which will give a workable margin for contingencies. Several small tanks are better than a few very large ones, as there is less risk of difficulties arising when the tanks have to be stopped for cleaning out or for repairs.

In England, shallow tanks, having a depth of about 4 ft. to 5 ft. at one end and about 6 ft. at the other, are generally used. The bottom should have a fall towards the inlet end, to which the sludge can be swept with facility. The tank is emptied by means of a floating arm which falls on drawing off the supernatant water and insures its being taken from the upper layer of fluid in the tank. A valve controls this drawing off, so that as soon as there is any appearance of floating matter in the water being let off the valve is closed and the sludge remains.

Candy's System. A recent arrangement of tank [36] by Mr. Frank Candy deserves mention. The bottom of the tank is made flat, and in the centre is pivoted a horizontal perforated pipe which reaches to the side of the tank. This is pivoted on another pipe, which is carried up to within a foot or two of the full water-level of the tank, and at that point the sludge is discharged without pumping. The pivoted pipe is revolved by hand from the outside of the tank when it is being cleaned. The perforations in the pipe being on the under side of it, and only a few inches apart, and the pipe itself being but a little above the bottom of the tank—enough to clear it—the rotation of the pipe covers the bottom, and the sludge

is drawn or sucked away from the whole of the surface. The pressure of water in the tank forces the sludge through the connecting pipe and out to a higher level, whence the sludge can be run into a sump. The perforations in the pipe are larger than the space between the bars of the screening grid. The sludge produced is thicker than the sludge usually drawn from other precipitation tanks. The removal of the sludge by this arrangement does not interfere with the flow of the sewage into the tank, and when the tank is started its working is continuous. The usual precipitants that are or have been employed are lime, sulphate of alumina, protosulphate of iron (copperas), alum, sulphate of iron, ferrozone.

Lime being a cheaper precipitant than sulphate of alumina and other chemicals, it may seem that its use necessarily produces economic results. This is, however, not always the case, as any saving in the purchase of the cheaper precipitant may be more than counterbalanced in dealing with the large volume of sludge produced.



37. S. H. JOHNSON & CO.'S SLUDGE PRESSES (Pneumatic system)

The sludge that is the result of precipitation has to be got rid of, after the tanks are cleared of it, and if it can be dug into some waste land the expense of putting up and operating what are known as *sludge presses* will be avoided.

Sludge. Sewage sludge is usually converted into a portable material in filter presses [37], made by Johnson & Co., Manlove, Alliott & Co., and others. The principle of construction consists generally of a series of circular or square iron discs, the faces of which are grooved and recessed, and are covered with a filter cloth. The plates slide on guides, and when they are close together they form a nearly cylindrical mass of discs, with hollow spaces between them into which the wet sludge is forced, generally by compressed air. The fluid passes through the filtering material to the grooved surfaces of the plates, whence it is conveyed by holes at the bottom of the inner part of the plate to the outside of the press. The solids are retained in the space between the discs, from which they are removed by sliding the plates away from each other on the guides by hand. The writer, some years ago, devised a plan for rapidly opening presses of this kind by connecting the series of discs together with links and attaching the whole to a crosshead. This was drawn along the guides, either by a knuckle-joint lever worked by hand or by a piston rod actuated by compressed air or steam, so that, as the piston rod drew the crosshead forward, it was followed by the whole string of discs.

Sludge Treatment. The sludge, before pressing, is usually stored in an iron receiver, into which it is drawn from the sludge pit by exhausting the air in the receiver. With some sludges a little lime is added for the purpose of assisting the water to filter through the cloths. The sludge is generally forced from this receiver into the interstices of the discs of the filter presses by compressed air—at from 60 lb. to 100 lb. per inch—which, being turned into the receiver, displaces the sludge. It is sometimes pumped direct from the sludge pits without a receiver. The cost of converting fluid sludge into this pressed cake is from 2s. to 2s. 6d. per ton of cake containing about 50 per cent. of moisture, in which state it represents approximately one-fifth of its original bulk.

Sludge consists of about 90 parts of water to 10 parts of solid. As it dries its weight diminishes, and the following simple rule defines this:

Let X = weight of sludge to be ascertained;
S = weight of solids in the sludge (which is constant);
P = percentage of moisture in the sludge.

Then
$$X = \frac{S \times 100}{100 - P}.$$

For instance, to ascertain what weight 25 tons of sludge containing 90 per cent. of moisture would be reduced to when it is dried to 15 per cent. of moisture:

Twenty-five tons of sludge with 90 per cent. of moisture contains 2·5 tons of solids (which is constant); therefore, applying the formula,
$$X = 2{\cdot}94 \text{ tons}.$$

Detailed descriptions of various sewage disposal works are given in the writer's book on "Sewerage and Sewage Disposal."

James I. and Charles I. Gowrie Conspiracy and Gunpowder Plot. The Civil War. Hampden and Cromwell. The King's Trial and Execution

By JUSTIN McCARTHY

WE must now return for a time to the history of our own country, which we have followed up to the end of Elizabeth's reign.

Queen Elizabeth was succeeded by James, the only son of Mary Queen of Scots and Darnley. But James succeeded not as the son of the Queen of Scots, but as the great-great-grandson of the English Princess Margaret, wife of James IV. James I. of England and VI. of Scotland had received much of his education from George Buchanan, the celebrated Scotch scholar, writer, and reformer. James remained in a guardianship which became a sort of imprisonment because of his extreme youth and the ambition of those who had charge of him to govern according to their own ideas; but in 1578 the Regency was taken from the Earl of Morton, and James became—at least, nominally—King of Scotland.

He had many quarrels with the clergy and the nobles during his reign, and showed a strong dislike both for the Presbyterians and for the Catholics. He seemed, for a time, determined to restore Episcopacy to Scotland, and did indeed establish bishops there. In 1585 he made a treaty with Queen Elizabeth, and he co-operated with the English against the Spanish Armada. In 1589 he married the Protestant Princess Anne of Denmark, thus allying himself with the Protestant Powers.

The Gowrie Conspiracy. In 1600 occurred the famous Gowrie conspiracy, the story of which is that the young King was hunting in Falkland Park on August 5th, when Alexander Ruthvin, brother of the Earl of Gowrie, met him, and induced James, who was always in need of money, to go to Gowrie House by telling him that a Jesuit, with a large sum of money, was a prisoner there. When James arrived he found only an armed retainer of the earl, and no Jesuit. Ruthvin then tried to kill James in revenge for the execution of the Earl of Gowrie, Ruthvin's father, in 1584. But the King managed to call to his aid Sir John Ramsay, who stabbed Ruthvin twice, and he and his brother, the Earl of Gowrie, were afterwards killed by two other followers of the King. This story, however, was, and still is, much disputed. Some said at the time that James, wishing to get rid of the Ruthvins, had arranged the whole affair; but it seems certain that there was a conspiracy among them to carry off or kill the King. It was said, also, that Queen Elizabeth was privy to the plot.

When James came to the throne of England, in 1603, he was well received by the people in general, but he soon made himself disliked. Mr. Green says: "No Sovereign could have jarred against the conception of an English ruler, which had grown up under the Tudors, more utterly . . . His big head, his slobbering tongue, his quilted clothes, his goggle eyes, stood out in as grotesque a contrast . . . . as his gabble and rhodomontade, his want of personal dignity, his coarse buffoonery, his drunkenness, his pedantry, his contemptible cowardice;" but "under this ridiculous exterior was to be found a man of much natural ability, with a considerable fund of shrewdness, mother wit, and ready repartee."

He had much literary ambition, and wrote various essays and tracts, one being the famous "Counterblast to Tobacco," a treatise published in 1604, and intended to discourage the practice of smoking, then recently introduced into England.

Gunpowder Plot. James was always under the influence of some favourite, the best known being the Duke of Buckingham. On them he lavished titles, offices, peerages, and emoluments of every kind, while to relieve his own immediate wants he degraded the prerogative of the Crown by the actual sale of titles to rich and ambitious men. In 1604 the abortive Gunpowder Plot was devised, its object being to spring a mine under the Houses of Parliament on a day when the King would be present in the House of Lords, and when the Commons also would be assembled, and thus to annihilate the King, Lords, and Commons at one fell swoop. The plot was devised by Robert Catesby, a Catholic of good family and fortune, who had been fined and imprisoned for his faith. Several other men of high family were undoubtedly concerned in the plot, which was discovered in time by an anonymous letter written to Lord Mounteagle. A search was made, and Guy Fawkes was discovered in some vaults under the House of Lords, which had apparently been hired for some supposed, and not unlawful purpose, and in which the mine had been prepared to explode at a given signal. Catesby and some others fled on the discovery of the plot and sought refuge, but were pursued by soldiers and killed. Guy Fawkes and some others were executed in the January of the following year.

"The Wisest Fool in Christendom." The reign of James was made up of continual struggles against his Parliaments, and against the principles of the Reformation. He was an advocate of the Divine Right of Kings, and though he often spoke and wrote in favour of constitutional liberty, he was in practice an opponent of all such theories. Sully, the great French statesman, soldier, and author, called James "the wisest fool in Christendom." Macaulay, in one of his flashing epigrams, describes him

as "made up of two men—a witty, well-read scholar, who wrote, disputed, and harangued, and a nervous, drivelling idiot who acted."

James died on March 27th, 1625. His reign was, in almost every sense, unfortunate for his country as well as for himself, and the utmost one can do is to excuse him because of his bringing up, because of the unsuitable position to which his elevation to the throne brought him, and because of the fatal weaknesses of his intellect and character. He might have had a meritorious career if he had never been called to a throne.

Charles I. His son, Charles I., was born in Scotland on November 19th, 1600. In his childhood and early boyhood he was delicate. This, however, he soon outgrew, and became not only proficient in all physical exercises, but a scholar of much distinction. He became Prince of Wales in 1616, and negotiations were soon in progress for his marriage with a Spanish princess, and it was for this reason that Charles, under the influence of his father's favourite and his own, the Duke of Buckingham, made his romantic expedition to Madrid in the disguise of an ordinary traveller to see for himself whether the princess was likely to prove to his taste. He found that the Spanish Court and the Papal Government would never allow a Spanish princess to become the wife of any but a Catholic, and Charles would not accept these conditions. We may assume that devotion to his own faith was the main cause of this resolve.

Charles came back to England filled with bitter resentment against Spain. The English people gave him a generous welcome when he returned, on account of his devotion to the principles of the Reformation. But the public sentiment was soon changed by the news of his betrothal to the French Princess, Henrietta Maria, sister of Louis XIII. of France, and the discovery that the marriage articles made it an obligation on him to allow his intended Queen the free exercise of her religion and the care of any children of the marriage until each had reached the age of thirteen. The marriage, which was carried out soon after his accession to the throne, was a happy one. But Charles became, as years went on, more and more dependent on the counsels and the influence of his wife.

The Duke of Buckingham. He had been for a long time under the influence of the Duke of Buckingham, but Buckingham made so many mistakes in home and foreign policy that he became intolerable to the English people, and in August 23rd, 1628, he was assassinated at Portsmouth by John Felton, a dismissed officer. This act was partly one of fanaticism and partly of private vengeance.

After the death of Buckingham, Charles was more than ever under the influence of the Queen in his public policy, and, mainly under her direction, he tried to make himself absolute ruler of the State. Even when in the conditions of the times some course he proposed to take might in itself be justified, he made the mistake of endeavouring to carry it by his own decision instead of through the authority of Parliament. During the first four years of his reign three Parliaments were summoned and dissolved.

The Petition of Right. In the last of these, that of 1628, Charles was compelled, after a long struggle, to assent to the famous Petition of Right, demanding four things: "(1) That no freeman should be obliged to give any gift, loan, benevolence, or tax without common consent by Act of Parliament. (2) That no freeman should be imprisoned contrary to the laws of the land. (3) That soldiers and sailors should not be billeted in private houses. (4) That commissions to punish soldiers and sailors by martial law should be revoked, and no more issued." To this, Charles at first replied evasively, but was in the end compelled to assent. Then followed an interval of eleven years, during which he summoned no Parliament, but ruled according to his own authority, supported by subservient Ministers, judges, and courts of law.

His greatest difficulty was to get sufficient money to maintain his Court and his policy. He allowed himself to be drawn into some futile quarrels with France and Spain, which ended in a patched-up peace, but cost him a considerable amount of money, and from which he tried to retrieve himself by increased taxation at home.

One of these taxes was that of Ship Money, which imposed on various cities and counties of England the obligation of providing funds to maintain a certain number of ships and men. It was an old tax which had been levied to maintain a navy to oppose the Danes, and had passed out of use for many generations. Charles revived it on his own authority, and the Court of the North and the Star Chamber fined and imprisoned those who resisted demands the legality of which was doubtful, although Charles obtained in 1635 from ten of the judges the opinion that the tax was lawful. It was met with a determined resistance by John Hampden, a distinguished patriot, whose trial for refusing to pay the tax began in 1637.

Beginning of the Civil War. At the same time that this tax made the King unpopular he was pursuing an ecclesiastical policy which was contrary to the feelings of the people in general, and his attempt to impose an English Church Service on the Scotch Presbyterians led to risings in that country. The attempted arrest of the five members of Parliament—Hollis, Hazlerig, Hampden, Pym and Strode—on an accusation of high treason, in January, 1642, combined with these other causes to bring about a rebellion. [See FRONTISPIECE, Part 31.] Charles left London to prepare for war, and on August 22nd he raised the Royal Standard in Nottingham, and thus the great Civil War began. Charles led his army in person, and showed great courage with some military skill. But he had set the great mass of the people against him by his autocratic conduct; and soon there came into the field against him Oliver Cromwell, the man who was destined to be his most formidable antagonist.

Cromwell, like Hampden, had sat in the House of Commons, and, although he had no gift of eloquence and never became a Parliamentary

orator, his opposition was powerful. But his real gifts came out when he entered the army and fought as captain of a troop of horse at Edgehill and in other battles.

Cromwell's Ironsides. Then it was that he organised his famous Ironside troops, whom he taught to combine rigid discipline and resistless military force with strict personal morality and with political enthusiasm. At the battle of Marston Moor, near York, on July 2nd, 1644, he opposed Prince Rupert, who commanded the right wing of the Royalist army, himself a brilliant and reckless cavalry leader. Cromwell, at the head of the army trained and disciplined by himself, won a complete victory over his opponent, and from this defeat the cause of Charles never really recovered. The battle of Naseby (June 14th, 1645), in which Charles himself took part, ended in the hopeless destruction of his army and his cause, and in less than a year he surrendered to the Scottish army at Newark, and by them was handed over to Parliament. He was imprisoned for a time, but escaped; was again made captive, shut up in Carisbrooke Castle in the Isle of Wight, and finally brought to trial at Westminster.

Charles behaved then, as at many other periods of his eventful reign, with dignity and courage. Three times he refused to plead, declaring that the Court had no authority or capacity to try him. But such a declaration was futile before a court that had been created for the distinct purpose of his condemnation. He was in the hands of his enemies, whom he had made such by his arbitrary conduct; but it must have been evident to everybody that no pleading, and no defence which he could have made, would in any case have affected the decision of his judges.

A Great Declaration in Parliament. Behind the Court, and all the civil authorities, was the army which had fought against and conquered him. The House of Commons, where there was still a majority of members in favour of Charles, had been put through a process ever since known as "Pride's Purge." Colonel Pride, with a list of names in his hand, prevented those known to be in favour of the king from entering the House, and imprisoned any who resisted him. One hundred and forty members were forcibly expelled, and it was then that the resolution was passed to bring Charles to trial, and to nominate the Court. The House of Commons, thus newly constructed, passed a resolution—"That the people are, under God, the original of all just power; that the Commons of England in Parliament assembled—being chosen by, and representing, the people—have the supreme power in this nation; and that whatsoever is enacted and declared for law by the Commons in Parliament assembled has the force of a law, and all people of this nation are concluded therebye, although the consent and concurrence of the King or House of Peers be not had thereunto."

This declaration foreshadowed the coming of that Commonwealth which was for a time to set aside the monarchy. But it was not a Parliamentary declaration in the true sense, and only came from a House of Commons reduced by force to the necessity of adopting it. The power behind the tribunal which tried Charles was not that of Parliament, but of the army. Charles had committed actions which no Parliament and people worthy of freedom could possibly endure; but the declaration exacted from the House of Commons was in its meaning a demand for the foundation of a republic, and the demand was, for the time, soon to be satisfied.

The Trial and the End. Charles faced his judges with calm and dignified courage. It was one of the finer qualities of his nature that upon a really great occasion he was able to shake off the hesitancy and vacillation which he so often showed in the ordinary business of life; and when he stood before the tribunal constituted to pronounce his sentence of death he presented as picturesque and dignified a figure as the art of the painter or the sculptor could have reproduced. Although Charles had denied the competence of the Court and had refused to plead, the trial lasted for several days, and numbers of witnesses were examined to prove the truth of the charges made against him. Charles was found guilty and was sentenced to death as a tyrant, traitor, murderer, and enemy of his country. On January 30th, 1649, he ascended the scaffold which had been erected at Whitehall, and was awaited there by two masked executioners. He bore himself with stately and superb composure, and one stroke of the axe brought his death. On February 7th, 1649, he was carried to his grave in Henry VIII.'s vault at Windsor.

The King's Mistakes. The whole story of Charles's reign was a struggle between the principle of absolute monarchy and the principle of republican government. Charles committed many errors as a ruler and as a man, but he was not a worse sovereign than many of his predecessors who were never brought to trial. He had miscalculated his own power when he asserted himself the master of his Parliaments, while he did nothing to conciliate the great mass of his people. He turned against him an army which a more judicious despot might have found means to hold for ever on his side. He had the will but not the capacity to be an absolute despot. He allowed himself to be ruled by favourites; but where the policy of the favourite failed, as in the case of Strafford, he had not the nerve to stand by him to the last. Charles sacrificed Strafford—who, whatever his faults, was at least devoted to his Royal master—to his fears of a popular rising. He turned Churchmen and Dissenters against him; he made Scotland and Ireland hostile to his rule; he failed to appreciate the genius, popularity, and the rising power of Cromwell, and brought upon himself the ruin which he might have diverted by displaying a spirit of fairness and of justice.

He left six children behind him, two of whom, Charles and James, were destined to succeed him when the Commonwealth of Cromwell had passed out of existence.

SUGAR ANALYSIS & GLUCOSE

The Polariscope and How to Use it. Making and Refining Glucose or Starch Sugar. Testing. Plant Required. Commerce of Sugar

THE chief analytical operations required deal with the density of juices and syrups, the amount of sugar in a given sample of sugar, the proportion of glucose, the moisture, the soluble and insoluble ash, and the rendement.

Density. Density is conveniently taken by means of an instrument known as a *hydrometer*, the method in which a specific gravity bottle is employed being too lengthy for general use. The two hydrometers in ordinary use are the Baumé and the Brix, or Balling. The latter is preferred, as the graduations of the scale give close approximations to the percentage of total solids present; 10° Brix, for example, in a clean juice indicates 10 per cent. of sugar. The hydrometer is a long glass bulb with a slender spindle so weighted with mercury at the lower end that it maintains the upright position when immersed in a liquid. The spindle is graduated and the instrument sinks or rises in the liquid in relation to the density; the point at which the liquid cuts the spindle being read off on the scale indicates the degree.

Principles of the Polariscope. The amount of sugar in raw sugar is determined by the *polariscope*, the degree of polarisation being the basis upon which sugar is bought and Customs duty levied. A ray of light is capable of being reflected or refracted in any direction; but if a ray of light be placed under such conditions as will restrict its vibrations to one particular direction it is said to be *polarised*. There are several ways by which light can be polarised; in the instrument with which we are dealing the method adopted is that of double refraction. There are certain substances—Iceland spar, for example—which have the power of splitting up a ray of light into two others of equal intensity, the phenomena being known as *double refraction*. [See PHYSICS.] In a crystal of Iceland spar the line connecting the points at which the three obtuse angles meet is the principal axis; if a ray of light be passed through the crystal parallel to this axis, it is not split up; if, however, the position of the crystal be altered, the emerging ray is found to be divided into two. The degree of separation depends upon the angle through which the crystal has been turned; when this angle amounts to a right angle, the separation is at its greatest, and if the crystal be still further turned through another right angle, they coincide [26]. For polarimetic observations, only one of the rays is used, the other one being thrown completely out of the field of view by means of a *Nichol's prism.* This is a crystal of Iceland spar the terminal faces of which are cut obliquely so as to give the new faces an inclination of 68°. The whole crystal is then divided into two at right angles to the new faces, and the faces are then polished and cemented together with Canada balsam.

26. THREE APPEARANCES IN THE POLARISCOPE

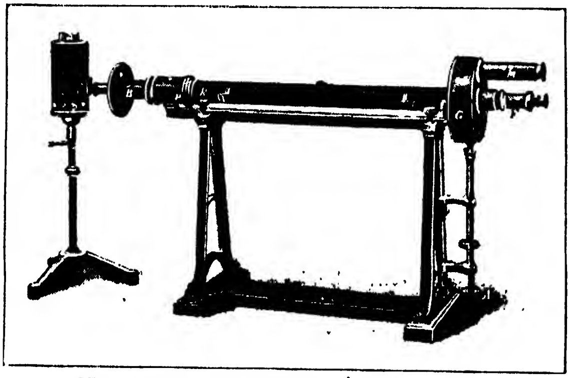
Polariser and Analyser. In examining a polarised ray it is necessary to make use of a second Nicol's prism, placed in such a position that its optical axis is in a line with that of the first. The two prisms are then termed the polariser and the analyser. If an ordinary ray of light be passed through the polariser and then through the analyser, it is refracted in the direction of an extraordinary ray, and emerges from the analyser in that condition. If the plane of polarisation or analyser be so adjusted that it is at right angles to the plane of the polariser, no light will leave the analyser, because the ray, after passing through the polariser and entering the analyser, takes the direction of the ordinary ray, which is absorbed in the case of the prism. If the analyser be rotated to the extent of 180°, the same thing happens; at intermediate positions the field of vision becomes more or less illuminated.

If a ray of light be passed through a plate of quartz (cut at right angles to the axis of the crystal) it is separated into two rays, which proceed in opposite circular directions; such a ray is said to be circularly polarised, and is designated right-handed or left-handed, as the case may be. If a plate of quartz be displaced between two Nicol's prisms when their planes of polarisation are at right angles to each other, a red light is seen; the angle through which it is necessary to rotate the analyser to make the field again non-luminous is termed the *angle of rotation.* Of the several types of polariscope the *half shadow* instrument is the one preferred. The principal feature of this type is the division of the circular field of vision into two halves. When the vernier is placed at zero the two halves of the field are uniform in shade. If an observation tube be filled with an optically active liquid such as a solution of sugar and placed between the polariser and analyser, the equilibrium is destroyed, the result being that one half of the field becomes dark and the other half bright; the analyser is then turned to the right of the right half beshaded, or to the left of the left half beshaded, until the field is once more of a uniform shade; the rotation is then read from the scale.

Schmidt and Haensch's Polariscope. The form of polariscope or saccharimeter in use in the British Customs Department and the United States Internal Revenue Bureau is that of Schmidt and Haensch, Berlin. This instrument is adapted for use with white light illumination from coal gas. It is convenient

and easy to read, requiring no delicate discrimination of colours by the observer. It is adjusted to the Ventzke scale, which may be defined as "such that the degree of the scale is one-hundredth part of the rotation produced in the plane of polarisation of white light in a column 200 mm. long; by a standard solution of chemically pure sucrose at 17·5° C., the standard length of sucrose in distilled water being such as to contain at 17·5° C. in 100 Mohr's c.c. 26·048 grammes of sucrose." The instrument should be adjusted by means of control quartz plates, three different plates being used for comparative adjustments, reading approximately 100, 90, and 80 degrees on the scale respectively.

A Description of the Polariscope. The illustration [27] shows the latest form of this polariscope. The tube B contains the illuminating system of lenses; the polarising prism is at P, and the analysing prism at G. F carries a small telescope through which the field of the instrument is viewed, and just above is the reading tube M, which is provided with a mirror and magnifying lens for reading the scale. The tube containing the sugar solution is marked R. To use the instrument the operator seats himself with his eye level with the tube F, which tube is moved in and out until the proper focus is secured so as to give a clearly defined image, when the field of the instrument will appear as a red luminous disc, divided into two halves by a vertical line passing through the centre, and darker on one half of the disc than on the other. If, now, the milled head A be rotated first one way and then the other, the appearance of the field changes, and at a certain point the dark half becomes light and the light half dark. By rotating the milled head delicately backwards and forwards over this point, the exact position when the field is neutral or of the same intensity of light in both halves can be found. When the milled head is set at the point which gives the appearance of the centre disc in figure the eye of the observer is raised to the reading tube M and the position on the scale noted. On each side of the zero line of the vernier a space corresponding to nine divisions of the movable scale is divided into ten equal parts enabling fractional parts of a degree to be indicated.



27. SCHMIDT AND HAENSCH POLARISCOPE

Method of Manipulation. Begin by weighing out 26·048 grammes of sugar, dissolving it, clarifying the solution, making it up to standard volume (100 c.c.), and filtering and filling the observation tube, regulating the illumination and making the polariscope reading. The sugar is conveniently weighed in a counterpoised nickel or German silver flask with a large lip, whence it is readily washed into the flask. The solution, before being filled up to the mark, is clarified by the addition of lead subacetate or phospho-tungstic acid until no further precipitate takes place. Filtration and clarification may often be made easier by adding a few drops of suspended aluminic hydrate after the lead. The flask is filled with pure water until the lower line of the meniscus coincides with the mark on the neck. The mouth of the flask is closed and its contents well shaken and poured on to a folded filter; the first few cubic centimetres of the filtrate are rejected. The subsequent filtrate, if not perfectly clear, is returned to the filter until it shows no cloudiness. The polariscope tube is then filled and placed in the polariscope, the scale of which, after neutralising the rotation produced by the sugar by turning the analytical prism of moving the quartz wedge, will give the percentage of sucrose in the sample taken. A dark solution may either be read in a 100 mm. tube or decolorised by bone black. A weak solution may be read in a longer tube.

Estimation of Glucose. The reagent required for estimating reducing sugar is known as Fehling's solution. Take 34·64 grammes of pure crystallised sulphate of copper, and dissolve it in 200 c.c. of distilled water. Also take 187 grammes of tartrate of soda and potash and 78 grammes of caustic soda, and dissolve in 500 c.c. of distilled water. Add the copper solution to the second solution, and make up to 1,000 c.c. with distilled water. The copper in 10 c.c. of this solution is completely reduced by 0·05 gramme of glucose, which is shown by the blue copper solution turning red and throwing down a precipitate of red copper oxide. To make the estimation, place 10 c.c. of the Fehling solution in a flask over a Bunsen burner, and make it boil. Then from a graduated tube (burette) run in a few cubic centimetres of the sugar solution, again boil, and note if any blue colour remain in the liquid. If there be still some blue liquid over the red precipitate, run in more sugar solution until all the blue colour has disappeared. From the number of cubic centimetres of sugar solution required, the amount of glucose is determined by calculation. The best results are obtained when not less than 10 c.c. or more than 50 c.c. of sugar solution are needed for 100 c.c. of Fehling solution, and after making a rough estimation the strength of the solution is adjusted to conform with these requirements. The strength of the copper solution can be checked or

standardised by comparing it with a solution of pure invert sugar, prepared by heating cane sugar solution, with a few drops of sulphuric acid to invert it.

Moisture. Weigh from two to five grammes of the sugar into a flat-bottomed nickel or platinum dish, and dry at a temperature of 100° C. for three hours. Cool in a desiccator and weigh; return to the oven and dry for an hour. If, on weighing, there be only a slight change in weight, the process may be considered finished; otherwise the drying must be continued until the loss of water in one hour is not greater than 0·20 per cent. From the quantity of loss of weight of the sample taken the amount of moisture or water is calculated.

Ash. Take five or ten grammes of sugar in a platinum dish, heat at 100° C. until the water is expelled, to allow the action to take place slowly, and finally heat in a muffle to low redness. Then, by weighing the ash that is left, the percentage of ash in the sample is obtained. The quantity of soluble ash is estimated by digesting the ash with water filtering through a Gooch crucible, washing with hot water, drying the residue at 100° C., and weighing. The difference in weight from the above determination equals the soluble ash.

Rendement. Rendement is the French term for the net amount of sugar in a given sample of raw sugar. It is deduced from the fact that each 1 per cent. of ash in the raw sugar prevents 5 per cent. of sugar from crystallising, and each 1 per cent. of glucose causes an equal amount of sugar to be retained in the molasses. Hence, from the amount of sucrose shown by the polarimeter deduct five times the weight of ash plus the weight of the glucose present, and the refining value, or rendement, is obtained. For instance, a sample of sugar polarised 93 per cent., the glucose was 2 per cent. and the ash 1 per cent., $93 - (1 \times 5 + 2) = 86$ per cent. of available sugar.

Sugar of Milk. The source of sugar of milk is the whey from cheese factories or the skim milk from creameries. As separated from milk, it is a white crystalline mass which appears in commerce in thick sticks. Switzerland for many years controlled the milk sugar industry and supplied the markets of the world, although small quantities were made in other countries—for example, Germany. Between 1880 and 1890 the manufacture was taken up in the United States, and the industry grew so that by 1895 some milk sugar was exported to Great Britain and Germany. Enormous quantities are now made, one factory in Illinois turning out 16 to 18 barrels (225 lb. each) a day. The Swiss process of manufacture on a large scale is to evaporate 50,000 litres of whey to dryness, a residue of about 1,250 kilos being obtained. This is dissolved in water at 65° C. in a copper pan, ½ kilo to 1 kilo of alum added, the solution filtered through animal charcoal, boiled down to a syrup, and allowed to crystallise on cords or sticks. It is purified by recrystallising and repeated precipitation by alcohol. The best grades are used in food and pharmacy. The methods of evaporating the whey vary from open boiling pans to expensive vacuum boilers such as are used in cane sugar making. Filter presses like those described in the article dealing with beet sugar making are also employed.

That maker whose process of making milk powder consists in allowing milk to trickle on huge metal drums heated from the interior prepares milk sugar from it by simple solution in water. The casein of the milk, which is the other chief constituent of milk, is rendered insoluble by the heat, and is left behind when using water for extracting the sugar.

Ramage's method consists in evaporating slightly alkaline whey to half its bulk, adding an acid to remove the casein, and then, after further concentrating, precipitating the milk sugar by adding methyl alcohol.

In Kennedy's process the milk is concentrated to between 11° and 27° Baumé, and the product chilled to 32° F. until the sugar crystallises. The crystals are removed by submitting the liquid to centrifugal action, and washing with cold alkaline water.

Glucose, or Starch Sugar. Enormous quantities of glucose are manufactured and used in the manufacture of confectionery, jams, beer, golden syrup, and for other purposes in the industries. Allegations have been made as to the wholesomeness of glucose as an addition to articles of food. The matter was investigated by the National Academy of Sciences at Washington, and the committee of chemists who examined the conditions of the industry reported that, provided no objectionable substance were used in the manufacture of glucose, the product was quite wholesome and unobjectionable. It was the use of sulphuric acid contaminated with arsenic for converting starch into glucose that caused the remarkable "arsenic in beer" scare of 1904. The use of glucose as a preservative of jams, in the sense that it prevents the crystallisation of the cane sugar, seems a legitimate use of the substance, but it should not be forgotten that, as glucose is cheaper than cane sugar, it is not inconceivable that cases may arise in which an illegitimate profit may result, to the prejudice of the consumer.

The starch used is extracted from maize, potato starch, sago and rice starch, and is converted into glucose by heating it under pressure with weak acid. This process being complete the acid is neutralised, and the product filtered and evaporated in a similar manner to that employed in refining sugar.

Manbré's Process. In Manbré's process place in a converter 56 lb. of sulphuric acid of a density of 66° Baumé, add 560 gallons of water, and heat to 212° F. Into a wooden vat provided with steam pipe and stirring apparatus place 560 gallons of water and 56 lb. of sulphuric acid, heat to 85° F., and add one ton of starch. Mix well, and raise the heat to 100° F.; then pour the diluted starch into the converter containing the boiling diluted sulphuric acid and blow in steam to raise the temperature to 320° F., equivalent to a pressure of six atmospheres. When this

temperature is attained, open the cock of the distilling pipe and let the steam escape, when it will carry the volatile matters out of the converter with it. Test the mixture with iodine to find out whether all the starch be converted, no blue colour being obtained when this result is attained, and also with silicate of potash and lead acetate for absence of dextrine, no turbidity being given in the absence of dextrine. It takes two to four hours for conversion. Run the liquor into the neutraliser, and add lime to combine with the acid, and pass in carbonic acid gas to precipitate the remaining lime. Filter the liquor, and evaporate to 20° Baumé. Clarify in a blow-up pan with charcoal, again filter, and evaporate to 28° Baumé for glucose syrup, or 38° Baumé for hard glucose. This process is still followed in some factories; but the modern practice, as used in the United States, was the subject of a paper before the Institute of Brewing by Messrs. G. W. Rolfe and G. Defreu, from which the following particulars are taken.

Glucose Manufacture in the United States. Maize is placed in steeptubs capable of holding 2,000 bushels or more. Water at 150° F. is added and the steep allowed to cool to 90° F. Sulphurous acid is added to prevent putrefaction and to assist softening, and the steeping is continued for from three to five days. The separation of starch is brought about by grinding the wet grain mixed with water, separating the starch grains from the woody pulp and germ by washing through rapidly shaken sieves of bolting cloth, and settling out the starch from the gluten by subsidence while passing over gently inclined runs, called "tables," resembling a bowling alley. In many factories the germ is removed separately by a special process.

The starch collected on the runs, and containing about 50 per cent. of water, is mixed with water to a thick cream of 20° Baumé, and then converted with hydrochloric acid in large copper boilers at a steam pressure of about 30 lb. The amount of acid used is about 0·0006 of the weight of the starch. In some factories sulphuric acid is used, and seems to be advantageous, in the manufacture of candy goods. Oxalic acid and hydrofluoric acid are also sometimes employed. The point of conversion is controlled by the disappearance of the dextrine precipitate when the liquid is poured into alcohol. In making syrup glucose, the acid is mixed with about fifty times its bulk of water, and run into the converter. Steam is then turned on, and pressure maintained at 30 lb. while the starch-milk is being pumped into the boiler, which takes about half an hour, and the heating is continued after this for 40 minutes or more. The degree of conversion is, in this case, entirely controlled by the iodine test. As soon as the conversion is complete the liquid is blown out into the neutraliser, where sodium carbonate is added. The neutralisation is a process of great delicacy, as any excess of acid or alkali will seriously affect the refining operations which follow. Properly neutralised liquor should show only the acidity caused by carbon dioxide or the weakest vegetable acids. It is of a clear, bright amber colour, and contains large flocculent masses of coagulated gluten, which, in a test-tube, form a layer of about half an inch thick. When the proper point of neutralisation is attained, this layer is greenish-drab, owing to the precipitated iron.

Refining Glucose. The refining process is, in general, similar to that of sugar. *Glucose liquors* are, as a rule, put twice over bone black (free from ammonia or caustic lime) first at their original concentration of about 18° Baumé, and again after concentration to 28° to 30° Baumé, the denser syrup going over fresh black. The revivifying of the bone black is carried out on lines similar to those of sugar. The *heavy liquor* goes direct from the filters to the vacuum pan in most modern factories, and in this final concentration sulphites are added in amounts varying from 0·008 to 0·050 per cent. of sulphurous acid. The function of these sulphites is to prevent oxidation and consequent coloration due to the formation of caramel-like bodies, to bleach ferric salts as a prevention of fermentation of low, concentrated products, and as a preventive of oxidation of candy goods in the candy kettle. Confectioners' goods are more heavily "doped" than others.

In refining *grape-sugar* liquors, the concentrated syrups are drawn off into pans or barrels, and allowed to solidify, a seed of crystallised sugar being often added to facilitate crystallisation.

Anhydrous grape-sugar is made in a similar way to the syrup, which is refined at lower concentrations throughout the process in order to obtain a purer product. When crystallisation is complete, which takes about three days, the sugar is purged in centrifugals. Glucose syrups are made of six concentrations—39°, 41°, 42°, 43°, 44°, and 45° Baumé. Mixing goods are generally finished up to 39° or 41° Baumé, the latter being the grade usually sold to brewers. The higher concentrated products are used by confectioners and are characterised by a greater perfection of refining and a large amount of sulphites. They are frequently "whitened" with a little methyl violet.

Testing Glucose. A well-refined glucose is practically colourless and clear. If a white glass cylinder be filled with glucose, its colour, as well as any turbidity, may be seen. If the colour be a pure white the sample is dyed, as can be proved by exposing to the light for a few days, when the darkening which all glucoses undergo disturbs the colour balance, and the presence of dye is made more evident. If no dye be present the glucose, unless quite turbid, will show some colour, usually green or yellow. These tints are almost invariably present, and seem to be caused by traces of iron salts and vegetable colouring matters. They are of little consequence, except as indicators of the thoroughness of the refining and the removal of albuminoids and oil, which affect the colour of the product. As to turbidity, cloudiness caused by faulty conversion, separation of dextrins, or sugar, is of rare occurrence. A smoky appearance is

often caused by bone-black rust, or, in some cases, by iron sulphide when a large quantity of new black is used in refining. These, of course, are the results of improper preparation of the black. White cloudiness is caused either by calcium salts or by organic growth due to fermentation. The valuation of solid starch sugars is practically based on their dextrose content. Whiteness, of late years, seems to be more of a desideratum than formerly; hence the practice of dyeing is becoming common. The principal mineral impurity is iron, which, however, is rarely present in more than traces. A delicate test for it is *cochineal.* Sulphites must be first removed and the solution made neutral or faintly alkaline. If iron be present the crimson of the cochineal gradually passes to violet. For some purposes glucose is tinted with caramel to make it resemble cane sugar.

Glucose Manufacturing Plant. We now describe the plant used for making glucose. Two open converters for receiving the starch liquor from the settling tanks, or two wooden vessels, should measure 5 ft. 9 in. in diameter, 8 ft. 9 in. deep, be secured by bands on the outside, be lined with thin sheet copper, and be provided with a copper heating coil and agitator.

The closed converters consist of two copper cylinders 5 ft. in diameter and 12 ft. deep, with closed ends ½ in. thick and shell ⅜ in. thick, with the necessary inlets and outlets for liquor and steam and condensation, and copper coil, also the safety valve and pressure gauge.

The bag filters should be of the Taylor type, and have a capacity of filtering 10,000 gallons in 10 hours.

The animal char department should consist of four cast-iron filters 4 ft. in diameter and 18 ft. long, in three or four lengths, and have the necessary inlets for different liquors, washwater and steam, also the liquor outlets.

The revivifying kilns should consist of 14-pipe kilns with a capacity for revivifying 10,000 lb. of bone black per day of 24 hours.

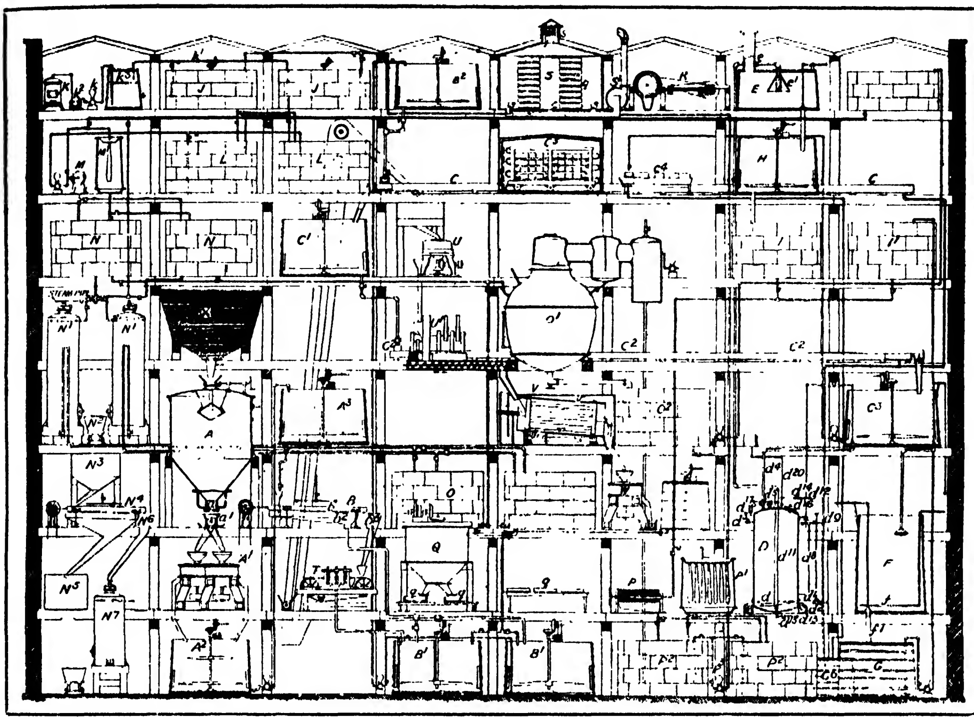
Elevators are necessary for conveying the char from the kiln to the receiving tank, which will supply the four char filters.

Concentrating plant should be the triple effet type, the vacuum pan to be a copper pan 5ft. 6 in. in diameter with 5 ft. depth of curb, incline bottom, dome, overflow and condenser, arranged to work on the dry system; the heating surface of the pan to consist of three 2½ in. seamless copper coils held in position by braces thoroughly bolted within the pan. All bolts within the pan to be of Muntz metal; the bottom of the pan to have four lugs so as to rest upon the beams of the building.

Complete Plant for Making Glucose. The illustration [**28**] is a sectional elevation of a factory described by W. T. Jebb, Buffalo, New York (4094 of 1882). A shows steeping vat, *a* discharge spouts, A^1 disintegrating or crushing mills, A^2 agitating vats, A^3 another set of agitating vats, B separating machine, *b* shaking-sieve, b^2 receiving hopper or receptacle, b^3 separator for coarse offal, B^1 settling vats, B^2 agitating vats, C tables or runs where the starch is deposited, C^1 mixing tub, C^2 another set of starch tables or runs, C^3 tub for grading starch, C^4 draining box, C^5 dry kiln, C^6 refuse cistern, D closed converter, *d* perforated steam coil, d^1 pipe for admitting steam, d^2 valve, d^3 steam outlet pipe, d^4 pipe for conveying liquid to converter, d^5 valve, d^6 and d^7 test cocks, d^8 pipe, d^9 steam pipe, d^{10} valve, d^{11} blow-off pipe, d^{12} and d^{13} steam pipes, d^{14} and d^{15} globe valve, d^{16} manhole, d^{17} steam gauge, d^{20} pipe, E blow-off tank, *e* vent pipe, F tank or vat, f^1 pipe to G neutralising tank, H neutralising tank, I settling tank, J bleaching tanks, *k* furnace, K pump, k^1 pipes, k^2 cooling vessel, k^3 washing vessel, L receiver, M filters, M^1 bag filters, N receiving tank, N^1 bone black filter, N^2 conveyer, N^3 hopper, N^4 shaking sieves, N^5 box receiver, N^6 spout, N^7 steam tank, O tank, O^1 vacuum pan, O^2 receiving tank, P press filters, P^1 bag filters, Q cooling apparatus, *q* pans or moulds in which the glucose hardens, R cutting machine, S drying chamber, S^1 suction fan, T horizontal rollers, U centrifugal machine, U^1 disintegrating machine, V drying apparatus, *v* steam jacket, v^1 rollers, v^2 steam supply pipe, v^3 rotating pipe, v^4 branches, v^5 space between walls of steam jacket, v^6 hollow head, v^7 openings, v^8 tubes, v^9 steam pipes, v^{10} condensed steam discharge, v^{11} strips or buckets, v^{12} cylinder casing, v^{13} inlet openings, v^{14} suction fan, v^{16} hood terminating in tube, v^{16}, connected with chess-hopper, v^{17} tube, v^{18}, v^{19} and v^{20} hoppers, v^{21} feed roller, W disintegrating mill, X storage bins.

The Bounty System. It has been the practice of European countries to give bounties to the manufacturers of beet sugar on all sugar exported, the idea being to stimulate the industry in the countries where bounties were given. This policy had the effect of making sugar for local sale more expensive, and of depriving the people of a nutritious food. Sugar refiners also felt the effects very severely, and the West Indian cane sugar industry was affected. This, and countervailing duties on sugar imported into India, brought matters to a head, and a conference was called in 1898, which ended in the *International Convention,* which has for its object the equalising of the conditions of competition between beet and cane sugar, and the promoting of the consumption of sugar.

The Sugar Duty. The Finance Act, 1901, imposed an import duty on sugar and sugar-containing articles as from April 19th, 1901. The following are the chief rates: sugar of a polarisation exceeding 98 deg., 4s. 2d. per cwt.; sugar of a polarisation not exceeding 76 deg., 2s. per cwt. The intermediate duties are calculated from these charges. Molasses and invert sugar, if containing 70 per cent. or more of sweetening matter, 2s. 9d. per cwt.; if containing less than 70 per cent. and more than 50 per cent., 2s. per cwt.; not more than 50 per cent., 1s. per cwt.; glucose, solid, 2s. 9d. per cwt.; glucose, liquid, 2s. per cwt. The imposition of sugar duty involves also duty on blacking, candied peel, caramel, cattle foods



28. COMPLETE PLANT FOR MAKING GLUCOSE

containing molasses, cherries, chutney, sugared coconut, confectionery, crystallised flowers, canned or bottled fruit containing syrup, preserved ginger, marmalades, jams, sweetened spirits, marzipan, condensed milk, Nestlé's milk food, soy, and tamarinds.

Effect on Price of Sugar. The effect of the Convention and Sugar Duty, combined with a shortage in the Continental beet sugar harvest, has been to raise the price of sugar in Great Britain, and to affect businesses which depend largely upon cheap sugar. The following table from De Silva's circular shows the fluctuation in the average "spot" price of sugar for the last three years:

—	1903.	1904.	1905.
	s. d.	s. d.	s. d.
Java D.S., 15, f.l. terms	8 4	9 7¼	10 11¼
Pernams, 87° polarisation ..	6 10¾	8 1¼	9 2½
German beet, basis 88 per cent., Prompt, f.o.b., Hamburg ..	6 7½	8 2½	10 0
First marks granulated	8 1¾	9 9	11 9¼

It will probably need further statistics to prove whether the rise in price is due more to shortage of crops and more local consumption than to duties, but meanwhile it is interesting to note that the amount of sugar consumed in Continental countries has much increased.

Sugar Weights and Marks. On the London market, refined sugar contracts are made in the form laid down by the Refined Sugar Association. The contract embodies the conditions of the Association as to weight, delivery, and payment. The cwt. is taken as equivalent to 50¾ kilos, and bags, when used, must be new, and weigh not less than 850 grammes before filling. There are separate conditions for Dutch, French, German, Austrian, and Belgian sugars. French cube sugar comes in cwt. cases, and Dutch crushed sugar in barrels of about 2 cwt.

First Marks. *German Granulated Sugar.* These are, Bonart, C.F., C.R.M., D.V., E.C.H., F.M.S., G.D., Glauzig, Grœningen, Grasso, Hansa J.B.R., J.H., J.H.B.M., O.F., R.A.C.L., R.A.V., S.P.R., Star, Z.H., Z.A., Z.A.F., Z.R.B., Z.R.D., Z.R.M.

German Cubes. Hansa, C.Z.F., A.S.P., S.P.R., F.K.L., T.T.D., A.C.L., S.Z.G., Z.R.D., F.M.S., R.A.V., Meyer, X.L.R.

German Cut-loaf and Loaves. C.Z.F., A.C.L.

German Crystals. A.S.P., S.Z.G., E.A.R., A.Z., R.F., S.P.

German Castor Sugar. Skene, A.S.P., G.S., X.L.R.

French Granulated. Lebaudy, R.P., A.T.

French Cubes. Lebaudy, E.S., R.P., Say.

Dutch Cubes. A.S.R., S. & T., W.S.R.

Dutch Cut-loaf and Loaves. A.S.R.

Dutch Crushed Sugar. A.S.R., S. & T., W.S.R.

Dutch Crystals. W.S.R.

Belgian Cubes. R.T., R.B., Super.

Belgian Cut-loaf and Loaves. M.F.

Belgian Crushed Sugar. R.B. Super.

Group 24 PHYSICS 32	# THE STRUCTURE OF MATTER
Continued from page 4450	The Science of Crystallography. Its Value in Industry. The Molecular Structure of Metals. The Physics of the Stars. The Problem of Solution

By Dr. C. W. SALEEBY

Of the many new subjects to which reference has lately been made we must choose only those which are of wide interest, or, rather, those which we can already recognise as being of wide interest. The scope of our course will have been very wide, but the reader must not imagine that it has been possible for us to keep pace with what one of its most distinguished workers, Mr. Whetham, calls "the recent development of physical science." We cannot, for instance, discuss the newest work which has been done by Sir James Dewar and his followers in the liquefaction of gases, a process which has been successfully accomplished with every known gas, with the solitary exception of helium. Sir James Dewar, however, has lately been able to return to active work, and we may hope that he will at last conquer even this gas.

The Study of Crystals. We may briefly refer to another very important study which is also concerned with our conception of the three states of matter. This is the study of solidification and crystallisation. We can merely direct the reader's attention to the subject on three distinct grounds.

First, we must recognise that the study of crystals will help us to understand the molecular structure of matter. We must believe that the varying shapes of crystals depend, in some way, upon the varying shapes of the molecules of which they are composed. We conceive of molecules, of course, in terms of *stereo-chemistry*—that is to say, in terms of three-dimensional space. In our recent studies, both in physics and chemistry, we have seen how different kinds of crystals are able—ultimately in consequence of their molecular structure—to produce remarkable changes in a beam of light, and we have also noticed the extraordinary fact that there are certain forms of life which have a selective affinity for crystals, or, rather, for molecules of certain shapes, but do not act upon other molecules which are identical in every way but for the one difference which corresponds to the difference between the right hand and the left, or between any object and its mirror image.

The Crystalline Structure of Metals. Secondly, the study of crystals and crystalline structure is now seen to be of extraordinary practical importance; just as all trees have flowers, though the flowers are inconspicuous, so the metals, though we do not readily recognise it, have a crystalline structure. Further, we find that to this crystalline structure, to these mutual relations of the molecules, must be referred the gross physical properties of any specimen of a metal. The ultimate difference between the rod of steel, or the tube of steel, which remains intact and another which bursts on board a steamship and kills a dozen men with scalding steam is to be found in crystalline structure, in the relations which the molecules assumed when the steel, or other metal under consideration, underwent the process of solidification. It is interesting to note that the microscope, invented in the interests of biology, and long used by biologists alone, now forms an invaluable part of the *armamentarium* of the metallurgist, who is enabled by its means to make minute study of the crystalline forms of various specimens of various metals and alloys, and to correlate differences in this respect with physical properties, such as brittleness, elasticity, density and the like.

Value of Crystallography in Industry. If the reader should ask where he must look for the most noteworthy advances in this subject, and for the most extensive knowledge, he may be referred to the University of Sheffield, the metallurgical work of which affords an admirable instance of that wise tendency towards specialisation which the universities of this country are now exhibiting.

In this connection we may quote from Dr. A. E. H. Tutton, F.R.S. ("Times," June 20th, 1906). Speaking of crystallography, he says: "Its bearing on engineering, moreover, is of no trifling character, since the whole of the metallic materials employed by the engineer are crystalline substances. Hundreds of valuable lives have been sacrificed by the existence of flaws in metallic beams, girders, tie-rods, bolts, rails, wheels and axles, consequent on local development of crystalline structure, or on the local separation of crystals of a particular constituent in an alloy or a steel. Many of these might have been saved if we had possessed exact knowledge of the crystallographical character of metals, and of the influence upon it of the various metallurgical and mechanical processes to which steels are subject. Investigations to this end are at length being tardily initiated, and the practical utility of this branch of crystallography is so obvious as to appeal to all, and from motives equally economic and humanitarian."

"Neither Alive nor Dead." Thirdly, the study of crystals is of the most extraordinary interest in relation to the problems of life. In the narrow sense crystals are not alive; but they display certain characters which strongly suggest that, from some points of view, they may be regarded as intermediate between the living and what we are pleased to call non-living. M. von Schrön, the Director of the Pathological Institute of the University of

Naples, has been working for many years at this subject, and appears to have reached some amazing results. He believes that a crystal is an organised evolving being like an animal or a plant, and having its own biological laws. In rocks he discovers what he calls petro-cells (from the Greek word for a rock), and in these he recognises by the microscope a definite nucleus. He has taken thousands of photographs of what he believes to be crystal cells which are formed when a salt crystallises out of a solution, and he declares that the struggle for existence can be detected amongst such cells. In his view, all minerals are colonies of beings which live or have lived.

Does all Matter Respond to Stimulation? A very distinguished Indian physicist, Professor Chundra Bose, of the Presidency College, Calcutta, published in 1902 a remarkable book, entitled "Response in the Living and the Non-Living," in which he was enabled to show that various crystalline forms of matter exhibit response to electrical stimulation, and show fatigue and electrical phenomena identical with those which the physiologists have hitherto described as characteristic of living muscle. His work was met with the usual and necessary incredulity accorded to the pioneer, but his results have stood, and in the present year he has published another book, called "Plant Response," which carries his work still further, proving the identity of response to stimulation in the animal, in the plant, and in various kinds of crystalline inorganic matter. We may briefly quote from page 40 of Professor Bose's remarkable book, published in this country by Messrs. Longmans, Green & Co.:

"By following the electrical method of inquiry which has just been described, I have been able to prove that the power of responding to stimulus, and, under certain conditions, the arrest of this power, is the characteristic, not of organic matter only, but of all matter, both organic and inorganic; and that, in general, the various agencies which bring on the modification of response in one case—such as fatigue, temperature changes, stimulating or depressing chemical reagents—act in the same way in the other. The capability of responding, so long regarded as the peculiar characteristic of the organic, is also found in the inorganic, and seems to depend in all cases, both qualitatively and quantitatively, on the condition of molecular mobility."

All Elements have Crystalline Forms. We may conclude our brief review of this big subject by one or two more references to the work of Dr. Tutton, which is of extreme importance. He says:

"The fundamental fact of the science is that every solid chemical element, whether metallic or non-metallic, and every solid substance of definite chemical composition, be it naturally occurring or artificially prepared (with the exception of the few which have never yet been obtained in the crystalline condition owing to the great viscosity of their solutions or of their molecules when in the state of union), has its own definite crystalline form, which is just as much a characteristic feature of the substance, by which it can be identified, as is any one of its chemical or physical properties. This is a statement which it has only quite recently been possible to make with certainty. For it was for a long time thought that the members of the numerous well-known series of analogous chemical compounds (which only differ in containing a different member of a family group of chemical elements as their dominating and generally metallic constituent) were absolutely identical in their crystalline form, and they were consequently classed as 'isomorphous.' But the author of this article has been able to prove, as the result of fifteen years' work, that although the forms are very similar, and although they belong to the same type of symmetry, the angles between their corresponding faces are different, to the extent it may be of only a few minutes of arc, but in some cases by as much as a couple of degrees. Moreover, the amount of the difference is governed by a definite law, which connects the atomic weight of the metal or other dominating (acid-forming) element present with the whole of the properties of the crystals, whether of exterior form, of optical character, or of internal structure.

"The main result of the highest refinement of crystal measurement has been to establish the fact that perfectly developed crystals of the same chemical substance invariably exhibit faces inclined at precisely (to within one or two minutes of arc) the same angles, whatever may be the variations in the relative sizes of the different faces. In brief, the interfacial angles of crystals of the same substance are constant, and are the peculiar property of that substance, differentiating it from all others."

The Physics of the Stars. The term *astro-physics*, which has been popularised by the work of Miss Agnes Clerke, is equivalent to what is usually meant by the "new astronomy." It is obvious that the law of gravitation is a law of the physics of the stars; but this is not quite the meaning of the term astro-physics. It is practically astronomy as studied by the spectroscope, and depends upon the application of our knowledge of optics. Partly, as we have already seen, astro-physics deals with a purely physical problem, such as the effect of radiation pressure upon movements in the heavens, or the study of the motion of stars in the line of sight. But mainly, perhaps, astro-physics deals with chemical problems—only that they are solved not by chemical but by physical means. But we have discussed, in concluding the course on Chemistry, the chemistry of the stars and the manner in which physical means have enabled Sir Norman Lockyer and others, even before the demonstration of the transmutation of the elements on the earth, to declare that such transmutation takes place in the heavens. Here we merely ask the reader to obtain a definite idea of what is meant by astro-physics—a new astronomy of which the telescope is only a subordinate instrument, which entirely depends for its prosecution upon the employment of physical methods, of which by far the most important is the spectrum analysis of light.

The Problems of Solution. The moment we turn the mind to such a simple phenomenon as the melting of a lump of sugar in a cup of tea we realise that, commonplace though this be, it is profoundly interesting, and must surely be profoundly important. In the present outline discussion of it we shall follow Mr. Whetham, whose "Theory of Solution" (John Murray) is the most authoritative book upon the subject.

The problems of solution are important on every score. They have always been recognised as important for the physicist and the chemist, but we are only now beginning to recognise their extreme importance for the biologist and the physiologist. The reader has only to refer to such a book as "Recent Advances in Physiology and Bio-Chemistry" (by numerous authors; Arnold. 1906) to see that the greater our knowledge of the facts of solution in general the nearer we shall be towards understanding the facts of life in general and, notably, the facts of the relations between the infinitely complicated and numerous processes that are necessary for the life of the higher organisms. According to Mr. Whetham, "*the application of physical conceptions to the problem of living matter chiefly depends on the knowledge we possess of the physics and chemistry of ordinary solution.*"

It is of interest that the biologists were the pioneers in the modern elucidation of this subject, which began about a generation ago. The biologist Traube, followed by Pfeffer, showed how to construct what are called "semi-permeable membranes," which will permit water to pass through them, but will completely arrest certain substances that may be dissolved in the water. These membranes are in general made of porous unglazed earthenware, which has been impregnated with certain salts. The remarkable fact is that such semi-permeable membranes are found almost everywhere within the bodies of animals and plants, and play, as we now know, a most important part in their life.

The Laws of Osmotic Pressure. If we prepare a cell, the walls of which have this property, and fill it with a solution of sugar in water while we bathe its exterior in pure water, we find that this forces its way into the cell up to a certain point. This point can readily be measured if the cell has a glass tube containing mercury attached to it. Such a pressure gauge will indicate for us what is called the *osmotic pressure* of the solution after the maximum amount of water has forced its way into the cell from without.

This osmotic pressure follows certain laws, and these have been elucidated by the most distinguished student of physical chemistry now living, Professor Van't Hoff, of Berlin. We may quote the following two laws as stated by Mr. Whetham. The results obtained by Pfeffer show:

(1) That the osmotic pressure was inversely proportional to the volume in which a given mass of sugar was confined.

(2) That the absolute value of the pressure in the case of the solution of sugar was the same as that which would be exerted by an equal number of molecules in a gas when placed in a vessel with the same volume as the solution.

These laws are of extraordinary interest, for they must instantly recall to our minds two other laws with which we have long been familiar, and of which these new laws are verily no more than extensions. We already know the law of Boyle, that the volume of a gas is inversely proportional to its pressure. We now discover that this general proposition holds true not only of gases, but also of dilute solutions—evidently a splendid result.

Secondly, we know the law of Avogadro, which states that the pressure of a gas depends upon the number of molecules present and not upon their nature. We now discover that this law is true not only of gases but also of dilute solutions—an equally splendid result.

Several workers have shown by other arguments "that the osmotic pressure must be equal in amount to the gaseous pressure exerted by the same number of molecules when vapourised, and must conform to the laws which describe the temperature, pressure, and volume relations of gaseous matter." This holds good whatever may be our precise theory of the nature of the process of solution. It may be almost impossible to frame any clear idea of what actually happens when sugar melts in tea, and yet we are enabled to frame laws of solution which are absolutely identical with the corresponding laws of gases.

Mixtures and Compounds Again. How far do these laws help us to determine whether solution implies the formation of anything that can be called a chemical compound, or whether it means no more than a mixture? Elsewhere, of course, we have seen evidence to show (in the case, for instance, of the relation between water and alcohol) that some chemical action must be involved; and on the whole the present evidence is rather in favour of the view that solution is a chemical rather than a purely physical fact; in other words, that "a solution, say, of salt and water is in some way a chemical compound of these components; a compound in which the relative proportion between the components can vary continuously between certain wide limits."

It was soon discovered that there are certain noteworthy exceptions, as it would appear, to the usual law of the osmotic pressure. If we compare solutions of sugar and of alcohol, each containing the same number of molecules in the same volume, we find, as the law asserts, that they possess equal osmotic pressures; but if, instead of comparing sugar and alcohol, we compare sugar and salt, we find that, even though the two solutions contain equal numbers of molecules, the osmotic pressure of the salt, if the solutions be fairly dilute, may be almost twice as high as that of the sugar. It remained for another great physical chemist, Professor Arrhenius, of Stockholm, to show that it is not necessary, as Van't Hoff supposed, to regard this case as an inexplicable exception. On the contrary, we have only to suppose that the molecules of the salt

undergo a splitting up or dissociation, and we see that the abnormally high pressure may be explained. This dissociation is rendered much the more probable when we realise that these abnormal osmotic pressures are found in the case of solutions which conduct electricity.

What Happens to the Molecules. According to this theory, then, which is now well established, common salt does not exist as such when it occurs in dilute solution in water. The molecules have been dissociated, and exist as particles or atoms of sodium and chlorine, these being associated with electric charges. "Each salt molecule thus gives two pressure-producing particles in solution, and the double value of the osmotic pressure is explained. In stronger solutions this dissociation is not complete, and the osmotic pressure is less than twice the normal value."

This theory, then, shows us that Van't Hoff's laws are valid, even in the case of apparent exceptions to them. It recognises that these exceptions consist of solutions of *electrolytes* as distinguished from non-electrolytes, this new term being applied to substances capable of conducting an electric current, meanwhile undergoing change; and it explains abnormalities of pressure in terms of molecular dissociation.

An entirely different method of studying the facts lends further support to the dissociation theory. In this subject Faraday was again the pioneer. He showed that there was a constant proportion between the amount of electricity conveyed through an electrolyte and the amount of decomposition which that electrolyte suffered. This seemed strongly to suggest that when an electric current is conveyed through, for instance, a solution of sodium chloride in water what really happens is a dissociation of the molecules of the salt, the positively electrified atoms of sodium going with the current and the negatively electrified atoms of chlorine going against it. These "goers" Faraday termed "*ions*," a Greek term which has that meaning. The ion which moves with the stream, and towards the electrode which is called the cathode, is known as the *positive ion* or *cation*, while the ion which travels against the stream, and moves towards the electrode which is known as the anode, is called the *negative ion*, or *anion*.

The Movement of Ions. We have here, perhaps, the very first hint that electricity, and even an electric current, is particulate and atomic in structure. Said Von Helmholtz in his Faraday Lecture of 1881, years before the discovery of radio-activity: "If we accept the hypothesis that the elementary substances are composed of atoms, we cannot avoid concluding that electricity also is divided into definite elementary portions, which behave like atoms of electricity."

The next question which opened itself for study was plainly the character of the ionic movement. Since we measure the conductivity of a solution by the amount of electricity which it will convey in a given time under the action of a given electric force, and since the conduction of the current depends upon the movement of charged ions, the conductivity of the solution, which is a measurable thing, must depend upon the *number* and *velocity* of the ions. Now, the number is ascertainable, since we can ascertain the strength of the solution, and thus we are in a position to ascertain the speed at which the ions move.

Mr. Whetham himself is largely responsible for the means by which we are now able actually to see the ionic movement—not, that is to say, the movement of the individual ions, but their movement *en masse*. This can be done by means of an apparatus which permits us to place next one another solutions of two salts, one coloured and the other colourless. Says Mr. Whetham: "The solutions should be of the same molecular concentration, the same conductivity, and the denser solution must, of course, be placed below the lighter. Let us take as an example the case of solutions of potassium bichromate and potassium carbonate, which fulfil the necessary conditions. The colour is here due to the acid part of the salt, the bichromate ion, which has the chemical composition represented by Cr_2O_7; the potassium ion is colourless. When a current of electricity is passed across the junction between the liquids the colour boundary is seen to move, and, from the rate at which it creeps along the tube, the velocity of the bichromate ion under a given electric force can be determined."

The Speed of Ions. The reader will almost certainly imagine that the speed with which the ions move will be very great, but it is really remarkably small. Much the fastest moving ion known is hydrogen, but when the electromotive force is one volt per centimetre, the hydrogen ion moves only at the rate of 4 in. per hour, and this is about ten times as fast as the speed of most other ions. We must distinguish this movement, of course, from the movement of the electric current—or, rather, we must distinguish the two speeds. The movement of the current is almost as rapid as that of an electric wave—that is to say, is almost equal to the velocity of light. Mr. Whetham compares the two movements with the case of the movement of a stick. If you push one end of the stick, the whole of it moves on. Its velocity may be as slow as that of a hydrogen ion—a mere 4 in. per hour. But something else moves with an immeasurably greater rapidity, and that is the wave of compression, which is induced by the push, and which must travel along the whole length of the rod before its advancing end can move. "The slow movement of the rod as a whole, when once started, corresponds with the slow drift of the ions; the almost instantaneous passage of the wave of compression along the rod corresponds with the velocity of electricity in the electrolytic solution."

MILLINERY

Essential Qualifications of a Good Milliner. The Apprentice. Importance of Suiting a Customer's Style. Stitches and Accessories

By ANTOINETTE MEELBOOM

MILLINERY is essentially a woman's profession, but to be successful she must have a light and delicate touch, accuracy and neatness, good taste in blending colours, a correct eye, judgment in adapting the style to the wearer, and a liking for working with dainty and pretty materials. Few tools are needed.

There are two seasons in the millinery trade, spring and autumn, with six to eight slack weeks in the summer and winter—July and August, and December and January.

The Apprentice. A girl of about 16, wishing to become a milliner, is usually apprenticed. The period is two years, in the second of which she receives about half-a-crown a week pocket-money. In some houses a premium is asked; others take girls without a premium, but through introduction. The girl is taken on approbation for some weeks to see if she has the necessary qualifications. At the end of the two years, if she has given satisfaction, she is usually taken on as improver, with a weekly salary starting generally at about 15s. a week. In the slack time some houses work their apprentices half time, or give them a holiday till the next season opens.

The head assistants and head milliners are engaged by the year, with salaries varying between two and five guineas a week.

It is well for a girl to be apprenticed to a small business, although it should be a first-class one, as she will then have a good opportunity of seeing all kinds of work done. In the larger houses the work is divided up into different branches, one room being set aside for making hats, another for toques and bonnets, and so on. An apprentice will never regret the time spent in matching—that is, obtaining from the warehouses patterns of silks, velvets, ribbons, etc., which tone exactly with a particular pattern. Until one has tried, it is difficult to realise how difficult some colours are to blend.

Advising a Customer. A milliner who thoroughly understands her work is able to advise her customers which of the many prevailing styles suits her, and a good business woman is sure to be a success.

Though the fashions change so rapidly many of the principles never change, and, when mastered, the worker will find herself able to adapt them to prevailing fashions.

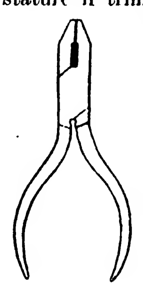
The importance of wearing what is really becoming without considering whether it is the latest fashion or not cannot be over-estimated. A clever milliner's aim is to adapt the prevailing fashions to suit the face.

Modern styles are so elastic that it is perfectly easy to be well dressed. No rules on how to dress can be laid down, but an important point to remember is that in choosing a hat or toque it is not only well to decide with what costume it will be worn, but, if possible, to try it on when wearing the dress. It will avoid possible disappointment, as that which looks well and in perfect style with a tailor-made costume may look small and insignificant when worn with an elaborately trimmed dress or big furs.

Hair-dressing and Millinery. The way in which the hair is dressed is another consideration in the choosing of headgear. The most fashionable headgear is modelled on the way the hair is dressed at the moment; thus, if the hair is worn low down at the neck, the brims will be long at the back. When the hair is worn at the top of the head, a short brim at the back with high crown, or a low crown and bandeau, looks best. For hair worn rolled back from the face, a turned up brim in front is most suitable.

Thin faces should have the hair dressed loosely over the temples, and a soft-looking edge to hat or full front to a bonnet. When no fringe is worn and the hair brushed smoothly back, a bonnet with rucked edge, or a brimmed hat, will be the best style to adopt. Hair dressed in coils and plaits at the back usually requires a large headline. Coils and plaits round the front require the headline cut rather wide there.

Large picture hats look well on tall people, though they may be worn by persons of small stature if trimmed very lightly. A hat should *never* be over trimmed.



1. WIRE NIPPERS

A full face needs a broad trimmed hat.

A long face looks best in a brimmed hat, trimmed broad and worn over the face. High trimmings, which lengthen the face, should be avoided. Broad toques, fitting well on the head, may be worn.

The most becoming hat for a round face is a round hat with an equal brim all round, except at the back, and worn tilted slightly off the face in the front. No very small hats or toques are becoming to this style of face.

Drooping brims of the flop and mushroom type are not becoming to people past their youth, as they cast a shadow on the face. They are best suited to young, round faces.

Brims turned up in front can be worn by small round and oval faces.

Let your customer wear the colours that suit her. Do not advise her to wear a colour that

does not match her complexion, hair and eyes, no matter how fashionable.

The blonde may wear delicate shades of blue, pink, and green.

The brunette looks well in deeper and richer colours.

The choice of shades depends greatly on the complexion, as the colour may suit the hair but not the skin.

White is very becoming to fresh and rosy skins, but should be avoided by those with pale and sallow complexions.

Black is not becoming to pale and sallow complexions, unless combined with lace and a colour in the trimming. It looks well on fair people with a little colour in the face.

Requisites. We must now consider a milliner's "tools."

Gum or Gum Labels.

Tissue Paper.

Bowl and Damping Rags. For steaming and pressing.

Notebook and Pencil. For writing down measurements.

French "Doll's Head." Used for cap-stand.

Block for Shaping Crowns.

Kilting Machine.

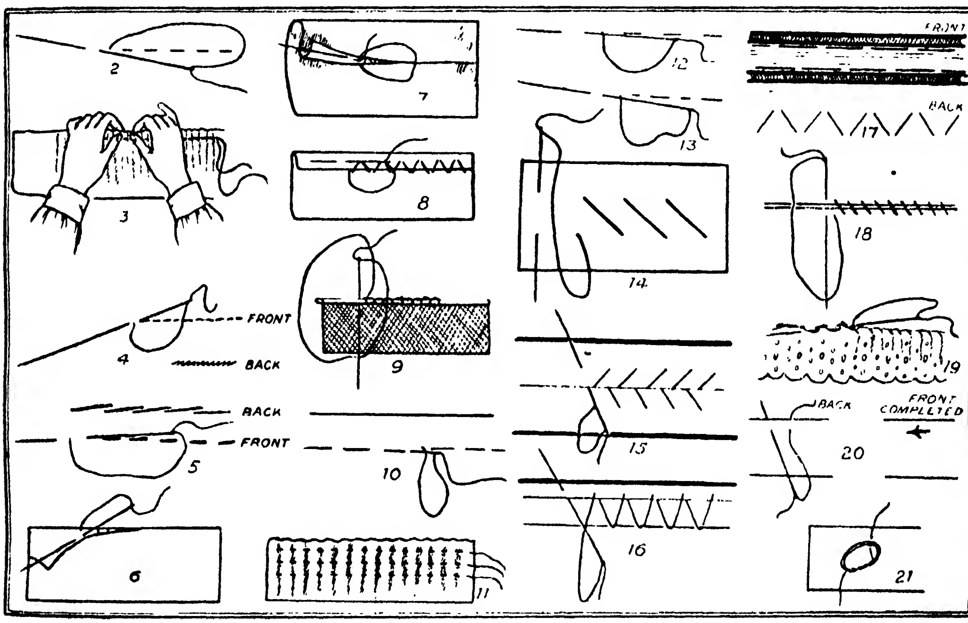
Accordion Pleating Machine.

Pinking Machine.

Velvet Brush.

Stitches. The following are the stitches used in millinery:

Running. Pass the needle and cotton in and out of the material at equal distances. The stitch appears the same on both sides. Used



2. Running 3. Fly running 4. Back stitching 5. Long back stitching 6. Slip stitching 7. Slip hemming 8. Velvet hemming 9. Wire stitching 10. Gathering 11. Shirring 12. Tacking 13. Tacking for crape 14. Basting 15. Lacing stitch 16. Catch stitch 17. Straight bandeau 18. Oversewing 19. Whipping 20. Tie stitch 21. Stab stitch

Millinery Wire Nippers. Price 1s. to 2s. 6d.; the latter are made of English steel. They must be light, small, and with broad noses [1].

Needles. Packet of straw needles, mixed, sizes, 5, 6, 8. Price 1d. No. 5 for wiring, and No. 8 for hemming.

Steel Pins. For pinning silk, velvet, etc.

Lillikins. For pinning velvet edges, joining laces, etc.

Thimble.

Scissors. About 7 in. long, with sharp points.

Tape Measure. Dean's are the best.

Sewing Cotton. Fine and coarse, white and black, No. 10 for sewing on trimmings.

Sewing Machine.

Flat Irons. No. 2 and No. 8, for pressing straw and steaming velvet, etc.

Ironing Blanket. For pressing.

Pocket-knife. For ripping fur.

for making the hem of head-linings, and joining two parts together where no great strength is needed [2].

Fly-running. Place the needle in the material and hold it lightly, close to the point, with the right thumb and forefinger. The thimble should propel the needle. The left hand holds taut the material, which is pushed on the needle by the left thumb and forefinger. As the needle fills with material, push it off from the eye end. The needle is not drawn through until the whole length is gathered. For long lengths, thread the needle from the reel of cotton or silk, which will prevent it knotting [3]. It is a rapid way of running, and is used for all branches of millinery that require gathering, such as tuckings, casings for silk hats and bonnets, tuck running in chiffon, tulle, etc.

Back Stitch. Insert the needle exactly where the last stitch was begun, and bring it out in front the same length of the stitch just made. To obtain a regular row of stitches, each stitch must exactly meet the last, and be of the same size [4]. Used for joining two pieces of velvet, silk, or cloth, wherever the material is likely to be stretched and requires strength.

Long Back Stitch. Instead of inserting the needle in exactly the place where the last stitch left off, as in back stitching, take a short stitch back, which in straw-working will be slanting in the direction the straw is plaited [5]. Used in straw-working; for sewing in head-linings, bandeaux, mulling; in shape-making, joining side band to head-line of brim shape; in covering, sewing upper and under covering of brim to head-line, also material tip to that of shape.

Slip Stitch. Take one stitch on the turning of one piece of material, and the next exactly opposite on the turning of the other piece [6]. Used for joining the upper and under edges of hat brims covered in velvet, cloth, or silk, and wherever invisible joining is required; stitching on rouleau to covered or felt hats, etc.

Slip Hemming. Use a fine needle and cotton, or silk to match material, and take up one thread of the material under the fold. Slip the needle into the fold and make a short stitch as in running; draw the needle out, and just take one thread again of the material under the fold. Do not pull the stitches tight; they should not show on the right side [7]. Used for invisibly hemming velvet, silk, crape, etc,

Velvet Hemming. Turn down the raw edge of material once; take a stitch as in running through the fold, and take one thread of the material under the fold in a slanting direction. Work from right to left with fine needle and cotton [8]. Used for neatening cut edges of velvet, and where it does not require a roll hem.

Wire Stitch. Hold the wire firmly in place, stab the needle in the hat *above* the wire, holding back a loop of cotton under the thumb. Stab the needle back again *under* the wire, bringing it through the loop from behind and pull tight. Work from right to left. The stitches must just fit the wire [9]. Used for all parts requiring to be wired.

Gathering. Take up half as much on the needle as has been passed over [10]. Used when a long length has to be gathered into a small space.

Shirring. Rows of fine gathering placed underneath one another. The stitches must exactly correspond with the row above, and the cottons are drawn up together [11]. This stitch is used for fancy linings for brims, for children's millinery, etc.

Tacking. A large running stitch [12]. Used for keeping two parts temporarily together.

Tacking for Crape. A long and small running stitch [13]. Crape being a springy material, this stitch keeps it better in position than ordinary tacking.

Basting. A long and a short stitch, the first taken slantways, the second perpendicular [14]. Used for holding together temporarily the material and lining previous to being tacked.

Lacing Stitch. Place the needle under the fold, bring out in a slanting direction. Place the needle in again on opposite side, also in a slanting direction [15]. Used for securing the raw edges of velvet folds. It is sometimes called Milliner's Herringbone, but is always worked from right to left.

Catch Stitch. Take the needle under the turning and bring out to right side. Pass under the wire, then over the wire, and under the turning again, and repeat [16]. Used for fastening down the upper side of material brim to the second edge wire of under brim.

Round Bandeau Stitch. The stitches are taken close to the edges of the ribbon wire to prevent curling up. Make a long stitch of ¾ in. on upper edge of ribbon wire. Bring thread to bottom edge of wire at the back, take the needle through at nearly half the length of the upper stitch already made. Then take another ¾ in. stitch, and so on. On the reverse side a series of /\ /\ will be seen. Use black cotton on white net and wire, and vice versâ [17]. Used for sewing ribbon wire to net for foundation of round and straight bandeaux.

Oversewing. Place needle pointing straight towards you in the raw edge, hold the work round first finger of left hand. Repeat this, forming a slanting stitch from right to left on the right side, and a straight one between each [18]. Used for joining lace, sewing fur, neatening the raw edges of velvet for straight bandeau where a turning will make it too clumsy and thick.

Whipping. The needle is taken over the raw edge of the material, put in from back to front, and over the edge again. The stitches are taken fairly long, and the needle, as for "fly-running," is not taken out until the finish [19]. Used instead of gathering, to prevent ravelling in lace or tulle.

Tie Stitch. Stab the needle through from the right side; leave an end of cotton, bring back the needle from the back, and tie a knot [20]. Used for securing light trimmings, trails of flowers, lace, tips of feathers, loops of ribbon on a brim; fastening head-linings in position inside bonnets and hats.

Stab Stitch. Proceed as with the tie stitch, but take the needle through and through the hat for extra strength [21]. Used for sewing on trimmings that require strength.

FIFE. PICCOLO. FLUTE. OCARINA

Construction and Peculiarities of the Instruments. Attitude of Player. Fingerboard. Scales. Positions. Effects. Exercises

Continued from page 4488

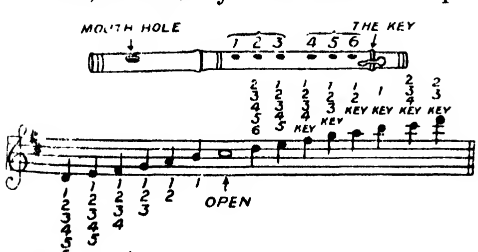
By ALGERNON ROSE

FIFE

The fife, unlike the flageolet whistle, is provided with a single key. The instrument has a compass of two octaves, from D on the fourth line treble clef.

The instrument should be held horizontally. Keep the head and body upright, and rest the instrument on the middle joint of the first left finger. Place the thumb just below the first hole. Put the right thumb opposite the fourth hole, against the side of the fife, and not underneath it. This will permit the little finger to remain over the D♯ (or E♭) key. Following these directions, keep the first and second left fingers carefully curved, and the third nearly straight. Round, also, the first and second right fingers. Except when used for the key, or keys, the two little fingers do not rest upon the fife. They must never hang beneath it. Do not hold the fife tightly in the right hand, nor press the fingers forcibly on the holes, as this will impair neat execution. Avoid raising the fingers more than half an inch above the holes. Aim at delicate surface-playing rather than force of finger attack.

Blowing. Close the lips, and compress them a little. Holding the instrument as described, place the mouth-hole against the middle of the underlip. Make sure that the upper lip comes within the radius of the aperture. Relaxing the upper, press the fife against the lower lip. Blow into the instrument with moderate force. Take care that the air passes into the mouth-hole and not over it. If it does, there will be a hissing sound and waste of effort. While blowing, endeavour to pronounce the syllable "too." With practice, a clear steady sound will be produced. Do not close, at first, any of the holes. The open



sound of the tube is C♯, third space, treble clef. To get B, a tone below, put down the first left finger, and blow "too," as before. For the A below, add the second finger. To get the G, add the third. For the F♯, cover the fourth hole, and so on, as for the flageolet. The annexed diagram of the fife, with the holes numbered, and the staff showing the scale from D to D of two octaves, indicates the manner of fingering for the production of different tones.

Exercises. Simple as this scale may appear to be, there is a great deal to be learnt from it by diligent study; but the only way by which progress can be made is through regular daily practice. The first thing for the beginner to understand is the relative value of Time, or duration of sound, and Pitch, or variety in sound. Starting at the lowest note, D, blow into the instrument steadily and clearly, counting mentally four, regulating the beats by the ticking of a clock or a metronome. Having done this softly, repeat the sounds with more force during the first and second beats, articulating the same note sharply twice on the three and four. In the same manner, next try the E above the D, the F♯ above the E, the G, and so on up the scale, blowing with increased pressure ascending, and gradually softer descending. After getting facility on each note of the compass, as regards time, or speed in playing, proceed to the next department of study.

Intervals. An interval is the distance between any two sounds, and the facility in which musical tone is made to pass from one interval to another gives the charm to what is known as melody. Now try to get accustomed to the simplest intervals, known as seconds. Play the low D, counting two. Without break, pass to the E above for the three and four. Repeat the E on two beats, making the F♯ follow on the next two. In this way go up, step by step, to the highest notes, descending the ladder of sound in the same fashion. Next try thirds. Sound the lowest D, counting two as before. Skip the next note, but, without break, play the F♯ on the three and four, F♯ being a major third above D. Sound the E, passing over the next note and following with G. Play the F♯, skipping the G and blowing A. Thus, in thirds, practise slowly and carefully up and down the scale.

Proceed to fourths. Sound the low D as before, then skip two notes, and blow the G easily and without pause between one sound and the other. Blow the E, and follow it by A, a fourth above the F♯, succeeding it by B, G, and C♯, and so forth up and down the instrument. Next try fifths. These may sound ugly, but no matter. Check the intervals on a piano at first. Returning to the low D, skip three notes, and blow the A above. Count two beats on the first sound, and complete the three-four on the second. In the same way follow the E by the B above, F♯ by C♯, G by D, thus going up the compass by fifths, and going down in like manner. Try sixths.

Sound the low D. Now skip four notes, and, without interruption, pass to the B above. The student should write these exercises out on music paper. Sound the E, linking it with the C♯ above. Play the F♯, following it by the D. Thus, in sixths, go up and down the compass. In the same way try sevenths. Follow the low D by the C♯ above it, always blowing in strict time, and endeavouring to avoid any hissing sound with the upper lip. Blow the E with the D above, the F♯ with the E above, and so up and down the compass.

Finally, take the octaves. After blowing the low D get the second note at the higher pitch, with the same fingering but increased pressure of breath. In the same way blow the low E with its octave above. As before, get the F♯. But now, to facilitate the sounding of the octave above, with the little right finger put down the key, and, in like manner, use this key for the octave notes of G, A, and B. After playing the C♯ with all the holes open, to get the octave put down the second and third left fingers, the first right finger, and the key. To get the top B, close the second and third holes only, using the key. Descend in octaves in the same way. The student should now find little difficulty in executing the march tune of the Guards, given at the head of this page.

PICCOLO

The piccolo is an octave higher in pitch than the ordinary flute. It is called "E♭," although the lowest note really sounds D♭. As the embouchure is small and the holes are rather close together, this instrument is a good one for a boy to take up, as it is more suited to his lips and fingers than the big concert flute. Besides, it is less than half the weight of the latter, so that it is much more portable. On account of the shrillness or brilliancy of its tone, one piccolo suffices in a military band of brass and reed instruments consisting of as many as sixty-two players.

In the score, the piccolo is always written for an octave lower than the notes which are actually played, and the part is invariably noted in the G, or treble clef. The compass of the piccolo is from D, first space below staff, to D above, fourth ledger line, and the instrument gives all the intervening chromatic notes. The cost of a good piccolo ranges from 15s. to £15 15s., according to whether it is of cocuswood or ebonite, or has from four to ten keys in brass, German silver, or silver. The lowest octave being weak and of little value, the student should particularly practise that part of the compass which begins at D, fourth line treble clef, and goes up to F♯, two octaves above. This gives a range of notes which possesses remarkably effective qualities, used in a beautiful way by Beethoven in the "Pastoral" Symphony, or Berlioz in "Faust."

The instructions given for the fife and flute apply also to the piccolo. But, although this instrument lacks the nobility of tone of the big flute, the student should note that it excels in

Ex. 1.

certain trills and florid passages, one of its most charming characteristics being the rapidity in which reiterated notes can be articulated by double and triple tonguing.

We give here an example of *double-tonguing*. Tongue the first note, and blow the second very strongly from the throat. Do not hurry at

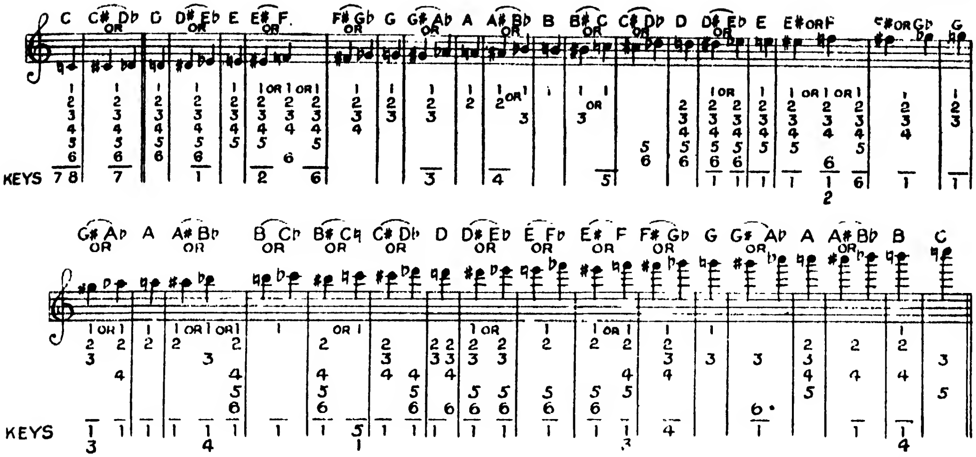
Ex. 2.

first. With practice, the player should be able to imitate in velocity and neatness of execution the roll of a side drum. [Ex. 1.]

In triple-tonguing, tongue the first and second notes, and blow the third. [Ex. 2.] This sort of thing when properly done is well worth hearing in solo work. At the same time, the student should practise daily chain-trills, going from note to note in the different major scales, because the piccolo is frequently employed to imitate bird-like effects. Those trills which are most difficult of execution should, of course, be given special attention. For example, practise those on the lowest D♯, with the E♯ above; the E♭ with the F above; F♯ with the G♯ above; A♭ with the B♭ above; C♯ with the D♯ above; C♯ with the D♯ above; and the A♭ on the first ledger line with the B♭ above.

FLUTE

The flute is one of the most important instruments in the modern orchestra. The flageolet and the church organ pipe exemplify one great division of the flute family, known as the *flute-à-bec*. The other great division, with which we are now treating, comprises all the different kinds of *flauti-traversi*, or horizontal instruments. The reason why to-day, in the most advanced orchestral music, the flute plays such an important part is owing to the acoustical discoveries of Captain Gordon, made practical through the



system of manufacture known as the Boehm. Before such improvements the flute, in many respects, was defective in intonation and difficult to finger. As it may not be within the means of every student to purchase an instrument with the latest system of fingering, he will probably have to content himself with an ordinary military instrument.

One to Eight-Keyed Flutes. The *one-keyed* flute, described under Fife, has a D♯ lever pressed down by the little finger of the right hand. The *four-keyed* flute has a second, or E♯ lever, worked by the third right finger; a third, or G♯ lever, worked by the fourth left finger; and a fourth, or A♯ lever, worked by the left thumb. The *six-keyed* flute introduces a fifth lever (C♯), and a sixth (or C♮), both worked by the fourth right finger.

Coming to the *eight-keyed* flute, we have an additional seventh lever, or C♮ shake-key, worked by the first right finger, and an eighth lever, or E♯ key, played by the fourth left finger. Familiarity with the different keys is easily acquired if the student who begins with the fife has an opportunity of learning afterwards the flutes with four, six, and, finally, eight keys. A well-made instrument of this class, guaranteed for six years, can be obtained new for £3, or for considerably less second-hand.

Military Scores. In a military score the piccolo comes at the top. Beneath it is the F flute. Beneath that, again, is the E♭ flute. The actual pitch of the E♭ and F flutes respectively is D♭ and E♭. In most bands, as they are seldom wanted together, one man plays both instruments. Should they be needed simultaneously, the piccolo player takes the second instrument. The tone-quality of the F flute is lighter than the E♭, the latter being richer and fuller. Although regulation flutes used in the drum-and-fife bands have but one to four keys, those employed with the brass and reed instruments require the eight mentioned. It is only possible here to give the chromatic scale of the last-named instrument, which will be easily understood by the diagram at the head of this page.

Concert flutes, on the other hand, have ten, eleven, or twelve keys, besides rings. Most players master the eight-keyed fingering before proceeding to the instrument with cylindrical bore and larger holes adopted by Boehm. Amongst the many methods for the latter may be mentioned those by Bousquet and Taffenel (Paris), and Svendsen and Pratten (London). As regards pitch, the tuning-slide enables the instrument to be flattened but not sharpened when closed; but all wind instruments get sharper as they become warmer through the breath of the player or the heat of a concert-room. Before playing, therefore, warm the instrument well with the breath through the mouth-hole.

OCARINA

The ocarina is of terra cotta, resembling in shape the body of a little goose, the Italian word "oca" implying that bird. Because the large interval cavity has no outlet, or bell, the musical quality of the tone is of acoustical interest. There is a peculiar hollowness in its character, somewhat like that of a stopped organ pipe.

Compass and Construction. The compass of the solo ocarina comprises a chromatic scale of 20 distinct semitones extending, in the C instrument, half a tone below middle C to F on the top line, treble clef. Made of larger sizes, at different pitches, the compass is extended downwards by increasing the cavity. Effective combinations of six players have made monetary harvests, especially on the Continent. The tone is sweet and pure. Although incapable of great force, it has a remarkable carrying quality. The mouthpiece is where the head of the goose should be, and the tuning-slide is situated in the region of the creature's breast.

Pull out the slide to lower the tone. Push it in to raise it. The body of the bird is pierced by ten holes, five for each hand. Place the mouthpiece to the lips. Two holes only should then be at the back; cover these with the thumbs. Place the first finger of the right hand over the hole at the bird's tail. Put the second, third and fourth fingers over the three holes which follow in the direction of the mouthpiece. Close, with the first finger of the left hand, the

hole nearest the tuning-slide, and, with the second, third and fourth fingers, those which are in line with the first.

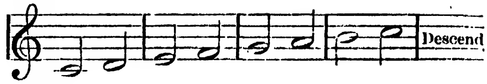
All the holes should now be covered, not with the tip but with the ball of each finger, so as to prevent any escape of air and a bad effect. Put the mouthpiece, not into the mouth, but between the lips. Blow lightly into the instrument. Breathe through the nose. Endeavour to get the tone even; never force it. The note sounded will be C on first ledger line below staff. Check this with a piano.

C Major. After sounding middle C, raise the first right finger, covering the hole by the bird's tail. Blow as before, softly. This should give D, a tone above the C. Lift the second right finger. The result will be E. Raise the third finger. This will sound F. Withdraw the fourth finger. The result will be G. To get the A above, raise the third finger of the left hand. This may require practice, as the third is the weakest digit. But the other notes of the left hand must be kept firmly closed. To get the B above, lift the second finger. Raise the first for the C. Take away the left thumb for the D, and the fourth left finger for the E. With all the holes open, sound F. Descend the scale in the same way [Ex. 1].

Tone Production. Sustained and gliding effects are accomplished by steady blowing in the way described, and the endeavour should be to make the sounds of the scale travel as smoothly as possible from one to another. Staccato is the reverse of this. The way to do it is, on producing each sound, to articulate the syllable "too," by giving to the tongue the same action as is done in spitting a bit of fluff out of the mouth. This tone-stroke emphasises the initial vibration, and quick withdrawal of the member allows the necessary air to pass into the instrument [Ex. 2]. Having obtained facility in playing the scale staccato, make a triplet of each note, so that it is heard three times distinctly before the next is played. This is done by pronouncing, mentally, "too-tle-too" for each note [Ex. 3]. After this, endeavour gradually to increase the speed with the first method of blowing. Until the student becomes familiar with the fingering, this will require daily practice. He should not be satisfied until he is able to run up the scale with one breath, and down again with the next [Ex. 4]. Then take practice in intervals. The Violin course will suggest appropriate exercises [page 2121]. Expression is added, when sustaining a note in a melody, by the use of the vibrato. This is done by fluttering the breath in the mouth rather than in the throat, as in singing.

Chromatic Scale. The fact that the ocarina can be played chromatically gives it a legitimate musical value. Sound the C, as before. To get C♯, the same fingering may be used by blowing harder. A more artistic way is partly to uncover the hole stopped by the first right finger. Taking off the first finger entirely, sound the D. To get D♯, replace the

Ex. 1.



Ex. 2.

Ex. 3.

Ex. 4.

Ex. 5.

first finger, leaving the second hole open. Sound the E and F as before, by uncovering the first and second, and then the first, second and third holes.

To get the F♯, close the third hole but uncover the fourth. Sound the G, as before, by opening the four holes, and the G♯ by stopping the third hole and uncovering the fourth and fifth, the latter by the third left finger. Sound the A by opening the five holes, but replace the third finger of the right hand and take off the second finger of the left for the A♯. For the B, remove the third finger, leaving the six holes uncovered. Sound the C, as before with the seven holes open. For the C♯, take off the left thumb, but put down the third right finger. For the D, remove the third finger. For the D♯, take off the fourth left finger and put down the third of the right hand. For the E, displace the third finger. For the E♯, as for the F, all the notes are open. But the note is "humoured" by the breath [Ex. 5]. Descend in the same way.

Having returned to the C, if the instrument is blown very softly, with all the holes closed, the semitone below the pitch-note, B, will result. Therefore, it will be perceived that what is called "humouring" the breath greatly affects the intonation. The student must know what tone he desires to produce. His ear will then enable him to get it.

The Trill. An excellent way of getting accustomed to the fingering of the chromatic scale is to practise trills a semitone apart. Begin slowly, and play softly, gradually increasing the speed. After regular daily practice, the knack will be acquired of ascending and descending the scale in this way without break either in intensity of tone or regularity in rhythm.

DETAILS OF CHEESEMAKING

The Cheddar Process. Scalding, Grinding, and Pressing. Cheshire, Blue-veined, Stilton, Gruyere, and Soft Cheeses. Best Dairying Books

continued from page 4492

By Professor JAMES LONG

The Cheddar Process. All things considered, Cheddar is the most popular cheese in the world. The best is produced in Somerset, Ayrshire, and Wigtownshire. It is the staple cheese of Canada and the United States, as well as of the Australian Colonies, and there is no other variety which approaches it as a pressed cheese from the point of view of combined texture and flavour. The system of production may be regarded as a type, and the most perfect type, of that adopted in the manufacture of pressed cheeses of other varieties, to which, therefore, we need but briefly refer.

The milk supplied by the cows in the evening is strained and poured into the cheese vat, and stirred until sufficiently cool to prevent the too liberal rising of the cream, which ascends with greatest rapidity in warm milk. On the following morning the cream which has risen is removed by skimming and mixed with a portion of the milk in the vat. In some cases this mixture is poured into a smaller vat and heated to such a temperature as will raise the remaining milk of the evening with that of the morning, when the latter has been added, to the required temperature for coagulation. The morning's milk is strained and poured warm into the vat already mentioned, and if the vat has a double lining or jacket, so that the milk can be heated by hot water or steam, the second vat becomes unnecessary, as the whole volume is then raised to the required temperature at once. Where two vats are employed, this temperature may be reached with accuracy by the aid of the following formula from "Elements of Dairy Farming," by James Long.

Method of Raising the Temperature of Milk. "Multiply the number of gallons in the tub by the number of degrees which it has to be raised or lowered, and divide the number so obtained by the gallons of milk in the warmer. The result shows the number of degrees above or below 84° F., to which the milk in the warmer must be brought. Thus, if we have 45 gallons in the large vat, and 15 gallons in the small one at 80° F, and we desire to heat the whole to 85° F.,

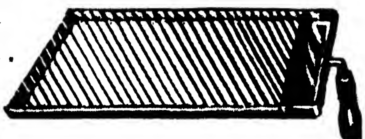
35. POND'S CURD BREAKER

we must raise the smaller quantity through 300° F. of heat (45 + 15 × 5), thus:

$$300 \div 15 = 20° \text{ F.}$$

"If we add the result (20° F.) to the desired temperature (80° F.), we get 100° F. as the temperature to which it would be necessary to heat the 15 gallons. It is, however, undesirable to heat milk much above 90° F., and we consequently make a fresh calculation, with the result that we find it will be necessary to heat half the milk to 90° F. to bring the whole volume to 85° F."

Care must be taken that too much heat has not been lost before the temperature is artificially raised. The required temperature being reached, the milk is stirred, the requisite quantity of sour whey—if this be employed—is then added at the same temperature, and all is ready for the addition of the rennet. The quantity of whey should be regulated in proportion to the acid it contains—and here again a test for acidity becomes necessary. If the evening's milk has not fallen below 70° F., although in some cases 68° F. may be safe, sour whey may not be needed. The milk for renneting is heated to different temperatures in accordance with the practice or custom of the district or of the individual maker. In Scotland, 84° F. is largely employed; in the West of England, from 85° F. in autumn to 90° F. in spring; but the maker, who should invariably be a trained hand, will in most cases adopt that temperature to which he has been accustomed, although he may see occasion to modify it where conditions change or are new. Coagulation is complete in from 40 to 50 minutes. In the United States, however, the curd is brought much more quickly, but the cheese is less fine in quality and keeps less perfectly, for the smaller the quantity of rennet used the better the keeping properties of the cheese.



34. POND'S CURD KNIFE

Cutting the Curd. Coagulation being perfect, the curd is cut, either with the knives commonly employed in the dairy, with the American knives already referred to, or with the oblique bladed knives made by Pond [34]. The curd should be cut evenly throughout, that each piece may be of similar size. After cutting, the vat may be covered and left for a short time, but stirring and breaking is usually begun within the hour. During this operation large pieces of curd will be broken smaller, but the work must be very gentle, that the curd may not be damaged and the fat it contains lost [35]. Stirring lasts from 15 to 30 minutes, when the work ceases for a time—the vat being again covered—to be followed by the scalding process, during which acid rapidly develops, while the tender curd

becomes firm, and at first comparatively tough. Stirring continues during the process of heating, whether a portion of the whey has been removed or heated separately and subsequently returned to the vat, or whether the whole mass be heated together through the medium of the jacket. In Ayrshire makers scald to 98° F., sometimes to 102° F., while in Somerset, scalding point varies from 90° F. to 94° F., many American makers employing a still higher figure—sometimes as much as 104° F. On many farms there is a second scalding, the curd having been allowed to settle for a few minutes after the first. In this case the scald varies from 94° F. to 98° F., which is reached at the end of the season; but in all cases it should be remembered that the temperature to be adopted depends upon the acidity of the milk at the time of renneting, and the employment or not of sour whey. Stirring is again resorted to in order to help the curd to acquire condition—and this needs both skill and judgment on the part of the maker. If the acid in the milk be one degree more than was present before the rennet was added, that condition has generally been reached. The object is to obtain an elastic curd, in which there is practically no toughness. The curd, indeed, should string out when attached to a hot iron gradually drawn away by the hand.

After stirring, the curd settles at the bottom of the vat, and here it remains for a time, the whey being drawn off, passing through a strainer on its way; but it is important that it should not be drawn unless the time is opportune. If it remain too long there may be too much acid; if too short a time an insufficient proportion. It should be pointed out that where sour whey is not employed, not only is the evening's milk maintained at 68° F. to 70° F. until the morning, but that the second scald may sometimes need a temperature of 104° F. to 106° F.

Scalding. In the scalding process the temperature of the curds and whey should be raised slowly, otherwise the curd may be toughened, and the whey then prevented from escaping sufficiently for the maker's purpose. The whey having left the vat, the curd remaining at the bottom in the form of a mat is cut and piled in cubes about 6 in. square. These cubes are from time to time changed in position, that each may be properly aerated, but they are still kept together in a mass that heat may not escape, for that is still essential—so much so that the mass should be covered with a cloth, which may be doubled if acidity need extra promotion. Indeed, the vat itself may be covered with its lid if circumstances demand it. The curd is then left until it is sufficiently acid—a condition which the maker must determine for himself. It is then broken up into small pieces, tied in a cloth or cloths, and, under some systems, slightly pressed either in the bottom of the vat, the rack being placed beneath it, or in a curd cooler, which many cheesemakers use. Where there is no pressure employed, the curd is usually again cut into cubes, the pieces turned or changed in position, and still left to drain, this process being repeated if it be found necessary. During the whole of this work, however, the temperature of the curd should be maintained at as near 90° F. as possible until it be sufficiently ripe or mature for grinding in the curd mill.

It is almost needless to say that the process thus briefly described is one which permits of variations in practice, for there is no method which is really empirical, so long as the desired result is achieved in reasonable time—and it is important that the process should not take too long, for cheesemaking is at the best an industry which demands considerable attention and some anxiety from day to day. A mellow cheese of fine flavour cannot be produced unless sufficient acidity has been developed in the curd. If the whey contain 1 per cent. of acid when the curd is believed to be ready for grinding, good results may be anticipated; but the maker may be more confident if he be able to test the acidity of the curd and to find it equal to that which on other occasions has been followed by the production of fine cheese.

Grinding. In grinding, the pieces of curd after passing through the mill [36] should be of uniform size, but the work should be performed slowly, otherwise damage may occur owing to friction or squeezing. The mill should be simple and easily cleaned. The ground curd is subsequently weighed and spread in the vat or cooler for salting—the salt employed being at the rate of 2½ lb. per cwt. of cheese, and quite dry and fine. Where the cheese is intended for early sale, and is to ripen early in consequence, 2 lb. may be found sufficient. Under some systems, however, where the work is quickly performed, or where it is protracted, a smaller or still larger quantity of salt may be used. There is a greater loss of salt in the drainage from pressure when the curd contains a large quantity of whey than when it is comparatively dry. Salt not only acts as a preservative, but it influences the action of the rennet, while it slightly affects the flavour. After the salt has been thoroughly mixed with the curd, the latter is ready for placing in the mould or cheese hoop [37] in which it goes to press.

36. CURD GRINDING MILL AND CURD COOLER
(Pond & Son, Ltd., Blandford)

Pressing. When the curd is placed in the hoop for pressing, its temperature should be 70° F. If the heat be greater, it is liable to lose fat under pressure. The student of cheese-making should take a lesson in the process of clothing cheese for the vat, of vatting, and of putting to press, as well as in bandaging after pressure is complete, the shape and quality of the cheese depending largely upon these processes. When in the press, pressure must be applied until the whey runs; it is then gradually increased for two or three hours, and left until the following morning, when it is clothed with a clean cloth, returned to the press, and the pressure again increased. This practice is followed until the end of three days, when the cheese is removed, bandaged, labelled with the date of manufacture, and such details as are necessary for reference, and taken to the ripening-room.

37. PRESSED-CHEESE HOOP OR MOULD

38. CHEESE PRESS (T. Corbett, Shrewsbury)

Cheese Presses. The best cheese presses [38] are made of iron—light, strong, and capable of giving both progressive and continuous pressure. With progressive pressure alone a crust is formed on the outside of the cheese, while the whey within may be enclosed and thus prevent the production of fine texture. The ripening-room should be kept at 60° F. to 70° F.—preferably by the aid of hot water pipes which can be controlled, stoves being most undesirable. The cheeses should be placed on clean wooden shelves, systematically turned, and their places changed from time to time from a higher to a lower shelf or vice versâ.

The Ripening of Cheese. The ripening of cheese, apart from the question of the influence of acid, the temperature of the room, and the quality of the milk, depends upon daily care and examination. A system of cold curing has been discovered in America, and Drs. Babcock and Russell, of the Wisconsin Station, have shown that it is a success; but it is practically unknown in this country, and until British experts are in a position to practise and demonstrate the process with equal success to that which we now achieve, it will be well for the English maker to continue to follow a system under which the finest cheese in the world is produced.

During the ripening process the insoluble curd becomes soluble, and the richer the milk in fat the more rapid is the change. If, however, milk be skimmed, that change is protracted, and the larger the quantity of fat removed the longer the time required, until when made from milk perfectly skimmed, a ripe cheese is neither mellow nor perfectly soluble. Ripening is due to fermentation, the work of bacteria. As the acid, the product of the lactic ferment, is diminished, greater energy is displayed by the casein ferments which decompose the albuminoid matter and liberate ammonia, which neutralises the remaining acid, with the result that solubility rapidly follows.

Cheese Yield. The quantity of cheese made per gallon of milk depends chiefly upon the richness of the milk in fat. In the New York experiments with rich milk the yield of cheese per gallon averaged 1·23 lb. varying from ·97 lb. to 1·4 lb.; while the water retained in the cheese produced from a gallon of milk averaged ·47 lb., varying from ·32 to ·63 lb. The following facts were ascertained from these and other experiments conducted on a large scale:

1. In America the quantity of fat bears a uniform relationship to the quantity of casein both in milk and cheese.

2. When rich milk was used, the loss of fat was smaller per cent. than when the milk was of poorer quality.

3. The cheese produced per pound of fat is generally uniform.

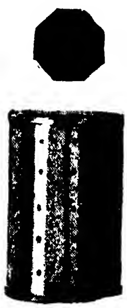
4. The weights of solids lost, and of solids recovered in making Cheddar cheese are almost identical.

Results of Experiments. Combining a large number of British and American experiments in Cheddar cheese production, we add the following highly important and closely-condensed results. It was found that the quantity of fat per pound of casein in cheese varied from 1·4 to 1·5 per cent.; that the loss of fat per 100 lb. of milk employed in making cheese varied from 6·3 per cent. in the case of extra rich milk to 10 per cent. in average factory milk; that the quantity of cheese produced per pound of fat in the milk varied from 2·67 to 2·75 per cent.; that the solid matter left in the whey for every 100 lb. or 10 gallons of milk used varied from 6·14 to 6·28 per cent.; and that the quantity of solid matter retained in the cheese from the same quantity of milk varied from 6·05 to 6·71 per cent. Approximately, therefore, the solid matter of the curd extracted from milk is about equal in weight to the solid matter left behind, chiefly sugar. Confirming this statement, we again point to the fact that the quantity of solid matter in the cheese for each pound of solid matter left in the whey varied from ·9 per cent. in the spring to 1·16 per cent. in October. The fat which was left in the whey per 100 lb. of milk varied from ·28 per cent. in June to ·42 per cent. in September, averaging about ·35 per cent.; while the quantity of casein and albumin left in the whey per 100 lb. of milk varied from ·64 per cent. in April to ·85 per cent. in October. When the milk contained from 3 to 3½ per cent. of fat, the fat left in the whey reached 9·5 per cent., while the cheese made reached only 9·1 lb. per 100 lb. of milk. As the milk increased in quality there was a systematic diminution of the loss of fat and increase of the cheese made, until the richest milk, containing 5 to 5½ per cent. of fat, lost only 6 per cent. of fat in the whey and made 13·6 lb. of cheese.

Some Practical Results in Cheddar Cheese Making. One of the best Scotch makers of Cheddar cheese, who supplied the writer with full details of his work for four years, for the conclusions of which we are able alone to find space, showed that when milking 100 cows the quantity of curd when ready for grinding practically averaged 1 lb. per gallon of milk, not reaching this figure in spring, but exceeding it in autumn. In this dairy 4 oz. of rennet are added to every 100 gallons of milk during the whole season, the curd being brought in 45 to 50 minutes, and heated to 98° F. in spring, the heat being gradually increased until it reaches 102° F. in September. Lastly, taking the results of many tests, it is found that the fat present in Cheddar cheese varies from 32 to 34½ per cent., and the solid matter from 62 to 64½ per cent.

Cheshire Cheese. Cheshire cheese, which closely resembles *Cheddar* cheese in appearance, except that usually it is coloured artificially, nevertheless differs in flavour and texture. It is made of three types: (1) the early ripening cheese, which possesses a stronger flavour, and contains more moisture, thus paying the producer a better price for his milk; (2) the medium cheese; (3) the long-keeping cheese. In the manufacture of Cheshire cheese the formation of acid is promoted by the addition of sour whey, usually 1 per cent., before the rennet is added for coagulation. The curd is cut larger in making the early ripening variety, while the whey is left in the vat longer. Less pressure, too, is applied, and the curd is not ground in the mill. In the manufacture of the medium type of Cheshire cheese the curd is cut finer than in the early ripening type; it is also ground, and subsequently placed in an oven when in the vat, or hoop, at a temperature of about 80° F., and not put to press until the following day, when it remains for some five days. In this case salt is used at the rate of 2½ per cent. In making the late-keeping cheese, coagulation lasts longer—some 60 minutes—while the curd is cut finer than in the medium variety, and subsequently ground, and when in the mould, or hoop, it is placed in the oven and submitted to a longer period of pressure. In Cheshire manufacture it is usual to increase the temperature of the scald from spring to autumn gradually. Cheshire cheese has a good market among the industrial population of Lancashire and the North, and by its production Cheshire farmers have become some of the most prosperous in the country.

Blue-veined Cheese. Unpressed cheeses, that are remarkable for the blue mould which runs in veins within them, are chiefly exemplified by *Stilton*, *Wensleydale*, *Gorgonzola*, and *Roquefort*. They are the production of pure milk, which should contain 4 per cent. of fat, milk of this character making a creamier, mellower, and heavier cheese. In the manufacture of Stilton and Gorgonzola the curd produced from the milk of two meals, morning and evening, is coagulated separately, and the curd subsequently mixed, although there are now many makers who produce Stilton from the curd of mixed milk instead of mixed curd. In Stilton manufacture the two curds are blended at about 60° F., while in making Gorgonzola the warm curd of the evening or morning is mixed with the cold curd of the previous milking. Two separate curds fail to cohere or unite like the curd of a single meal, with the result that interstices are formed, in which the blue fungus, *Penicillium glaucum* is enabled to grow. In the manufacture of Roquefort the growth of mould is encouraged by the addition to the curd of crumbs obtained from bread produced from barley and rye flour, upon which the fungus is already flourishing.



39. STILTON BOARD AND MOULD

Making Stilton Cheese. In making Stilton cheese the milk is allowed to stand hot from the cows until it has fallen to the required temperature, which varies from 82° F. to 90° F., the natural heat never being lost. Coagulation lasts 50 minutes, and when the curd is ready for removal it is taken in large slices and carefully laid in cheese-cloths, spread within shallow metal receptacles [41], where it gradually parts with its whey by gravitation. Subsequently, however, the four corners of the cloths are drawn together and loosely tied, the slight squeezing inducing the further drainage of the whey [32 and 33, page 4491]. Later, the corners are tightened slightly from time to time, as the maker finds necessary, the curd lying in the whey all the time. When drainage is sufficiently complete the whey is run off, and the curd, now comparatively solid, is laid in pieces in a vessel made for this purpose [41], and turned from time to time to assist it to mature; and it remains until the following morning, when, now soft and mellow, it is mixed with the curd produced from the milk of the previous evening, both lots having been broken into small pieces by hand and salted with fine dry salt at the rate of 2 per cent. By long exposure, the first curd has developed acid sufficient for the purpose of the maker. The mixed curd is next placed in cheese hoops, which are pierced with many holes [39 and 40], and taken to a warmer apartment, about 60° F., to induce it to drain. Here it remains, being turned from day to day, until it is fit to take out of the hoop, when it is bandaged with calico, each bandage being changed daily,

40. STILTON CHEESE DRAINING STAND, SHOWING DRAINING TUBE

until the coat or jacket-like crust begins to form on the outside, when it is once more removed, but to a cooler apartment, about 55° F., until the coat be fully formed. At this time change is again necessary, and it is removed to the ripening apartment, maintained at 60° F., which may be increased to 65° F. if it become necessary to hasten the ripening. Every cheese is turned daily and carefully examined, that it may be kept free from mites or flies, both of which should be excluded from the ripening apartments—an important feature in Stilton cheese manufacture. The ripening-room should be kept not only at an even temperature, but sufficiently moist to prevent the cheeses drying, and their consequent loss of weight and quality. From the beginning to the end of the process, the greatest possible care is needed to control the activity of bacteria, which are associated with dirt, and especially with unclean utensils. A large proportion of the Stilton cheese produced in England is spoiled as much from this cause as from want of knowledge of principles.

Gruyère. Gruyère, the leading cheese of Continental type so largely manufactured in France and Switzerland, where it is known as *Emmenthaler*, is to a large extent the product of milk delivered to factories by numbers of very small cowkeepers. The temperature for the coagulation of the curd is 95° F., while cutting begins in 30 minutes. After cutting, the curd is broken during the stirring process until it is about the size of a pea, when it is heated while in the whey to a temperature varying from 105° F. to 130° F. Salt is rubbed into the crust at the rate of $2\frac{1}{2}$ per cent. after the cheese is formed, it having previously been subjected to heavy pressure. In the process of ripening it is subjected to three temperatures, all of which should be under control—first to 60° F., then to 57° F., and finally to 52° F. The character and flavour of Gruyère is largely owing to the inoculation of the milk with the lactic ferment through the medium of sour whey. The eyes, or holes, of the cheese should be of medium size, bright, clean, and glazed, and the flavour should resemble that of a hazel nut.

41. STILTON CHEESE ROOM, SHOWING THE CURD IN THE VATS
From a photograph by Mr. Loudon Douglas

Soft Cheese. Cheeses of the soft or unpressed type are made for consumption in a white or fresh condition, or they are ripened by careful manipulation and subjection for some weeks to well-controlled temperatures. As we have already shown, fresh curd is insoluble; but whether a cheese be ripened while young and fresh or when some weeks old, it is practically soluble owing to the change which has been effected by the action of mould or bacteria, or both. The brick-shaped Yorkshire curd-cheese common to this country, like the fresh Coulommiers of France (which is now made and sold in England), are types of the white or fresh curd-cheese; while Brie and Camembert are examples of the finest varieties of ripened cheese. In the manufacture of fresh or white curd-cheese, the curd obtained at a given temperature and in a given time is removed carefully while still tender into the mould, which gives it its form, and from which it parts with its whey by gravitation. Moulds are now usually made of metal, and in some cases pierced with holes [42-44]. They are placed upon mats of clean, straight straws to facilitate drainage, and are turned from time to time that the whey may escape from both top and bottom. When drainage has been sufficient to give firmness to the young cheese the mould is removed, the cheese is salted on its various faces, and turned daily in an apartment kept at a given temperature until, in three or four days, it has become sufficiently mellow and has developed a delicate flavour, which qualifies it for the table. A fully-ripened cheese, on the contrary, although subjected to the first processes already named, is allowed to remain in the first of the ripening rooms, usually termed by the French the *drying-room*, until it is covered with a white, velvety down or fungus, which in most cases is succeeded by the blue fungus (*Penicillium*), the action of which is to neutralise the acidity of the curd, and in this way enable the casein ferments, or bacteria, to complete the work of ripening and converting the insoluble into soluble matter. It may be mentioned that as the mould grows upon the outside of the cheese, so ripening begins from the outside, proceeding towards the centre, which when reached becomes thin, and may cause the cheese to run. The reason is that the outside being first neutralised the bacteria there first become active.

Brie. A brief description of the process of the manufacture of the chief of all French cheeses must suffice as an example in this particular department of the cheesemaking industry. Brie is a creamy whole-milk cheese about 1 in. in thickness and varying from

8 in. to 12 in. in diameter. It is made in the famous Brie district near Paris, and realises, especially in the season, very high prices, which are lucrative to the farmer. The milk employed in the manufacture of Brie cheese alone, comparatively insignificant as it may appear to the British farmer, is quite equal to that produced by the whole of the cows of two of many of our English counties. It is probable that in all good Brie dairies the milk utilised in this way realises an average of 1s. a gallon, or probably 50 per cent. more than the average realised by leading British dairy farmers. The rennet is added to the milk at 82° F. to 86° F., the curd being ready in from two to four hours, according to custom. It should be tender, and very carefully placed within the double metal moulds which are employed in this industry. These moulds consist of two round hoops, which average 10 in. in diameter by 3½ in. in height, one fitting into the other, so that when the curd is drained sufficiently, and its surface has fallen below the bottom of the top hoop, this is removed, and it then becomes possible to turn the cheese. Each pair of moulds is placed on clean straw mats, upon which the maker lays the curd in thin slices for drainage, the temperature of the apartment being about 62° F. When ready for turning, a clean mat is placed on the top of the lower mould, and the cheese inverted, and, salt having been spread over the cheese on either side, this practice is continued from day to day in the drying-room, which is kept at a temperature of 65° F., until the outsides are covered with white mould. Turning, however, still continues until the blue mould appears, as it does at first in spots or buttons here and there. Gradually, however, the whole surface is covered with blue, and in the best managed dairies with isolated spots of vermilion. The cheeses are examined and turned daily until, in about six weeks, they are sufficiently ripe for the market.

General Points on Cheesemaking. Whatever the variety of cheese that is manufactured, the process involved is one which resembles those already described in its main characteristics. From what has been said already it will be remembered that the time of coagulation, and consequently the quantity of rennet employed and the temperature at which the milk is set, influence the process of drainage, the presence of acid, and the general condition of the curd Fine cutting facilitates drainage, and pressure reduces the quantity of moisture, and consequently of sugar, which, being in solution, remains in the cheese to a larger extent where the moisture retained is larger in quantity. It follows, too, that the temperature at which the cheese is exposed during ripening involves differences in the process of fermentation, and apparently also in flavour. The famous *Pont l'Évêque* cheese of France is produced from drier curd than the Brie or the Camembert, with the result that its flavour is entirely different, and, although science has not yet determined the point, it is more than probable that flavour, like consistence or texture, is in part governed by the quantitative relationship of the solid materials of which the cheese is composed—*i.e.*, the fat, the casein, the albumin, the sugar, and the mineral matter. Investigations have been made recently in the United States in the hope of determining the cause of the flavour of Camembert. It is believed, although no proof is yet forthcoming, that the vegetable organism *Oidium lactis*, which presents a creamy appearance on the surface of milk, but which below the surface closely resembles the cells of yeast, is to some extent responsible. We have, however, much to learn; but until properly substantiated facts are forthcoming, the cheesemaker will be well advised to follow the recognised processes of the day as practised by the most skilful and successful manufacturers.

THE BEST BOOKS ON DAIRYING

"The Dairy Farm." By J. Long. (Cazenove. 2s. 6d.)
"Practical Dairy Farming." By Prof. J. P. Sheldon. (Bell. 1s.)
"Elements of Dairy Farming." By J. Long. (Collins. 2s.)
"The Dairy." By J. Long and J. C. Morton. (Vinton. 2s. 6d.)
"The Book of the Dairy." Translated from Prof. W. Fleischmann. (Blackie. 10s. 6d.)
"The Farm and the Dairy." By Prof. J. P. Sheldon. (Bell. 2s. 6d.)
"Manual of Dairy Work." By James Muir. (Macmillan. 1s.)
"British Dairying." By J. P. Sheldon. (Lockwood. 2s. 6d.)
"Handbook for Farmers and Dairymen." By F. W. Woll (U.S.A.). (Chapman. 2s. 6d.)
"Practical Dairy Husbandry." By X. A. Willard. (Kegan Paul. 15s.)
"Economics in Dairy Farming." By E. Matthews. (Newnes. 7s. 6d.)
"Milk and Its Products; Nature and Qualities of Dairy Milk and the Manufacture of Butter and Cheese." By H. H. Wing. (Macmillan. 4s.)
"Milk: Its Nature and Composition." By C. M. Aikmann, M.A., D.Sc. (A. & C. Black. 3s. 6d.)
"Milk, Cheese, and Butter." By J. Oliver. (Lockwood. 7s. 6d.)
"Cheese and Cheese Making, Butter and Milk." With Special Reference to Continental Fancy Varieties. By James Long and John Benson. (Chapman Hall. 3s. 6d.)
"Cheese and Butter Making." By J. Oliver and M. Barron. (Bemrose. 1s.)
"Dairy Bacteriology." Translated from Dr. Ed. Von Frendenreich. (Methuen. 2s. 6d.)
"Principles of Modern Dairy Practice, from a Bacteriological Point of View." Translated from G. Grotenfelt (U.S.A.). (Chapman. 10s. 6d.)
"Dairy Chemistry." By H. D. Richmond. (Griffin. 16s.)

HOW TO WRITE

Continued from page 4431

The Use of Words. "Style." The Only Way to Write is to Write Naturally. The Only Good Style is to be Unconscious of Style. Helpfulness of Reading

By ARTHUR MEE

IT is one of the mysteries of things that half the quarrels in the world, half the time of Parliaments and Law Courts, half the misunderstandings and confusions of private and public life, arise from the inability of men to say clearly what they mean. It could be proved, perhaps, that half the time and energy of the world is spent in explaining the meaning of words.

There need be no apology, therefore, for pausing in our study of journalism to consider the use of words. It would seem, at first sight, that nothing could well be simpler; yet the experience of men in all times and in all ages has proved that nothing could well be more difficult. The meaning of a word may be perfectly clear, so clear that, standing alone, it cannot by any process of argument be made to possess any other meaning; yet that word, placed in a sentence, may divide parties in the State and involve the time of judges and juries through weary months and years. It may be said that if language had been a rigid thing of geometrical exactness, if words had been things like locks and keys, fitting one place and no other, the whole world would have been different, and the history of the human race would have lost more than half its bitterness.

Say What You Mean. It is one of the first duties of the journalist to realise that words are fearful things; that the proper use of them is perhaps the most delicate art in which men can engage. "Say what you mean" is a counsel that might well be printed in letters of gold across the journalist's horizon. It is the work of the journalist to say what he means, and to say it so that, as Dr. George Macdonald says, it may not be mistaken for what he does not mean. Journalism has no room for the man who cannot say that two and two make four without creating some confusion as to whether they do not really make five. The man whose mental temperament will not allow him to say that a spade is a spade should be a lawyer or a quack politician rather than a journalist.

He need not trouble about "style." Style, like happiness, is not to be found by looking for it. Nobody can create it for him. It is not a thing that he himself can make. It will *come*, born of his genius, of the very nature of him. He can no more invent a style of writing than he can invent a style of talking, and his style of talking, unless he would make himself ridiculous, is that created for him by a greater power than he can contradict. The best answer that can be made to the young man who asks how to write can be put in a word: he should write naturally.

The Books that Help Us. That does not mean, of course, that he need not train himself to write, any more than to say that a man should live naturally means that he need not choose good food. We may carry the simile farther and say that, just as the man who eats well is likely to live well, so the man who reads well is likely to write well. Though a man's style must come of itself, he may prepare himself for it by a careful reading of books. It may be questioned, perhaps, whether his reading need even be "careful." It is probably true that a free and simple style comes most naturally and easily from a miscellaneous and unregulated kind of reading. In any case his reading should be wide in choice of author and subject, and should be sympathetic. It is a wise rule never to read anything as a duty; to put a book down the moment it ceases to interest. The books that help us are the books that *possess us* as we read them; the books we pick up eagerly and are loth to put down.

It does not follow that the books that interest us most will help us to write best. It is conceivable that a man may be held as in a trance by a story which may have no good writing in it. But we remember that we are writing here for the young man who is fitted for journalism, whose tastes will lead him naturally to the right books. He may be safely advised, at first at any rate, to leave alone books that have a "style." Somebody has told us of a brilliant man of letters who ruined his style and immensely lessened his influence because in his youth he was an enthusiastic admirer of Carlyle, and formed his style on Carlyle's; and it is probably a familiar case in the tragedy of letters.

The Journalist's Reading. The young writer will do well to read books which, by their simple language, have commended themselves to the mass of mankind. After all, it is the best test. The journalist who would be as a John the Baptist writing in the wilderness may choose his own way; the man who writes to be understanded of the people will choose the way of those writers who have reached the people's heart.

He will become familiar with Tennyson and Ruskin, and he will find no more helpful examples of the way in which our language can be tuned to music. He will be fond, very fond, of poetry. The English poets, said Robert Buchanan, were "his best and only guides," and a love of poetry is of inestimable value in learning how to write. He will take Mr. Birrell's advice, and never let a day pass without reading a really good bit of English—"an essay by Addison or Arnold, a sermon by Newman or Spurgeon, one of Cobbett's Rural Rides, or a letter of Cowper's." He will read fine passages

again and again, read them aloud whenever he can, and if he has not a natural ear for the music of words he will turn aside from letters before he adds one more name to the long sad list of men who have failed.

The Natural Gift of Writing. There is not a day on which some letters do not pass through the post asking an editor for advice on how to write. Too often, alas, they bear stamped on their face the certain evidence that no advice would be of any use. It is remarkable that there should be in the world intelligent people who imagine that a man may be taught to write exactly as he is taught to make a table. It is true, of course, that no man can write unless he has the gift within him. That is a gift which, however much it may be cultivated, can never be acquired entirely from without; can never be learned, that is, unless the instinct is implanted in the mind. An appreciation of this truth will save much disappointment. It is, perhaps, too much to say that writers are born, not made, but to some extent at least this is true. It is possible to take a man utterly ignorant of mathematics and make him an accountant; it is possible to take a man knowing nothing of mechanics and make him a capable engineer. But it is not possible to take a man with nothing in him of the genius of art or of language and make him a painter or a writer. The difference is the whole difference between acquired and natural faculties, and to this extent it may be perfectly true to say that writing is a natural gift.

Writing and Speaking. It does not, of course, follow that all who are naturally endowed with this gift know how to use it. They must still discover for themselves the poetry of language, the subtle way of conveying thoughts through words. They must still drink into their souls the spirit of great books. They must still learn the mystery of putting themselves—mind, heart, and soul—into the thing they write; of letting their pen be, as it were, the lens through which their thoughts fix themselves clearly and indelibly upon the sensitive mind of him who reads. It is a high ideal, which is not always present when we write, but it is this way that great writing lies.

No rules can make a writer, but the experience of many writers may help him. Perhaps the truest thing that can be said about good writing is that it is unconscious. We use words lightly in talking, not always realising their effect; but how infinitely more weighty is the word that is written! Yet the good writer is he who, conscious of the weight of words, still writes as freely as he talks, who writes as if he were talking, who sends his thoughts direct from mind to mind across space and time as across a table. It is the natural thing said in the natural way that makes up literature. The best letter writer is the man who writes to his friend as he would talk to him face to face; the best letters are those in which we can almost hear a voice, in which we can almost see a soul.

The young writer will hear much of the criticism that "that is all very well to *say*, but you must not *write* it." It is, of course, perfectly good criticism sometimes, but in the main he need not pay much attention to it. There is no essential difference between the language that is spoken and the language that is written, and those who set up such a distinction are generally to be found among writers who have no conception of freedom in writing, and whose style is portentous and awful beyond reading.

Journalese, the Unpardonable Style. The stilted and formal use of words is of all things most to be avoided. A word out of place is like a discord in music. A stilted style is like a bad tune. It is easy to fall into the appalling style of writing which we call journalese. It is far too common in newspapers and magazines, and even in books. It is the hall-mark of mediocrity. Its worst feature is the continual use of mild adjectives which have no meaning, of set phrases of which we are weary; the saying of things that mean nothing at all, and the dragging in of familiar quotations. A small vocabulary learnt by rote, a few stock phrases and quotations, are all the capital the journalese bore needs. If he is a reporter he speaks of the "lurid glow in the sky" at a fire, and of the "progress of the devouring element" being arrested when the fire is put out; at a wedding he tells us that the "bride won golden opinions," and was "the cynosure of all eyes." If a leader writer, he calls upon us to "read, mark, learn, and inwardly digest" his opinions; he "indulges in a few reflections," and "inclines towards" a particular view.

And it is not only in newspapers that we are bored to death by characterless writing which is a mere putting together of platitudes and phrases. Hundreds of books appear every year of which the publishers ought to be heartily ashamed. A book we have just read, with a large circulation and by a capable writer, is full of such phrases as *and which*, wrongly used in almost every case; and *different to* is almost as common among writers as among speakers. But even these things are more pardonable than the persistent and annoying use of colourless phrases and the painful searching after little-known words.

The Use of Simple Words. Nothing can be worse for a man who must earn his living by writing than to give those who read the impression that he paused once at least in every paragraph to look up the dictionary. There are men who use the right word instinctively but who, by sheer perversity of "style," will change it for another. They judge the value of their writing, apparently, by the obscurity of their words. If they think of a word which only one in ten can understand, they use it in preference to a word which nine in ten will understand, and think their achievement clever. It is as clever as the trick of the sign-writer who puts a letter upside down to attract attention to a quack medicine advertisement outside a chemist's shop.

The young writer will set himself sternly against these things. He will never use a hard word where an easy one will do. "All distinguished poetry," says Emerson, "is written in the

oldest and simplest English words"; and it is not less true of prose. Long experience has given editors certain rough-and-ready guides in forming estimates of a man's writing almost at a glance, and, though these are difficult to define, they have to do largely with such things as we are now considering.

The great aim of writing is to express meaning clearly and quickly, and the ideal article has not a wasted word in it. An excellent rule is to use always short words and short sentences, and there should be no striving for phrases and scraps of foreign languages. "There is nothing which can be said at all," says Mr. Christie Murray, "which cannot be said in English"; and nearly everybody will agree with him.

The Best English. There should be no ugly words, no jarring ends of sentences. Nor need the writer be afraid of repetition. There is a pernicious doctrine that repetition is bad, and good writers are found who would rather not write about a village than use "village" twice in the same paragraph. Any synonym rather than that; and, ransacking their minds for other ways of saying what they mean, they write hamlet, locality, district, neighbourhood, community, collection of houses. Let us make up our minds that when we want to say village it is bad English to say anything else, and that it may be perfectly right and good—as, of course, it *may be* wrong and bad—to use the same word in the same sentence half a dozen times.

It is not the good ear for words or the pure love of good English that condemns repetition, but a petty fastidiousness. "Nothing," says Mr. H. G. Wells, "could be more alien to the spirit of contemporary prose than for a writer to dodge among imperfect synonyms to avoid saying what he has and wants to say." It is this fear of using the word we mean whenever we mean it that has largely brought about the habit of saying *commence* when we mean *begin.* There is not the slightest excuse, save in very exceptional circumstances, for *commence.* It is condemned by the fundamental principle of good writing that a pure English word should always be used in preference to a foreign word; it is condemned, too, by that other principle of good writing that the short, direct word is always best. There is something much nearer to the origin of things in *begin* than in *commence. Begin* is much the prettier word. In the book of purest English in the world, the Bible, *commence* is not once used, though there are nearly a hundred *begins,* and one shudders to think how some modern writers would have destroyed one of the most beautiful phrases in all language, and begun the Bible with *In the commencement God.*

The Awkward Way of Saying Things. The importance of cultivating the practice of writing in short, clear-cut sentences can hardly be overstated. A good journalist never writes "yesterday evening" for "last night"; never speaks of an "electrically-drawn train" when "electric train" will do. He has found that the best writing is that which contains not only the fewest possible words but the fewest possible syllables.

It is possible to begin a sentence at the wrong end and still obey all the laws of grammar; but the writer who does that obeys the laws of grammar by disobeying laws of much greater importance. He might say "With the greatest optimism the man was inspired; the bridge was built by him all difficulties notwithstanding." We should know what he meant, but we should know it much sooner if he said "The man was inspired with the greatest optimism. He built the bridge in spite of all difficulties." The writer is telling us something about a man, and it is simply bad construction to tell us what that something is before the man is in our mind. The awkward habit of beginning at the wrong end is the enemy of smooth, facile writing. It destroys the music of language and the natural flow of phrases, and it recalls that worst of all habits—the attempt to force a style which will not come, for nobody speaks like that; nobody says "An up-hill one was his task." Even the man who wrote that would say in conversation "His task was an up-hill one."

It is the danger of studying style that it may produce a conscious style in the student, and nothing could well be worse. There are exceptions to all rules, and there are cases of men who have achieved a reputation by creating a purely artificial style of their own. There are successful writers who write in a manner which has become easy to them only after long effort. But we can never call their writing natural, and the mere fact that an artificial style has succeeded in rare cases is no argument in favour of forcing a style of one's own. The thing which is laboriously written, in which, as we read, we can almost feel the laborious effort of the writer to express himself, is not the kind of writing of which great literature is made. Thought expresses itself best and lives longest in a simple setting.

Grammar should be Used, not Worshipped. But, when all is said that can be said, the best advice as to how to write is that we should write without any consciousness of style at all. Words are the vehicles of thought, and the grammar of words is the science of expression. Grammar, however, is a tool, and not a master, and the writer will find that at times his rigid tool is imperfect and in the way. He must not destroy his freedom of expression, or interfere with the natural way of saying what he has to say, through a slavish devotion to a rule of grammar. He will find at times that euphony is of more importance than grammar, and will not allow the second best to destroy the best. Just as the painter must paint things incorrectly at times that we may see them as they are, so the writer must write incorrectly at times in order that we may read him as we should. Grammar is to be used, not worshipped, and though the freedom to ignore it is a very delicate licence that we may give ourselves, there are times when we may use the licence without any fear for our reputation. That, indeed, is perhaps only one more way of saying what we have been saying all along—that there are no perfect rules of writing

anywhere. It has all been put excellently well by Allingham, the Irish poet:

Not like Homer would I write,
Not like Dante if I might,
Not like Shakespeare at his best,
Not like Goethe or the rest;
Like myself, however small,
Like myself, or not at all.

Know More than You Say. We shall come to consider in due course the business of the journalist as a contributor to the magazines, but we may consider very briefly here, perhaps, the method of preparing an article. It is of the first importance that the writer should understand his subject thoroughly. A little knowledge, it is said, is a dangerous thing, and it is dangerous enough when the man with a little knowledge mistakes himself for an expert. But it is the journalist's business to have a little knowledge of many things, and it need not be dangerous unless he makes it so. His little knowledge must be used to lead him to sources of greater knowledge. We have already discussed the importance of his being able to master facts quickly, and to enter readily into any subject. He must have the gift of engrossing himself in his subject, of knowing all that he can know about it while he is writing. He should be as interested in an article as if it were a book; he should take as much pains with the one as with the other. He should make it a rule to know twice as much as he can say about his subject. Nothing is ever lost by thoroughness. Nothing ever known is wasted. The man who writes with the fulness of knowledge writes all the better for knowing many things which he need not tell.

Preparing an Article. Let us consider the genesis of an article. A journalist was called upon to write three columns for an important London morning paper, and had six hours in which to prepare his copy. He took up a little book just published on the life of a famous statesman, and went to his library. He found a strong human note in the book which appealed to him. He made up his mind to tell the moving story of this man's life. The journalist looked up his library index, skipped through two or three other lives of the statesman, dipped into the lives of two or three contemporaries and histories of the time, found a remarkable anecdote almost unknown in a book of gossip, looked up opinions and impressions of the statesman's work and character, and glanced rapidly through a history of the most important transaction in which he was engaged. It took him perhaps two hours to make his notes, but in the end he was stirred by the story in which he had lived for those two hours, and he sat down and wrote his article *with hardly a single reference to his notes.*

The lesson to be gathered from this is plain. The writer's thorough preparation for his work, the research and the making of his notes, made him so intimate and sympathetic with his subject that the writing became a labour of love.

Put Your Facts in Order. The journalist must always be prepared for research of the most thorough kind, and must have the means for this at hand. Once he is master of his facts his work is easy. The rest, perhaps, is not so easy as Robert Louis Stevenson would have us believe. "If," said he, "a man has every word and every sentence and every subject in the right order, and has no other gift, he will be a great writer," even though his clauses are unmusical and his words colourless and ineffective. That is a remarkable statement which it is difficult to accept as the deliberate opinion of a great writer, but it serves, at any rate, to emphasise the importance of having our facts in order. And not our facts only, but our thoughts and ideas, for ideas as well as words must harmonise and hang together. It is well to read a sentence aloud; reading aloud, indeed, is excellent training for any writer. One of the chief values of dictation is that it enables us to appreciate the sound of our phrases.

One thing the writer of an article should never forget. He should assume that his reader knows nothing of the subject on which he is writing. There are, of course, the most obvious exceptions to this rule. If the journalist is writing, for instance, in the LANCET, the rule clearly does not apply. It would be impertinent for a writer in the LANCET to assume, say, that his reader did not understand physiology, and to waste time in describing the simple anatomy of the body. But we are speaking of general journalism, of papers and books which make a universal appeal, and not of papers catering for select publics. In general journalism, that journalist will succeed best who appeals most strongly to the mind of his simplest reader.

The Journalist's Duty to His Readers. But we must guard ourselves very carefully here against misunderstanding. The writer in a newspaper is in the position of a man, let us say an artist, who is taking part in a conversation with, say, half a dozen people who have come together promiscuously, without any interest in common. Let us suppose that the artist is interested in the question of the weight of the earth. If he raises the subject in conversation, he owes it to all six to make what he has to say interesting to them all. But among the six is a scientist who knows more than the artist himself about the weight of the earth, and a clerk who knows nothing at all about it; and here his difficulty begins. If he addresses himself to the scientist he will probably be unintelligible to the clerk. If he addresses himself to the clerk, he may be uninteresting to the scientist. What he should do is to interest the clerk at once by explaining the matter briefly and clearly, and proceed to discuss the matter in such a way that the clerk will be able to follow him, while the scientist will listen because, though the facts may not be new to him, they will be stated so clearly and firmly that they may confirm him in some point, and the discussion of them may bring a new light to bear upon them. If, in all he has to say, the artist has in his mind the fact that the clerk knows nothing and the scientist knows everything, he is likely to appeal to them both and to interest the other members of the party whose knowledge of the subject is of varying degrees between the two.

The Readers of an Article. It is the same with the journalist. He will not, of course, be able to interest all the people all the time in all that he writes. Not even Shakespeare could do that. The man who writes a short article in a popular paper on the composition of the stars must not expect that Sir Robert Ball will turn eagerly to it and become engrossed in it. But the consciousness of this need not blind him to the fact that millions of readers know nothing at all about the composition of the stars, and that, though he cannot reach these millions, he will reach a public in which a large number know nothing at all about the stars, in which a small number have a vague interest in them, and in which a smaller number still are as interested as he is, and know as much as he knows about the subject on which he is writing. And he must set himself to write in such a way that the large number who know nothing about the stars may be attracted to the subject, that the small number who know something may read to learn more, while those who know all about it will read for the mere interest of reading on a subject they have made their own.

The Man Who Knows Too Much. The good journalist learns to write for the man who does not know in such an interesting way that the man who does know reads without in the least resenting the carefully hidden assumption of ignorance. It is because this aspect of writing is so important that an editor rarely asks an expert to write if he can get a layman, and the experience of editors has proved abundantly that nine times out of ten the amateur is much more likely to write a good article than the expert. It seems almost impossible for an expert to understand that there are people who do not know as much as he knows, or that some people know nothing at all. It may be argued, indeed, that the man who knows least about a subject, assuming that he is a good journalist, is the best man to write about it. He brings himself in touch with a fresh side of things; he puts an enthusiasm born of new knowledge into his work; most important of all, he puts the matter as it appeals to the mind of the average man, and it is for the average man that papers are produced.

We are not dealing with expert papers, where experts are not only desirable but indispensable, but it is true of general journalism that where the expert interests ten the ordinary journalist will interest a thousand, and an appreciation of this will help the journalist to make his appeal to the widest public. It is for him to gather all the fish that he can into his net, and to strike at once a note of keen and general interest. There is a story of an old preacher, hundreds of years ago, who startled his congregation by beginning "There was once a woman who brought forth 600,000 men at a birth." His congregation became alert, and the preacher was sure of their interest as he proceeded to tell them of the birth of Moses, "who was equal in himself to 600,000 men." That witty preacher had mastered one of the secrets of journalism. He attracted his audience, and the rest was easy.

The Value of Feeling in Writing. The young journalist will be well advised to write at first about subjects he knows intimately, always assuming that he does not cease to be a journalist and become an expert. The danger of the expert, who usually writes in a manner quite unintelligible to ordinary people, is not, however, very real in the case of the journalist, whose intimate knowledge of his subject is balanced by his equally intimate knowledge of his public. So that the danger of knowing too much about a subject does not exist for the man who is at heart a journalist, and the advantage of knowing all that he can is difficult to exaggerate. If the subject is something about which he feels strongly he will find it all the easier to express himself, and will be able to say what he has to say with feeling and force.

It can hardly be said too often that earnestness is more than half of a good style, and the man who is interested in serious things and writes about them interestingly is not likely to fail for want of readers. It is the habit of writing about trivial things as if they were important, of trying to force an interest in a subject without any inherent interest of its own, that is responsible for much of the mechanical writing in newspapers and magazines. There is a kind of article, to be found in many of the popular penny weeklies, which bores one by its everlasting sameness and its utter lack of interest or importance. It tells us how many cows' tails would reach to the moon, or how many halfpennies would cover the earth, or some other pointless thing without reason or interest or imagination. The journalist whose misfortune it may be to have to write these inanities for a living may be greatly pitied. He will find that the habit tells against originality and vigour of expression, and produces merely a weaver of ingenious calculations, with a useless capacity for spinning and twisting hackneyed words and phrases.

The Best Training. Newspaper journalism is perhaps the best of all trainings for a writer in any sphere. The journalist is called upon to write on all sorts of subjects in great haste, and he develops a facility for arranging his facts and interpreting their significance and their relation to each other which becomes invaluable. He learns the value of not overloading a sentence with thought, of not alienating attention from one point by dwelling too much on another. He discovers that his best work is usually that which is done most quickly. We may take it as a main rule that the best writing in our newspapers is done at high pressure, when moments are precious and printers are waiting, when the journalist sets down his impressions, with the first glow of his enthusiasm still upon him, so rapidly that he is barely conscious of the form in which he is setting them. It is then that the journalist puts his nerves into his work, and writes a thing which he himself has pleasure in reading when he opens his paper the next morning.

SOME VARIETIES OF TOOLS

Machine Cutters. Files. Grinding Wheels. Shearing, Detrusive, and Percussive Tools. Moulding Tools. Tools that Operate by Leverage

By JOSEPH G. HORNER

Rotary Machine Cutters for Wood. The saws may be regarded as the roughing or breaking-down tools of the woodworker. For finishing and imparting all shapes required to timber, the tools used embrace knives and moulding cutters of many forms. These owe their efficiency to the very high speed at which they run. The exceptions are the broad shaving knives used in planing broad surfaces, operating precisely as a carpenter's plane does, and removing similar shavings, only wider and thicker. The thin wood for boxes is generally planed thus in a suitable machine. The method of mounting rotary cutters is to bolt four usually on the flat faces of a four-side block, termed a *cutter-block*. This being rotated at a high speed, the cutters remove the material rapidly. The largest of these are employed for planing flat boards in machines of various designs. As they are often as much as 2 ft. wide, the power required is great—two to three horse-power for a small machine. Hence some blocks are fitted with knives to arrange spirally to give a shearing cut, or one in detail, which lessens the strain. Figs. **55** to **57** illustrate knives and blocks.

The knives and cutters used in wood-working machinery are sometimes scraping and sometimes true cutting tools. The spiral or shearing cut given in many cases, as in metal-cutting tools, ensures sweet working. Planer knives and moulding cutters are formed with a bevel, as seen in **55** and **56**, and the cutting is done by the junction of the bevel with the front flat face, the latter leading, as shown in **57**, which is an end view of a cylinder or cutter-block. In the *milled* cutters, or bits, the form is imparted by milling into the face of the steel, instead of on the edge, and they are set as indicated in **57** B, with the bevel the reverse way to ordinary cutters. In each case there is some top rake given by the setting on the cutter-block, as seen by the radial dotted line drawn in each example. The milled bits are sharpened by grinding the bevelled face, which does not alter the profile, nor does it reduce the thickness of the cutters. The ordinary cutters are ground on the back, and so get thinner each time. The cutters in **57** A are held by tee-headed bolts passing through slots into tee-grooves in the block; another method is that at B, where vee-clamps are made to embrace the bevelled edges of the cutters, and hold them firmly.

Circular cutters, which bear a certain resemblance to milling cutters for metal, are made with two or more edges, shaped to any profile which has to be moulded. Top rake is given. A few sections are shown in **58** of cutters having ten cutting edges, on five teeth, which permits of reversibility of rotation. There is practically no limit to the shapes which may be moulded. Grinding is done in the grooves between the edges.

Files. Files are not true cutting tools. The teeth faces are always set back slightly from the perpendicular [**59** A, B—A being a hand-cut, B the same after sand blasting]. These tools are divisible into two main classes, the *float* or *single-cut*, and the *double-cut*. In the first-named, C, the cuts are made in one direction only, diagonally across the file, so that the scraping action is continuous right across. In the second, D, the lines cut across each other at definite angles, and the action is effected by multitudes of isolated points. The first-named are used more for wood and for soft materials, the latter for metal. But for sharpening saws, single-cut files are often used, being an exception to the above rule.

The teeth of files vary in size from the *coarse* to the *fine*, the terms being relative, since the coarse teeth of one file do not correspond in pitch with the coarse teeth of another of different length, being regulated by the size of the file itself. The use of the rough file should always precede that of the finer ones, in order to economise time. A *rasp cut*, E, is a file in which alternate points take the place of rows of teeth. It is used only on comparatively fragile materials, as wood, horn, cores, breadcrusts, etc.

By virtue of the sectional forms of files they are able to produce numerous outlines—flats, curves, and combinations of the same. The file section is a counterpart of the shape produced, sometimes absolutely, but often only approximately, hence the large number of shapes in which files occur. There are about 3,000 different files made, if we include all sizes made in all types. The importance of the file in some classes of work cannot be exaggerated, notwithstanding that its functions have been invaded largely by the work of machine tools. The principal file sections are shown grouped in **60**, according to their mutual relationships. The principal longitudinal shapes are seen in **61**.

Sections of Files. In **60** we have sections which are related to the first in each row, the square, A, and the circle, P. A is termed a *square* file, B to D are rectangles, differently named, according to proportions; the *pillar* B a thick file, the *flat* C thinner, the *mill* D thinner again, and the *warding* file E very thin, used by locksmiths and in fine fitting generally. These are cut on all four edges, excepting in the *safe-edge files* in which one edge is left smooth, which is often convenient. The sections F to J are those of flat files which have special names, according to the form of the edges; F and G, with the

bevelled edges, are *swaged reaper* files. H and J are the *topping* files and the *mill* files respectively, used for sharpening and gulleting mill saws. The foregoing have parallel faces, but succeeding ones have not. These are the *reaper* file, K, the *knife*, L, both having the sections of truncated pyramids, the *triangular* or the *three-square*, M, of equilateral section, and the *cant* file, N. Two triangles combined, O, form the *slitting* or *feather-edged* file.

A file of cylindrical section is termed the *round*, P; succeeding figures show forms related to it. Q, semicircular in section, is a *pitsaw* or *frame* file, because used primarily by sawyers for gulleting and sharpening various saws; R, the *half round* is less than a semicircle; S, T, the *cabinet* files, are very flat half rounds, and U, having its faces of opposite but unequal curvatures, is a *crossing* file; and one with equal curvatures, V, is a *tumbler* file.

Longitudinal Forms of Files. Other terms are those derived from the longitudinal outlines of files. In the group 61, A is a *parallel* or *blunt* file. But it is not perfectly parallel, to which form the term *dead parallel* is applied, the blank for which is produced by machining. Absolute truth is, however, not very necessary in a file, since results depend greatly on how it is manipulated, and if very accurate results are desired they must be produced by scraping. What is termed an *equalling* file is one that has a very slight amount of longitudinal curvature. The *reaper* files are parallel. The *knife reaper*, B, has a handle forged on, instead of the tang usual in the files. If a file has much curvature it is *bellied*, C. Files that are termed *tapered* are bellied also, as the *square* file, D, and the *triangular*, F. E is the *parallel three-square* file. Half-round and cognate forms are also tapered or bellied, G, and parallel, H; so are the round sections, the *rat tail*, J, a tapered form, and the *parallel*, K. L is a file or rasp used by cabinet-makers, and termed a *riffler*. It is handled in the middle. The forms of rasps follow nearly those of files.

Grinding Wheels. These include natural or artificial grindstones, and wheels of emery, corundum, or carborundum, etc. The action of each particle is incisive though minute, and the total action is similar to that of the cutting tools in regard to the quantity of material removed and the accuracy of results. The grains in wheels of emery and allied substances are cemented in various ways, so that the cement does not dissolve in water, and the wheels are moulded and pressed into numerous shapes and consolidated so effectually that they run safely at surface speeds of 5,000 ft. per minute. The action of an emery wheel has been likened to that of a file a mile long moved over that distance in a minute. Hence, though each grain removes a merely infinitesimal quantity of material, the total results are such as to come into rivalry with those produced by the ordinary cutting tools.

The forms in which wheels are chiefly used are the *disc*, operating by the periphery, and the

cup, by the edge, and each in several modifications and in a large range of dimensions. Wheels are used wet or dry.

Work Suitable for Grinding. Grinding wheels cannot be relied on to produce accurate profiles on repetition work, like form-milling cutters; but there are nevertheless a number of profiled shapes which are used for various straight and curved portions, especially in tool grinding operations, where the change in form is not sufficient to affect the results. The plain disc wheel shape, **62** A, is used more than any other; the profiled types include those of bevelled forms, B, C, and D, employed for work where the square edges of A could not be got in confined situations. These are used especially for cutter and saw sharpening. Curved outlines, E and F, are also used extensively. The sectional appearance of a disc wheel is indicated at G, showing the central bushing of lead. Wheels of this type may be several inches wide, or as thin as $\frac{1}{16}$ in., and vary in diameter from several feet to a fraction of an inch, in the tiny bush grinding rolls. Recessing, H, is often done in order to grind up to shoulders on cylindrical work, without fouling. Wheels are dished also, J, to overhang their spindles inwards, and so to lie more in line with the bearing of the spindle, a point which tends to obviate vibration. The same result is attained by dishing the wheel discs, as at K, which shows the end of a grinding head for a universal machine. Other dishings, L and M, are made to enable the wheel to reach out and operate on narrow edges of milling cutters, etc., grinding with the faces. This leads up to the cup wheels, N and O, which also grind by their narrow faces, the idea being that the speed of the wheel remains constant until it is worn out, whereas in the disc types, grinding by their edges, the diameter is constantly being reduced, and the speed of the wheel must be increased accordingly to obtain the proper efficiency.

Shearing Tools and Shearing Action. When two cutting blades are placed in opposition so that the face of one is in the same plane as the face of the other, the method of severance is termed shearing [**63** A]. The action is a truly cutting one, although the tool angles may be very thick, or from 80° to 85°. The action of the common scissors is identical, though the cutting angles are much less. The coincidence of the faces is essential to shearing, because if they were not, the material would be bent instead of cut, due to the lack of adequate support, as indicated at B. In the wire nippers, and in nippers for thin sheet metal, the cutting edges are in the same plane but do not pass each other, C. Strictly these are not shears, but chisels used in a particular way.

In the work of the engineer's boiler and plating shops, in bridge and girder construction, in the sheet metal work of the tinsmith and coppersmith, the shears in some form or another are in constant use. An inch thickness of steel is severed as readily as a tin plate, and as rapidly. It is only a question of strength and temper of blades, and stiffness of machines. The only alternative is the saw, either hot or cold.

The Shearing Cut. A *shearing cut* is not necessarily the same thing as cutting by shears. It signifies a cut taken in detail—that is, the act of severance does not occur along the entire edge of the tool simultaneously, but gradually from one end to the other, D, which indicates the longitudinal position of shear blades. Most shears for heavy metalwork embody this action. It takes place in the common scissors. Its importance can hardly be overrated. Some operations would not be practicable without it. Familiar instances are the shearing of thick plates of several feet in width, the cutting of profiled forms with diagonal edged form tools operated in the cross-slide of a turret lathe, the spiral teeth on wide milling cutters, the action of the Fox trimmer for woodworking, the skewing of the iron of a rebate plane, and that of many roughing tools for metal-turning and planing. Even in the plane there is a shearing cut. The slight convexity imparted to the edge is a true example of this kind, and the difference in the quantity of material removed by a well-rounded jack plane iron and a straight trying plane iron is well known in the economies of roughing down.

Detrusive Tools. Practically these are restricted to the punches, though shears are as truly detrusive in action as the punches are. In fact, if we consider a punch as a shear blade in cylindrical form, the analogy is perfect, for the punch is tapered upwards to give clearance. And if a spiral punch [**63** E] is taken and supposed to be unrolled, we have a shear blade with a shearing cut. Fig. **64** shows the common punch, A, in the act of penetrating a plate. It has no front rake, and therefore the operation is absolutely detrusive, whereas in the spiral punch [**63** E] there is a true shearing cut. The stress of punching is very severe, the metal of the *burr* or punching being partly squeezed into the mass surrounding. Support is necessary, which is afforded by the bolster, B, the hole in which is only very slightly larger than the punch for precisely similar reasons stated in connection with A and B, in **63**. The taper of the punch upwards is its clearance, to prevent sticking in the hole, and to help the severance, and the taper downwards in B gives freedom of escape for the burr.

Percussive Tools. These constitute a very large group which includes the hand hammers and mallets, the power hammers, and caulking tools. The hammers alone include some scores of distinct shapes, and most of them occur in numerous sizes. They may be classed best according to the trades in which they are employed, as woodworkers, engineers, smiths, coppersmiths, tinsmiths, coopers, etc. To illustrate these would occupy too much space, therefore a very few typical ones are shown.

The obvious function of a hammer is to strike a blow, hence the reason of the leverage afforded by the handle, which is short when manipulated with one hand; long when swung by both hands. The size and weight of the heads vary also in hand hammers and sledge-hammers, but the shapes of the faces which terminate the

heads is determined by the character of the work to be done, as are also the proportions and shapes longitudinally. Thus, hammers have flat faces—*flat pane;* or globular ends—*ball pane*, or narrow convex ends.

Hammers. The commonest hammers used by woodworkers are the Exeter [65] A, and the joiners, B, the latter being commonly employed by many trades, but in different proportions of length to size of body. The narrow cross plane is of value for driving nails in narrow spaces. C to E are the typical engineers' hammers; C the *cross pane*, D the *straight*, or *long pane*, and E the *ball pane*. They are often termed bench hammers, because used so much at the vice bench. But machinists and many other metal-workers also use them. F to J are the typical *sledge-hammers*, also *straight*, and *cross pane*, F and G; *double faced*, H; and ball pane J. K to M are boilermakers' hammers. They are narrow, to get into corners, their functions including riveting. Boilermakers also employ the hammers C to J. N is a *chisel-hammer* used percussively, and termed a *scaling hammer* because used for chipping off the hard encrusted scale from the inside faces of the plates of steam boilers. Many hammers have very broad faces for operating on large areas. To these belong the *planishing* hammers of the coppersmith, the *flatters* and *set* hammers of the smith and boilermaker, the hammers of the goldbeaters and the shoemaker. The huge power hammers have no resemblance to the foregoing, the hammer itself being absorbed in the machine. But both gravity and applied force above the hammers are employed to render the blows effective. Also the speed of operation in the small types far exceeds that of the human hand. And when with the hammer there is combined the matrix or die the results leave hand labour far behind.

Mallets. The mallets are hammers of wood. They have resemblances to the steel hammers in length of handle—short for bench use, and long for swinging, two-handed blows. They are used where metal would bruise the face of the material. For the same reason engineers have hammers made of lead, and of copper, for hammering on polished surfaces without leaving marks.

Centre Punches, etc. There is another class of percussive tool—the centre punch [66] A, by which centres are popped in work for chucking by, and by which the course of scribed lines is indicated more clearly and permanently than is possible by scribed lines alone. B shows a special adaptation of a centre punch, in which centres for rivet holes are being stamped on a plate, *b*, through holes already drilled or punched in an upper plate, *a*, with which holes the centres will be true.

Among detrusive tools must be classed the *drifts* [66, C, D] used for enlarging holes that have been punched, hence their bellied and tapered forms. Another detrusive tool is the *snap*, E, by which the tails of rivets are neatly finished, following the turning over, to be done by hammer blows. The smith's *flatter* is a hammer, only it is itself struck with a sledge-hammer. So are the various *fullers* and *swages*, which mould metal into shape by percussive action. The *caulking* tools of the plater, boilermaker, and pipe layer are percussive, being struck by hammer blows. And so are many other tools of which these are typical.

Moulding Tools. These include all forms by which materials of various kinds are shaped without cutting action. They are the most important tools used by the smith, as the fullers, swages, flatters, and the dies. They also include nearly all the tools of the moulder working in sand. Allied to these are those of the modeller working in plaster, some of those of the plasterer, mason, and slater, and of the artist's modeller.

Fig. 67 illustrates the common *trowels* used by moulders and in other trades for smoothing over broad, flat surfaces; A is the *square* trowel, and B the *heart* shape. Fig. 68 shows moulders' tools, A being a *cleaner* for smoothing sand deep down where a trowel could not reach, vertical faces being smoothed by the blade *a*, and a flat horizontal face with the part *b*. B is a cleaner reaching down also into deep sides, and bottoms; C is a *flange* sleeker for smoothing the edges of deep flanges, two different curvatures being provided at opposite ends of the tool. In 69, A and B are *square corner* sleekers for smoothing internal and external angles respectively. C is similar to A, but has one face curved to suit concave edges. D is a *button* or *bacca-box* sleeker. Each of these tools is made in different sizes and modified forms. But all alike are moulding tools, working in sand.

Tools Operating by Leverage. Besides tools already mentioned, in many of which leverage comes into play, there is a group which operate as levers pure and simple. To this class belongs the common brace or stock by which the wood-boring tools are rotated. The forms of these have been very much improved of late years. The pretty wooden brace, a century old, has had to give place largely to others of metal which will do what the wood brace cannot, namely, work in confined situations by means of a double-acting rachet; and some will bore in angular positions. The refinement of ball bearings also inserted in the handle, the head, and the tool grip avoids the friction inseparable from the old type. The tap wrenches, or double-armed levers by which screw taps are operated, belong to this group. These occur in many varieties, including the solid hole kinds, and those which combine provision for clamping the tap shanks firmly in the body; Pincers, pliers, and pipe tongs form another group of levers. The pincers are too well known to need description, but it may be pointed out that those with the flattish ends pull a nail out better than those with very convex ends. The pipe tongs are roughened or serrated in the jaws to grip the outsides of iron and steel piping. The spanners form another group.

BANK OFFICIALS

The Bank Manager and the Bank Clerk. Salaries. Codes and Cables. The Institute of Bankers. Examinations. Banking Abroad.

Continued from page 4444

By R. LAING

THE age at which the clerk enters the service of a bank varies somewhat—ranging generally from 15 to 19 years. As the duties first entrusted to a junior usually include the collection of cheques and other documents, it is desirable that he should possess sufficient physical strength and mental activity to prevent his being easily robbed of his valuable burden; in large centres the age of entry is consequently higher than in the country districts. An examination is usually undergone by the candidate for admission, but, except in special cases, this presents no difficulty to anyone of average intelligence. English banks doing business in foreign countries or in the Colonies recruit their staff from those of institutions doing an exclusively home business, being spared, by so doing, the trouble of tutorship. The age of entry in such banks is higher, but in nearly every case a limit—usually of 21 years—is in force. In such banks the staff is generally divided into two distinct classes—the home and the foreign staff, the members of the latter, after a certain period, proceeding abroad to take up their duties there.

Salaries. The salaries obtained abroad are, as a rule, higher than those in this country, but the seeming advantage may be greatly discounted by the increased cost of living and the danger to health which is probably incurred. As regards salaries in this country, the scheme on which they are based may be either a graded or a non-graded one. In the former case, when the clerk is given a certain rank, say, of junior cashier (cashier at a small branch), he will at once receive the minimum salary attached to such rank, rising by stated increments until he reaches the maximum applicable, at which he remains until promoted to a higher grade. The salaries, if the second method is in vogue, are not determined by the exact rank held by the individual officer.

Training of Juniors. The clerk at the outset may enter on a term of probation, at the conclusion of which, if his abilities are deemed satisfactory, he is placed on the permanent staff. It is not at all desirable that anyone should receive his early banking experience in a very large or even a moderately large office. In such a case he will be immediately set upon some routine task, the monotony of which will only be broken by a removal to another department, there to perform work of a similar nature. It will therefore be with great difficulty that he will gain any knowledge of the business as a whole, and, should he be a person of only moderate ability, or somewhat lethargic, the result will be a state of regrettable ignorance. A comparatively small office, doing, however, a varied business, whose senior officials have both the time and the inclination to instruct the newcomer, is best suited for the purpose. The junior will, in such a case, perform in turn all the office duties, and will, through the occasional absence of his seniors, have a good introduction to the responsibilities of the profession in which he is engaged.

Walk Clerks. In enumerating the divisions into which the staff of a large London bank fall, the first to be referred to are the *walk clerks*. The work of the clearing clerks has already been referred to, and it is the documents which do not come within the clearing that are dealt with by the walk clerks. The whole of central London is mapped out by each bank into various routes, each of them being termed a "walk." The cheques on the bank offices situated there are presented for payment daily by the clerk to whom it is given, the bills on firms within the area of the "walk" being also presented by him for acceptance or payment. Every morning the cheques and other documents are listed under the headings of the offices concerned, and balanced. On the clerk's return he accounts for his collection by a mixture of cash, cheques, or payment warrants drawn on clearing agents, and returned documents.

Pass Book and Ledger Clerks. He may, however, be set to keep a ledger or the pass books relating to it. This marks a distinct step in responsibility, as, in posting the various items he will be required to see that each is in order—*i.e.*, that the cheque is correctly drawn, endorsed and dated; that the signature of the client is not a forgery; and that the instructions regarding the account are not exceeded in any way. These duties (or some of them) may, however, be undertaken by the chief ledger clerk. The chief ledger clerk may also check each morning all the entries of the previous day; while the cancelling by means of a perforating machine of paid vouchers, and the subsequent sorting, will probably be undertaken by the youngest junior. The cheque forms for sale will be taken charge of either by an official in this department or by a cashier.

The work in connection with securities for custody or as cover for advances is usually performed by clerks of some experience. The securities lodged for safe keeping do not occasion much trouble, but great care requires to be exercised with regard to documents held as cover in offices where the amounts in question are large and the deliveries frequent. The loan ledger will usually be kept in the securities department.

Bill Clerks. The junior, again, may be placed in the bill department, to which is usually given a place of greater importance than that dealing with ledger accounts. The bill having

been passed for discount by some responsible official, the due date is found, the discount calculated and checked, the amounts, endorsements and stamp examined, the draft passed through the registers and the proceeds placed to the credit of the client. The posting of the discount ledger, the work attendant on bills received for collection, either from clients or other offices, the necessary advices to customers of bills dishonoured (with, perhaps, other correspondence), the making up of bill returns and the renewal of opinions on names appearing therein, will all be seen to by this department.

In foreign bills the amount is invariably payable so many days or months after sight. The due date in consequence cannot be ascertained until the draft has been remitted abroad and presented for acceptance, and no exact interest calculation can, therefore, be made. Bankers dealing with such bills payable in a country using British money charge in lieu of interest a percentage on the bill amount—*i.e.*, if their 60 days' sight rate is 2 per cent., the amount deducted from a bill for £350, at that currency, will be £7. The article dealing with long and short exchange sufficiently explains the procedure with regard to a bill payable in a foreign currency.

Correspondence Clerks. The clerks engaged in correspondence have a better opportunity of gaining a knowledge of the business in its different aspects than those in other departments, the greatest disadvantages from the clerk's point of view being the comparatively late hour to which his duties extend, and the fact that he is very much at the mercy of other departments. A knowledge of shorthand is usually not absolutely essential, the principal clerks in such a department being expected to be able to draft a suitable communication on an indication of its nature being given.

The youngest junior will be placed in charge of the postage desk, while the completion of printed forms (a large proportion of bank correspondence being of this nature), the keeping and indexing of letter registers, the despatch and confirmation of telegrams and the filing of letters received when finally dealt with (the numbering of each letter providing a check on their return from the other departments), claim his future attention until he is judged fitted to undertake the more responsible duties of correspondence. In banks whose offices are widely separated, duplicates of branch correspondence are despatched by the following mail, running numbers being also used.

Code Telegrams and Cables. In banks doing a large foreign or colonial business (invariably including a large class of transactions carried out by means of telegraphic advice) a special staff of officials will be entrusted with the duty of coding and decoding the messages despatched and received. The codes used may be either public or private, check symbols being also used. The translation of a code telegram received is best verified by its being recodified by another official into whose hands the original telegram has not come, the result arrived at by him, if no error exists, agreeing with the original code message. Cablegrams despatched are also checked in a similar manner. The codes in use will be constantly added to through the need of symbols being required to represent the names of new clients, special transactions, etc.; but if the transaction in question is not to be repeated, arrangements may be made on its completion to use the symbol again. All code telegrams received and despatched are confirmed and acknowledged by first mail opportunity, the full translation of each being given. Work of this nature calls naturally for the greatest care and closest attention to detail on the part of the officers concerned, a clerical slip having, perhaps, the most serious results.

Not included in the foregoing classes are the waste book clerks, the officer or officers whose duty it is to post the general cash book and ledger, the clerk who may be solely engaged in checking the bookkeeping entries of the previous day, the official or officials who may be entirely occupied with opinion work, the messengers—a uniformed body of officials regarded as quite apart from the clerical staff, and so on.

Cashiers. In an ordinary branch, an appointment to the rank of cashier entails a distinct promotion. In large offices, the cashiers, or the majority of them, will generally be junior to the principal clerks in the various departments; but in branch offices in which the duties of such clerks are undertaken by one official—the accountant—the cashier or cashiers are placed between this officer and the rest of the staff, the members of which correspond to the junior officials in the head office departments. It is essential that a cashier should be possessed of good address and appearance, and be able to despatch the business of the bank's clients with the least possible delay. Each cashier is responsible for the balance shown by him in his cash book (the actual amount on hand being frequently checked by a senior officer), an allowance against possible loss being probably made.

Daily Balancing. The cashier is not allowed (with the view to the prevention of fraud) to deal with any book other than his own cash book, and, in consequence, if he is a quick and accurate worker, he will always be the first of the staff to complete his day's duties, for, if no error has been made, the agreement of the balance shown in his book with the cash actually on hand will present no difficulty. Any difference will arise through a mistake in the entries in the cash book or an error in the intromissions with the cash. The first is bound to be discovered on comparison with the relative waste books, registers, etc.; and with regard to the latter the cashier will invariably discover an error relating to any documents or bank notes (if the numbers of the latter are recorded); but the payment of ten sovereigns instead of five is not so easily discovered and remedied.

A cheque left for payment by a walk clerk, the signature on which has been cancelled by the cashier, will be accepted by the former as unpaid on his returning for payment, if marked and

initialled by the cashier "Cancelled in error." To cancel the signature on a *bill*, however, precludes the possibility of the draft being returned; while the presenting bank may refuse to allow a cheque bearing a foreign endorsement to be so treated until sanctioned by its correspondent. The foregoing remarks apply also to documents received through the post or the clearing.

The Accountant. The succeeding grade is that of accountant, who is responsible for the work of the office being duly carried on, and who, in the absence of the manager, attends to the duties of the latter. An official on reaching this status is almost invariably empowered to sign on behalf of the bank, so that no delay may occur in the completion of any draft or receipt should the manager be at the time engaged. The qualities required in an accountant are of a somewhat different nature to those most required by the cashiers and the manager. A clerk whose capacity in carrying through and arranging the routine work of the office is admirable and whose grasp of the business is very good, but who is somewhat deficient in address if called upon to interview a client, or who cannot, through some unfortunate cause, occupy the position which, apart from his office duties, a branch manager is expected to maintain, will be better fitted to be an accountant at a large office than a manager of a small one.

The Manager. In all branches the final position is that of manager, the official attaining this rank receiving promotion afterwards in the shape of a transfer to a more important office. The principal duty of the manager is the continual receiving of the bank's clients, in the course of which he will have opportunity for the exercise of tact, if, for instance, he wishes to retain the custom of a client whose overdraft the head office desires to see reduced. His observation should be keen and his deductive powers good. The success attained by the manager depends on the ease with which he can adapt himself to the various individuals with whom he comes in contact; upon the interest he can naturally feel and show in their affairs; and upon the degree in which he possesses an intuitive insight into character; a temper not easily ruffled, a quick and ready decision, and a mind unprejudiced in business by personal feeling. The ability to take a clear-headed view of the future of a doubtful debt and the resolution to act accordingly, even to the extent of the drastic step of stopping the account, are not too common. To discover borrowers (of a kind) requires no exertion, but the attraction of deposits is a different matter, and the manager may spend a long period before forming connections leading to an increase in this class of business. The manager's responsibility may be restricted either as regards the total business or each particular item by a *limit* being fixed by the head office.

Arrangement of the Office. The banking hall, or general office, should, if the building is of more than one storey, be on the ground floor, the rooms above, if possible, being occupied by those members of the staff whose duties do not bring them directly into contact with the public. The windows, if the office is not roof-lighted, are usually found at the side of the room, with the desks at right angles to this wall.

The counter desks will be occupied partly by the cashiers, and partly by officials from the bill and other departments, to enable clients having business dealt with by these to be attended to with the least possible delay. Behind the cashiers the waste book and ledger keepers will be placed, the other officials being found behind the clerk who represents them at the counter; while the correspondence department will be accommodated at the back of the office. As many officials as possible should face the counter, the chances of theft being thereby greatly diminished, while the accountant should be able from his desk to survey the entire office.

Institute of Bankers. The office of the English Institute is at No. 34, Clement's Lane, from which forms for signature, syllabuses, specimen examination papers (a small charge being made for these), and all other necessary information may be obtained, and at which a large library is available for the use of members.

SCHEDULE OF EXAMINATIONS FOR BANKERS

Examining Body, Grade, Time and Place of Examination.	Subjects of Examination. Obligatory.	Subjects of Examination. Optional.	Fees and Age Limit.
English Institute. Preliminary. April. Various centres.	Political Economy, Practical Banking, Commercial Law, Arithmetic, Algebra, and Bookkeeping.	French, German.	5s. None.

Scotch Institute. Members. March. Various centres.	Principles of Political Economy, Stocks and Stock Exchange Transactions, History and Present Position of Banking and Currency, Theory and Practice of Foreign Exchanges, Principles of Scotch Law and Conveyancing, Law of Bankruptcy, Mercantile Law, Law of Bills, Cheques and Deposit Receipts, Practical Banking (Correspondence Branch Supervision and Advances).		None.
Scotch Institute. Honours. March. Various centres.	French or German, British History, British Government and Constitution, English Literature, Outlines of General History		None.

The subjects of examination (open to members only) are given in Schedule on preceding page. Certificates are granted to those passing the final examination, certain prizes are offered, and various banks reward, either by money payment or otherwise, a successful candidate. The annual subscription for a member is 10s. 6d., and a fee of 5s. is payable on each occasion by anyone intimating his intention of sitting for examination, the payment covering all subjects taken at the time. Such notice must be given not later than February 28th.

It should be borne in mind that before any examination of the English Institute can be taken it is necessary that the intending candidate be elected a member of the Institute.

The Scotch Institute. The principal centres of the Scotch Institute are at 27, Queen Street, Edinburgh, and at 218, St. Vincent Street, Glasgow, where libraries are available for the use of members, associates, and intending candidates (on payment by the last of a fee). No fee is payable for examination nor is any subscription (ranging from 5s. 3d. to £1 1s.) due until the individual becomes either by election or examination an associate or member of the institute. The examinations take place at the end of March, ten days' notice being necessary, and various prizes and gratuities are offered by the institute and banks concerned. All needful information will be supplied by the Institute authorities.

Banking Abroad. In almost every new country there will be found a bank, established with British capital, whose head office is in this country, and whose inception was principally due to the exchange business resulting from our shipping trade, but which also transacts a large *local* business oversea. No attempt has been made to establish banks to carry on similar French or German business, although the great importance of Hamburg as a shipping centre has caused certain institutions to open agencies there. Most of the larger Continental banks, other than those of State origin, possess, however, for the efficient transaction of exchange business, a branch in London, and the number of such offices is being steadily added to. A further extension of this practice is, in some instances, carried out by the establishment and maintenance of offices in all the principal Continental centres, and even in those still more remote. The principle of State banking possesses abroad a greater vogue than in this country, the principal banks in both France and Germany, for instance, being of this nature.

The banking business carried on in the United States is greatly affected by the regulations in force, which are too complicated to be dealt with here. In no other country has legislation regarding banking and currency been so prolific as in the United States, and the present arrangement probably does not constitute finality in the matter.

London Bill Brokers. Reference has previously been made to the London bill brokers, but one or two important points in connection with their method of business have been left untouched. Their funds are wholly composed of deposits at interest, the rate allowed by them being greater than that of the joint-stock banks. The margin of profit obtained is, in consequence, small, and, owing to periodical fluctuations in the rate of interest, is liable to entirely disappear, although the trend of interest rates may, of course, result in an unexpected increase. The brokers keep practically no reserve. The rates obtained by banks on the employment, with bill brokers and others, of funds for which no use can at the moment be found, or which it is desired to keep liquid, have a considerable influence on the profits of the banks. A large proportion of the bank's deposits—its current accounts—are obtained at what is practically an unchanging rate—the expense of working, no interest being paid by the bank. If money is a glut on the London market, the employment of surplus funds may be attended with loss; but if a tightness is in evidence, a large margin of profit will be earned.

Future of Banking. Banking may be said to have, in a certain sense, very probably no future, for history is, after all, but the record of the repair of accident and error, and a Utopia has no need of a chronicler. The progress of banking in this country during the past few decades is one of steady and continued growth, and is almost entirely free from those startling incidents which lend a romantic attractiveness to its earlier story. Its wild oats have all been sown long ago; it has now reached a vigorous manhood; but it is to be hoped that it will never, with the commerce and industry of the nation at large, descend in course of time to a decrepit and enfeebled old age.

Books Recommended. The practical details of banking business are somewhat neglected in the literature available, but the following list, which can be supplemented from that given in the Institute of Bankers' syllabus, may be studied with advantage:

Clare's "A B C of the Foreign Exchanges," 3s.
Clare's "Money Market Primer," 5s.
Moxon's "English Practical Banking," 4s. 6d.
Rae's "Country Banker," 2s. 6d.
Bagehot's "Lombard Street," 3s. 6d.
"Money and the Mechanism of Exchange" (Jevons), 5s.; and parts of Gilbart's "Principles and Practice of Banking," 10s.

BANKING *concluded; followed by* INSURANCE

TRACK AND RUNNING STAFFS

Conditions of Employment. Duties, Wages and Prospects of Track Inspectors and their Subordinates. Engine Drivers and Running Shed Hands

continued from page 4381

By H. G. ARCHER

TO maintain the permanent way and works of a railway, an elaborate system of organisation, together with a large staff of officers and servants is required. The head of this organisation is the chief civil engineer. As a rule, the chief engineer is given a lieutenant, who is specially charged with the maintenance of way and works. Then comes a number of divisional engineers. The number of engineering divisions of a railway depends upon its size. For example, the London and North-Western, with 4,000 single-line miles, has eight, and the London and South-Western, with 1,700 single-line miles, three.

Inspectors and Gangers. Each division is subdivided into so many chief inspectors' districts, and each chief inspector has under him four or five sub-inspectors. Inspectors' wages are from 7s. 6d. to 10s. 6d. per day. Each sub-inspector takes from 20 to 50 miles of single track, or about half that number of miles in territory. Below the sub-inspectors are the foremen gangers, who earn from 4s. 6d. to 6s. 6d. per day. A foreman's length averages two miles on a double track, or about four miles on a single. Below the foremen, again, come the platelayers, or surface men (wages 3s. to 4s. 6d. per day), the number of whom in a gang varies according to the density of the traffic, and the consequent wear and tear of the permanent way, or the number of junctions and sidings which have to be maintained. It stands to reason that the gangs' lengths, say, between Waterloo and Clapham Junction, have to be far more strongly manned than those of remote single-line branches. However, it is estimated that, as a general rule, one man per single line mile ought to suffice. The foreman and platelayers patrol it at least once a day to ensure that everything is in perfect order. They have to see to the condition of the joints, gauge, or horizontal alignment of the track, general condition of running surface of rails, and security of all keys, spikes, screws, etc.

Most careful attention must be paid to the spacing of rail joints. Directly spacing is found to be wrong, steps must be taken at once to adjust the rails. Inspectors, foremen, and gangers are supplied with spacing gauges. The spaces per joint, with rails up to 30 ft. in length, are as follows: Hot (summer temperature), $\frac{3}{32}$ in.; moderately cool, $\frac{5}{32}$ in.; cold, $\frac{1}{4}$ in.

Weak Points of the Track. The rail joint is the weak point of the track—that is, the place least likely to withstand strain. If joints be allowed to get out of vertical alignment, they play pitch and toss with the wheels of a train. The correct horizontal alignment of the track is tested by gauging with special rods, and the proper degree of superelevation to be maintained by the outer rail on curves is ascertained in the same manner. Platelayers [4] set right, with the tools at their disposal, all and sundry defects which they chance to find in any of the foregoing.

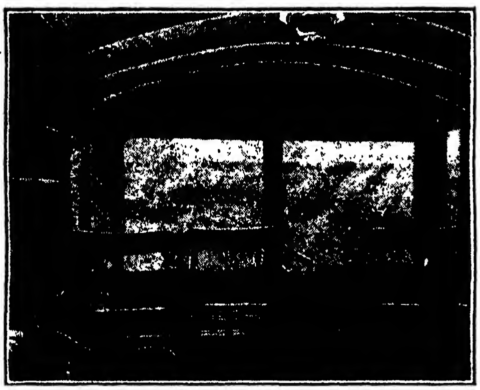
However, serious exception is now taken to the practice of entrusting platelayers with such a delicate matter as the adjustment of curves, which are originally laid out with mathematical precision, under skilled supervision. As in America, there ought to be a specially trained staff for the purpose, and we believe that one English company—the Great Western — is about to establish such a staff. Nevertheless, adjustment of curves, as conducted by platelayers, is not rule of thumb work. Every company issues a table setting forth the degree of superelevation in inches to be observed on curves of different radii.

4. PLATELAYERS "KEYING UP"

Duties of Platelayers, Foremen, and Inspectors. Further, platelayers have to move and repack the ballast, so that it may not concrete on the surface and hold water, to oil and clean the working parts of points and signals, and to keep in thorough repair all hedges, fences, slopes, drains, and "cesses" or footpaths. It stands to reason that the responsibilities of railway companies as regards fences and hedges are very heavy. Lastly, the platelayers have also to report anything they may detect amiss with the telegraph wires, signals, passing trains, bridges, culverts, notice - boards, quarter-mile posts, etc. The platelayer, of course, is an unskilled workman—a mere labourer, to begin with, and he learns his duties from a foreman. A man wishing to become a platelayer must be not less than 18 and not more than 35 years of age (which is the general rule with all railway companies in respect of ordinary labour); he must

be able to read and write, and possess sound health. There is also an eyesight test, but this is not of so stringent a character as with some other departments of railway employment. What are known as "half normal vision," as regards distance, and "defective colour vision," form the standard. On the whole, platelayers are a rather floating population. Many men stay in a company's service as such for only a few months at a time, then go off to join a contractor or another company, or perhaps to become ordinary labourers, and eventually return to put in another period of service with their original employers. A large number of platelayers is recruited from the employees of the contractors engaged in constructing a new railway—that is to say, the men who laid the line originally are taken over by the company *en masse* to maintain it.

Promotion for Platelayers. A platelayer can rise to the rank of foreman, inspector, and chief inspector, but any post higher than the

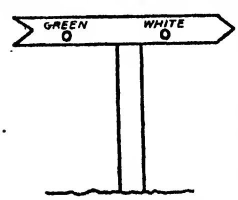


5. INTERIOR OF INSPECTION COACH AT REAR OF TRAIN
Showing seats for examining committee

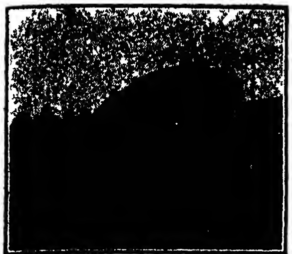
last-named he seldom attains, for educational reasons. Promotion rests entirely at the discretion of the company, and is judged by merit alone. The foreman, or ganger, is responsible for the work of a gang to his inspector, the inspector to his chief inspector, and the latter to the district engineer. By the way, among the younger school of railwaymen, great objection is evinced towards the old railway term "ganger." They seem to think it carries some reproach, suggests the idea of gangs in chains. Some companies are meeting the objection by calling the overseers *foremen* instead. Besides the platelayers and gangers who carry out all ordinary repairs, and therefore are known as "straight road" men, there are travelling gangs of ballasting men, or "packers," and relayers, who are employed in renewing the permanent way, and executing alterations and additions, when they are often strengthened by local men. About five per cent. of the whole permanent way of a railway is renewed per annum. The relayers, etc., are under the charge of chief inspectors, and each chief inspector also has allotted to him a complement of artificers, masons, bricklayers, carpenters, smiths, etc. (wages 6s. to 8s. per day), with their foremen and inspectors, who are responsible for the repair of everything that constitutes the "works" of a railway as differentiated from the permanent way. The sub-inspectors take charge of the relaying and repairing gang, when they get to work, are responsible for the discipline, hours of labour, and wages of every man temporarily or permanently employed within their districts, and keep a record of all materials received and used.

Relaying Precautions. Each gang of platelayers must be supplied by the inspector for the district with two red and two green flags, two hand signal-lamps, and a proper number of detonators. Before a rail is taken out, or relaying operations are begun, or if from any cause the line is unsafe, a flagman must go back, exhibiting a danger signal, and place three detonators on the line, 10 yards apart, at a distance of not less than one mile from the obstruction. Before a rail is taken out, the platelayers must have at the spot a perfect rail in readiness to replace it. In lifting the permanent way, no lift must be greater than 3 in. at once, and then it must be effected in a length of at least 20 yd. When both rails have to be lifted they must be raised equally and at the same time, and the ascent must be made in the direction in which the trains run, great care being taken, where there is a curve, to preserve the superelevation of the outer rail. Where the necessity for trains to travel at a reduced speed continues for a lengthened period, detonators and hand caution signals are dispensed with. In substitution thereof a warning board [6] painted green must be fixed in a legible position half a mile from the place to be protected. During the night one green and one white light are placed side by side on the warning board. When a lorry is run empty or used for conveying materials or men along the track, it must be taken in the same direction as the trains run, and followed at a distance of three-quarters of a mile with hand danger signals and detonators. On a single line the lorry must be protected in both directions, and in going through a tunnel it is signalled on the block instruments like an ordinary train. When not in use, the lorry must be taken off the rails, placed well clear of the line, and the wheels secured with chain and padlock.

Expert Scrutiny of the Permanent Way. Periodical inspections are made by the divisional engineers, the chief engineer, the general manager, and even the directors, to ensure that all the work is being properly performed, and a uniform standard of maintenance observed throughout the railway. Nevertheless, there is nothing definite about these periodical inspections by the higher officials, as is the case with Indian railways, where a divisional engineer has to certify



6. WARNING BOARD



7. ENGINEER'S INSPECTION COACH

that he has inspected every mile of track covered by his district at certain intervals.

Again, some of our readers may have noted passing references in the English newspapers to the grand field-days held by the principal railway companies of the United States for the purpose of inspecting the condition of the track and everything pertaining to it. The chief officers of the New York Central and Pennsylvania Companies spend annually two or three weeks travelling over their road in a special train, on which they live, eat, and sleep while the examination is being conducted. At the rear of the train is a large observation car, with seats arranged in tiers, for the accommodation of the various examining committees, whose duties are to scrutinise the condition of the permanent way, bridges, signals, stations, etc., and pronounce an opinion upon the general condition of the running surface of the rails. In the latter case, such a test as brimful glasses of water, which, of course, will spill over if the slightest oscillation be experienced, is applied. For the purpose of comparison, the whole extent of the line is marked out into the respective gangers' lengths, and the examiners keep scores testifying to the condition in which they find each. Premiums are awarded to the inspectors of, and every man employed in, the prize sections.

There is more in the system than meets the eye. The principal object in view is to bring down the unit of expenditure as regards the cost of maintenance and renewal to individuals—not highly-placed individuals, such as the district engineers, but the inspectors of districts, and even the gangers, who are entrusted with the care of only a few miles of the road. It is realised that the latter are the men who really hold the purse-strings, hence it would be a great thing to find out what they are giving for their money, and compare the different results. With the customary method of keeping accounts it is practically impossible to arrive at the details of expenditure on permanent way.

8. [illegible] BAR-BOY [illegible]

Premium Award System. The London and South-Western Railway has furnished the first instance of a British railway company adopting the American system of track inspection, with the view of splitting up and checking the expenditure that falls under this head, and at the same time trying to obtain better results for the same or less money. The system lends itself to raising the standard of efficiency from the highest to the humblest ranks of the army of men entrusted with the maintenance of the permanent way.

There is only one way to make the men at the bottom understand that better things are expected of them—convince them that their work is going to be individually examined and compared every year by the head officials. There is only one way to make them turn out better work than previously—namely, by instilling them with a new spirit of emulation, and encouraging them with the offer of money and other prizes.

A Common Factor of Responsibility. Everybody's responsibility is reduced to a common basis by charging him with the equivalent single-line mileage he has to maintain. He has so many running miles under him, including miles of sidings, of which two miles are estimated equal to one mile of running line, and he is allowed to reckon one mile of running line for every fifteen pairs of switches.

9. LOCOMOTIVE ROUND HOUSE

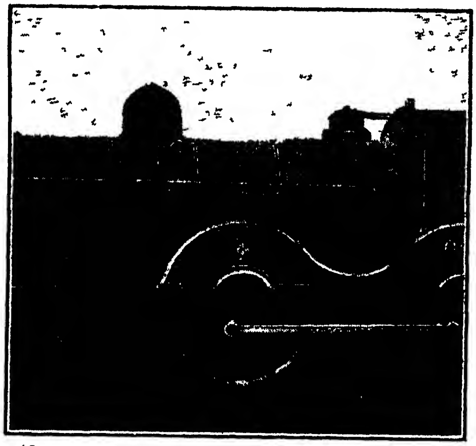
The chief engineer's road-book is arranged in consecutive order of inspectors' sections, as follows: (1) geographical beginning and ending of the section; (2) sub-division of running lines—that is, mileage of single, double, triple, or quadruple track; (3) total in single line miles; (4) total length of sidings; (5) number of switches; (6) total equivalent of switches in single-line miles. Next come particulars as to the manning: (1) names of the foremen, and their rates of pay; (2) number of men under each foreman, and their rates of pay; (3) total equivalent single-line mileage divided by the total number of men in gang, which produces the ratio of manning per single-line mile. It will therefore be seen that for comparative purposes the unit of expenditure is brought down to the inspector of a section. What is yet wanted is to bring it down to Foreman Smith or Brown, but that is still some way ahead.

A British Track Inspection. The track inspection occupies about eight days, spread over

a month or six weeks in the spring. The main line can be examined only on Sundays. Three examining committees are formed as follows: Class A, for condition of joints, alignment of track, and general condition of running surface of rails; Class B, for condition of ballasting; Class C, for general appearance of all works, including hedges, fences, slopes, drains, "cesses" or footpaths, notice-boards, and quarter-mile posts.

The system of premium awards instituted by the London and South-Western Railway offers a challenge cup and a money prize of £2 for the best inspector's section, and a challenge cup for the best foreman's length throughout the line. With the challenge cups go silver medals to keep In each inspector's section the foreman with the best length is awarded £1 and a bronze medal, while each man under the prize foreman receives 10s. and a bronze medal.

The Method of Marking. Let us see how the awards are arrived at. The line is divided into the respective gangs' lengths, and so many marks are allotted to each foreman under the three different classes by which his work is judged. Thus, in Class A, 200 marks represents perfection; in Class B, 120; and in Class C, 80. But the method of marking makes allowance for certain correcting factors. It is manifestly to the advantage of a railway company to get the work efficiently done by as few men as possible, and, as already stated, it is calculated that a ratio of one man per single-line mile ought to suffice Therefore, one mark is allowed for every hundredth of a man below one man per mile, and one mark is deducted for every hundredth of a man above the quota. The feeling among the men is that the age of the road also ought to count for something. Therefore it has been decided to apply another correcting factor in this respect. The average life of the road is assumed to be 17 years. For each year over 17 years five marks are added to the score, and for each year below two marks are deducted, the object of the discrepancy, of course, being to encourage men to take pains with sections of old road The weak point of the system is that it has not yet been found possible to apply other correcting factors in respect of density, weight, and speed of the traffic passing over the different sections. Obviously, a man whose section carries, say, 6,000 trains per mile per year, is not so hardly hit for wear and tear as his fellow whose section carries, say, 12,000 trains per mile per year. Further, the weight and speed of the trains in question ought also to be measured. This forms a good instance where the ton-mile statistics, instead of train-mile statistics, would prove invaluable were they but available.



10. CLEANERS AT WORK ON EXPRESS ENGINE

The Inspection Train. The special inspection train is made up thus: engine, inspection car, "resting" saloon, refreshment saloon, inspection car. The inspection cars [7] are four-wheeled vehicles, so that all shocks from the road may be transferred to the body, and provided with glass ends, so as to furnish a clear look-out. Only the inspection car at the tail end of the train is used for examining.

The interior of the inspection coach [5] is fitted up with two tiers of chairs, arranged in two pairs The examiners sit with their backs to the engine, and scrutinise the receding track. The committee for the condition of joints, etc., occupy the seats in the front left-hand corner, and the committee on ballasting those in the front right-hand corner, while the committee on the general appearance of all works sit in the back tier and look over the heads of the two former. To ensure impartiality, no examiner is connected with the section he is examining The committees, who usually consist of two members apiece, are on duty for about an hour at a time, and at the expiration of their turn the members leave the inspection car for the "resting" saloon, and their places are taken by others.

Inspecting the Line. The inspector of each section is in the inspection car while it is passing anywhere over his own length He has already marked out the various gangs' lengths, by means of white painted crosses at the side of the track, and now has to stand behind the examiners to answer questions and to give timely intimation of the change from one ganger's length to the next, mentioning each of his foremen by name On taking their seats, the secretary of the inspection has handed to each member of the three committees the whole of the award cards which they will respectively require for their turn of duty. The cards for each class are of different colours, and there is a separate card for each ganger's length. On the face of the cards are full particulars of each gang's length, together with information concerning the age of the road, weight of rails, etc., and at foot are spaces for the examiners' notes and awards. At the expiration of their turn of duty, the examiners return their cards to the secretary.

Success of the New System. The results furnished by the new system of track inspection, even at this early stage of its development, have been of a most gratifying nature. True, some of the older men are hostile to the innovation; but, taken as a whole, the

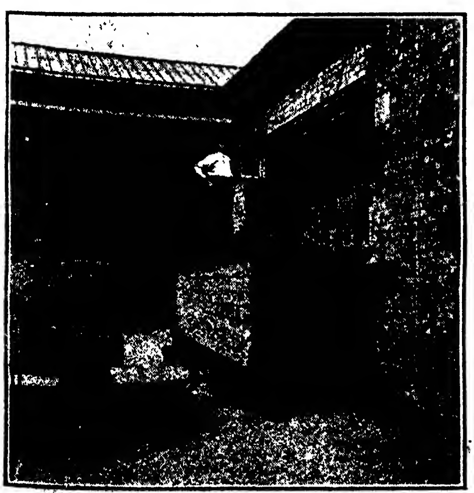
permanent-way staff has realised the importance and value of the new methods. There is no lack of evidence that since the system was inaugurated a new spirit of efficiency has impregnated all ranks, and the keenest rivalry may now be said to exist as to who shall earn the distinction of turning out the best stretches of road.

Running Sheds Staff. The headquarters of every individual connected with engines is one or other of the running sheds, or locomotive stables. It will be easily understood that engines are distributed in no haphazard fashion over a railway; on the contrary, each engine works within some well-defined area, of which the base of operations—the place where it is cleaned, prepared for the road, washed out, and kept in repair—is a running shed. A number of British railways find it useful in locomotive operation to paint the shed number on each locomotive, a good practice, followed by the London and North-Western, being to use a small enamelled plate bearing the number of the shed in which the engine is stationed at the back of the roof of the cab. An older, but still much used method is to paint the name of the shed on the engine frame or on the lamps. The running department of a railway comprises several divisions, each of which is in charge of a district locomotive superintendent, who is responsible to the chief locomotive or mechanical engineer. The office of a district locomotive superintendent is situated, as a rule, within the precincts of the principal running shed [9], from which he commands all other running sheds in his district. The regular staff of a running shed is distinct from enginemen proper—that is to say, it comprises a number of men and lads who are not passing through certain grades in order to attain footplate positions, although that may have been their original intention.

Skilled Workmen. The district locomotive superintendent's lieutenants are a head locomotive foreman and several sub-foremen,

11. TAKING IN COAL

and also a very important officer in the foreman fitter, who is responsible that engines leave the shed mechanically sound. To the foreman fitter is allotted a staff of skilled workmen, in the persons of copper, brass, and boiler smiths, who execute all ordinary repairs. The boiler-smiths are drawn from the most skilled artisans, as everything depends upon the efficient tightening up of tubes, hardening of stays, etc. The ranks of the less skilled labour employed consist of tube-cleaners, boiler-washers, lighters-up, sand-driers, and coalmen, who are under assistant shed-foremen. Stationary engine-drivers are found at all important sheds in charge of engines pumping water and driving repairing machinery, and they, of course, represent another branch of skilled labour. It may be thought that by opening with some description of the regular staff of a running shed we are putting the cart before the horse. However, the reason is that many railway companies recruit for the foregoing phases of more or less skilled labour from enginemen who have failed to continue a footplate career owing to defective eyesight or inability to obtain a driver's certificate, but some—notably the Great Central—enlist the regular staff of a running shed independently; men are engaged as labourers, and work their way up, or are taken on at once as fully-qualified fitters, smiths, mechanics, etc. In any case, however, men who break down on the footplate are given better positions than labourers. It is customary to put them on stationary engine work.



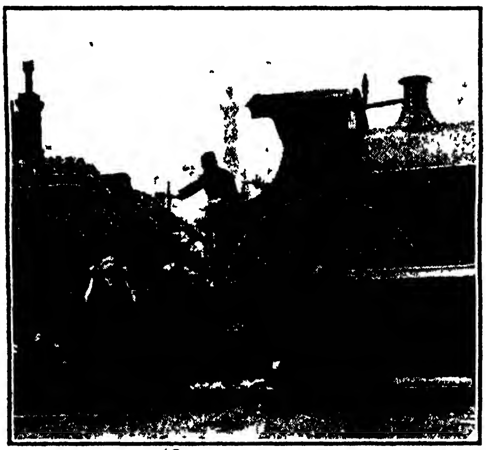
12. SAND DRIER

Bar-boys and Cleaners. A boy wants to become an engine-driver. How does he set about it?

The lowest rung of the ladder is bar-boy [8], rising to cleaner. The duties of a bar-boy are to creep through the fire-hole door of an engine, with a torch lamp, steel broom, scraper, and fire-bar lifter, to arrange the fire-bars, and to clean the bars, brick arch, roof stays, and tube ends of clinkers and ashes. However, many companies no longer employ lads under 18 years of age as bar-boys, since factory legislation prohibits them from being engaged in night work. In such circumstances, the youths of smaller stature who enlist as cleaners begin with bar work. When genuine bar-boys are employed, the age limit is 15, but candidates seldom have to pass a medical examination or eyesight test. When a bar-boy

is old enough to be promoted to cleaner, or, in the case of companies which begin with older lads, a lad presents himself to be taken on as cleaner, his age, height, physical and optical fitness, and educational proficiency are taken into serious consideration. Generally speaking, a cleaner must not be younger than 16, and not older than 21; he must be able to read and write; he must be physically sound; and he must pass one or other of the standard eyesight tests for colour and distance with both eyes. The standard of height varies with different companies; with some it is 5 ft. 4 in., and a promising boy a little below that height will not be rejected; while others have a rigid rule—5 ft. 6 in. without boots. The duties of a cleaner are to clean an engine as soon as it returns to the shed [9], for which purpose he is supplied with oil, waste, and tallow.

The Grooming of Engines. Sometimes cleaners [10] work in gangs of four, the senior of them being known as chargeman cleaner. In that case, one takes the wheels and framing, another the motion, another the "top" (which includes everything above the footplate), and another the tender. It takes several hours to clean an engine, and it is just as easy to clean it the wrong way as it is to groom a horse the wrong way. The art of cleaning lies in not delaying the hot work, when the oil and grease can be easily rubbed off, to do the cold work. The general rule now is for passenger engines to have their own two cleaners, while some companies go farther than this and book certain cleaners, sometimes one, more often two, to every kind of engine. Young cleaners are first put on to tenders, and occasionally they are classified separately as tender-lads, from which they are promoted to cleaning shunting, goods, and passenger engines respectively. As a rule, the cleaner's job is piecework, and he is paid according to the class of engine on which he is employed. For example, a half-crown is the ordinary scale of remuneration for cleaning a goods engine, while the work on an express engine is rewarded generally with 3s. 8d. In order to reduce labour, and consequently expenses, many companies give their shunting and goods engines a more sober livery than that of the passenger type. Should a cleaner discover any mechanical flaw, he must immediately report the same to the foreman cleaner, and some companies stimulate vigilance on the part of the cleaners by offering suitable rewards. The satisfactory completion of a cleaner's job is certified by the foreman cleaner of a shed. The foreman has a card, on which he ticks off each engine that passes his scrutiny. A cleaner is not allowed to leave the shed until the foreman has given him a pass which testifies that he has cleaned his engine properly.



13 LIGHTERS-UP

Promotion from Cleaners. A cleaner's length of service is entirely a company matter, with some companies it is purely a question of traffic exigencies—that is to say, if business be slack, a pass-cleaner will have to wait until it revives before being promoted to the footplate; while if business be extraordinarily brisk, a really promising youth may be promoted after cleaning for only twelve months. In ordinary circumstances, however, we should say that the average length of servitude as cleaner is three or four years, that very few cases of promotion occur till a lad has served 18 months, and that most companies are averse to promoting cleaners under 19 years of age, or until they have served two years, by which time they are expected to be pass-cleaners.

Then, the rank to which a cleaner is promoted is not always the same. A few companies advance him to fitter's assistant, meaning apprenticeship to a skilled mechanic for a period, during which he is executing repairs, and obtaining some first hand knowledge of locomotive machinery. But the tendency now is to employ none but permanent men in the fitting department of a shed. It is argued that a cleaner promoted to fitter's assistant is apt to lose touch with the footplate, and that the fitter himself is handicapped by having a constant succession of fresh mates. Therefore, the usual thing is for a cleaner to be promoted to shunting fireman. Shunting engines are employed in marshalling goods waggons and the vehicles of passenger trains. On their footplates the young fireman learns how to handle the shovel, injector, and brake, while he becomes well acquainted with the directions conveyed by signals.

The Fireman's Career. After a fireman has served his apprenticeship on a shunting engine, he passes through three higher grades in the same capacity; first, on engines working local or "box" goods train, or in those engaged in "banking"—that is, assisting all kinds of trains up inclines; secondly, on engines hauling main-line goods and mineral trains; and thirdly, on engines in charge of slow and express passenger trains respectively, according to his ability and experience. Some companies differentiate these three classes of firemen by name — third, second, and first-class fireman; others, again,

classify them by their length of service—namely, first year, second year, and third year fireman; but, whatever the names or methods of classification, the three grades invariably exist in actuality. Usually, when a man becomes a first class, trained, or pass fireman, he is expected to undergo an examination which proves him to be capable of taking charge of an engine if required. Some companies do not wait for him to attain that rank. For example, on the North-Eastern, after a man has been firing seven years he is due to pass as driver, and that examination he must then pass, or else leave the company's service. He is given three chances at intervals of three months.

Promotion for Firemen. The Great Northern Company, however, do not permit a fireman to present himself for the driver's examination unless there is actually a vacancy, or is soon likely to be one for him. Of course, every company is bound to keep a certain number of firemen qualified to act as drivers in reserve. Broadly speaking, companies employ their own discretion as to when they shall call upon a fireman, and it goes without saying that they limit their choice to men who have had considerable experience. With some companies, like the Midland, seniority counts for little; their aim is to pick out the men with a genius for driving.

While men are firing they have the opportunity of attending improvement classes. These are formed and managed by the men themselves, but the authorities are always ready to provide them with working models, and also to place an engine in steam, to be treated for all manner of imaginary mishaps, such as a broken piston, or valve, at their disposal. It should be added that some companies make a man pass an examination in the mechanical working of the locomotive even before he can attain the highest rank of fireman, when, moreover, he has to prove his ability to carry out slight repairs with the tools at his disposal.

14. CLEANING OUT THE SMOKE-BOX

Work of Locomotive Firing. There is considerable difference between firing a goods and a passenger engine. On the latter, a fireman has to accelerate the speed of his movements and economise time by thinking beforehand. The fireman of a modern express has not much time in which to admire the passing scenery. The leviathan engines now built demand to be fed with from 35 lb. to 40 lb. of coal per mile. Therefore, the fireman's task with a train which is booked to run for several hours without a stop and at a speed of over 50 miles per hour is Herculean. It would indeed be interesting to ascertain what he expends in feet-pounds of muscular energy by handling four or five tons of fuel at a stretch on the far from steady platform formed by the footplate of an engine which, for most of the run, is travelling at a speed of a mile a minute. In addition, the fireman has to attend to the water feed and lubrication. Any neglect on his part, or an error in judgment in firing heavy expresses, lands the driver in difficulties for steam supply. The idea has been mooted that engines making very long non-stop runs should carry a relief fireman, but the experience is that when three men are present on the footplate they are apt to get in each other's way, and also indulge in conversation. However, it is probable that sooner or later the fireman's duties will be lightened by the adoption of a mechanical stoking apparatus such as is being experimented with on the huge American engines.

Promotion to Driver. In course of time, the fully-trained fireman, having passed the necessary examination, commences a fresh career as a driver. His first post will be either in charge of a shunting engine, or fulfilling that which is variously known by the names of engine turner, or stabler, or, again, he may become a reliever. The duties of a reliever, or shedman, are to relieve an ordinary driver or fireman whose day's work is finished, perhaps at some distance from home, should he wire to be relieved. The duties of stabler, on the other hand, are more simple—namely, to meet engines when they return to the sheds after a trip. A stabler stables an engine—that is to say, he is the driver who shunts it from off the main track, conducts it to the coaling stage [11], turns it on the turntable, if required, and sees that it is hauled off to bed, a dead machine. The duties of both driver and fireman cease after they have dropped the fire and accompanied it to the coal stage. Engines coal for their next trip as soon as they come in, and before they are cleaned, as coaling is a dirty operation. The amount of coal which each engine receives is booked to the proper driver.

Fuel Economy. Some companies give a quarterly coal premium, in awarding which both timekeeping and good conduct are taken into consideration. Of course, anybody can save coal by losing time.

The customary procedure is to tot up the consumption of coal by each link or batch of drivers and divide the total by the number of drivers, which yields the average. The district superintendent then awards a premium to every driver whose coal consumption pans out less than the mileage rate. Where coal premiums are not given, drivers know that if they exceed the average mileage rate they will be reprimanded; but most companies, which do not give premiums quarterly, grant an engineman, on retirement, a lump sum corresponding in value to the coal he has saved during his total service. This makes a nice nest-egg for a man.

Learning the Road. Pass-firemen and shedmen are encouraged to devote their spare

time to riding on the engines of ordinary trains for the purpose of learning the road, and they are paid for doing so according to their rank. When a man claims to be acquainted with any section of road, he notifies the circumstance to the shed foreman, who examines him in respect of the gradients and signals, and, if satisfied, enters his name as qualified to drive an engine between such and such a place in the general route book, and on the route card which each engineman possesses.

The Express Train Driver. In due course the driver of a shunting engine, stabler of all and sundry engines, or shedman, is promoted to be driver of local goods, main-line goods, and passenger trains (including rail motor-cars) respectively, and ultimately the most experienced and intelligent men are selected to drive the express passenger and mail trains. Strictly speaking, there is little difference of rank or pay in the community of passenger train drivers. Needless to say, the best men are selected for the more important posts, but it does not follow that because a man drives the "crack" express of the day, say, from London to Crewe, he does the same in the reverse direction. On the contrary, he may have to work his way to town on a train, or several trains, which call at every intermediate station.

15. BREAKDOWN TRAIN

There is a prevalent misconception that the drivers of the "prides and glories" of the road are treated as superior beings; but from the financial point of view there is little in it. A few companies, like the North-Eastern, which gives a bonus to the driver of an East Coast express, single out the men in charge of the fastest passenger trains for extra emolument, but the general rule is to pay all passenger-train drivers at practically the same rate. There is a large proportion of drivers to whom promotion to the first-class division has no attraction. Such men are quite satisfied when they rule on the footplates of main-line goods and mineral trains; they have no ambition to go up another step. It is a fact, too, that the men forming the pick of the goods drivers earn more than the drivers of the fast expresses, but then their hours are considerably longer, and the work altogether is of a more fatiguing description. Goods drivers earn most in the winter time.

Enginemen and Their Engines. It has ever been the general practice with British railways that in both the passenger and main-line goods services the driver and fireman keep to the same engine for years. In America, however, the practice is "first in first out." Engines are sent out from the sheds in the order in which they come in, and when the enginemen sign on duty they take the first engine that happens to be ready. In America, again, engines are kept in steam or constantly at work for months at a time, and the footplate of each is successively occupied by fresh shifts of enginemen. There is no doubt that the American system has its advantages; the utmost is got back from the money sunk in the construction of locomotives when the latter are seldom allowed to lie idle, and although the life of an engine in such circumstances is much shorter, it is argued that it is really cheaper in the end to build an engine, work it to the scrap-heap, and replace it by another and newer model in two or three years' time, than carefully to tend engines so that they may last for more than a score of years. On the other hand, when the driver keeps to the same engine, he gets acquainted with all its peculiarities, and, therefore, can manage that engine certainly more efficiently, and often more economically, than another. The London and North-Western Railway has long worked many of its passenger engines with double shifts, and one or two other companies have recently adopted the American system where mammoth goods engines are concerned.

Ready for the Road. The driver and fireman come on duty together at the running shed an hour or so before train time. If their hour of duty begins during the night—that is, between 10 p.m. and 6 a.m. (although "night hours" vary with different companies)—they will have been called in good time at their homes by the "knockers-up" attached to the shed. The "bar-nippers" are usually employed as "knockers-up," and when bar-boys do not exist, members of the clerical staff may be entrusted with the duty, or boys who intend entering the railway service as cleaners when old enough are engaged for the purpose. Both men sign on at the time-office, and the driver, either here or at the stores, receives and hands to his fireman the keys which open the tool-boxes on the tender and the padlock round the fireirons. The driver then proceeds to the running-shed office, outside which is exhibited an array of notices which he is expected to read. Every week what is termed a "programme" is issued to the drivers. A programme is a book which tells the driver what parts of the line may be under repair, where new signals are being erected or old ones undergoing alteration, and gives him full particulars as to any altered train-working arrangements. Unless he makes himself well acquainted with the information conveyed by the programme a driver may involve himself in serious difficulties—in other words, "crimes" and "casualties"; therefore, he has always to

certify in writing that he has read and digested the programme. With the exception of those contained in the "water case," which notify the names of stations where water can only be obtained between certain hours, or, perhaps, is cut off altogether, the notices displayed on a board at the office are not so important. They usually refer to details of conduct. Drivers are warned that complaints have been made of unnecessary whistling at certain places, that ashes have been found thrown on to the point rods and signal wires, etc. Some companies make their drivers sign to having read these notices as well; but in any case failure to carry out their instructions is considered a "crime." An engine-driver makes a point of studying the contents of the "water case" first.

Stores Needed for a Trip. The driver then either goes himself, or sends his fireman to the stores, to draw oil, waste or sponge cloths, packing for glands, and the flags, fog-signals, etc., as scheduled in the rule book. Cotton-waste, for wiping down machinery, cleaning the hands, etc., has been almost entirely superseded by the use of sponge cloths, which, when dirty, are sent back to the stores to be cleaned, and so can be used over and over again. Companies which still issue waste generally allow an engineman 1 lb. a week merely for cleaning the hands. The amount of oil which the driver or fireman draws is booked to him. Several different kinds of oil are given out—namely, blended rape-oil for bearings and motion, mixed oil for axle-boxes, cylinder oil for sight feed lubricators, paraffin or colza oil for gauge and head lamps, and when a company employs the Westinghouse air brake, half a pint of special oil for the pump. As a rule, the fireman trims his own lamps, but in some large sheds this is done for him by a lamp-room staff. Not a few companies furnish their engines with destination discs, and the latter are issued from the shed stores.

Another part of the shed has now to be visited by the fireman for obtaining a supply of sand [12], which has been heated in furnaces and otherwise prepared for the road by the sand-driers. Some companies, however, make the stablers fill the engine sand-boxes.

Getting Up Steam. Driver and fireman repair to their engine, which they find awaiting them in a specified place. The engine is in thorough repair, coaled, cleaned, watered, and making steam. Some three or four hours before the enginemen are due to appear, the firebox has been cleaned and arranged by the bar-boys or other members of the shed staff to whom that job is assigned, as already described. The fire-lighters [13] follow the bar-boys, carrying fire in long shovels on their shoulders to the engine, which they insert into the firebox, and subsequently add to it about 1½ cwt. of fresh coal. One of the lighters-up takes charge of the engine until the driver arrives. He looks at it periodically on his rounds, and takes stock of what steam it is making. The time required to raise steam, say, of 160 lb. pressure from cold water will vary slightly, but about three hours is a fair average. This can easily be reduced, but it is not advisable to force the fire, as it tends towards straining plates and causing tubes and stays to leak. On the other hand, if an engine be found to be making steam too rapidly, the lighter-up lowers the damper.

The "Pit" Examination. The first act of the driver is to ascertain whether the engine is in complete repair, which is done by examining it over a pit, where it is placed in such a position that every part may be scrutinised without moving the machinery. The driver descends into the pit, and proceeds to oil all bearings, slide bars, and eccentrics, to wipe or renew trimmings if necessary, and to inspect the motion as closely as possible to discover any defects, doubtful parts being struck with a hammer, when any oil that may have lodged in a crack will ooze out and reveal the mischief. Special attention is paid to the crank axle, or "big end," as this cannot be got at while running. Sensational pictures are often published which depict drivers performing hair-breadth feats in oiling their engines when running at high speed. Some companies set their faces sternly against the practice. They wish it to be understood that sufficient time is always allowed a driver to oil his engine while at rest; and if he has to go "forward" on the road, it implies negligence on his part while in the shed.

Meantime, the fireman is cleaning the firebox, front and interior of the "cab," making up his fire to ensure a good head of steam, testing the feed injectors, looking to the tubes, and seeing that the ashpan and smoke-box [14] are clear of ashes.

Finishing Touches. On the driver returning to the footplate, the fireman and he test the gauge cocks to see if the water level is accurately shown in the glass. Afterwards the fireman prepares the coal by breaking it up to a convenient size for firing, and sprinkles it with the hose to lay the dust. The driver sees that the coal is not stacked too high, and that there is no danger of the coal, fireirons, tool-boxes, etc., falling off while running. With the huge engines and tenders now in vogue, it is no longer possible for the fireman to clamber about the tender without running the risk of being struck down when passing under a bridge or entering a tunnel. Consequently, the new pattern tenders are equipped with tool-boxes inside the tanks, and the inside of the latter are arranged so that the fuel is constantly slipping down where it is within reach of the fireman plying the shovel on the footplate.

Before leaving the shed the lubricator is filled with oil and the steam applied, so that all the water chambers may be filled up gradually without disturbing the oil; the tanks are replenished at the water crane, and as the engine steams gently out, the vacuum, compressed air, or steam brake, is practically tested.

Drivers are usually allowed from forty minutes to one hour between booking on and whistling out of the shed, and an engine generally leaves the shed for the train about half an hour before the

booked time of departure. When an engine leaves the shed punctually, the traffic department is held to blame if there be any delay in reaching the train. On coupling on to the train, the driver ascertains from the guard what number of vehicles and wheels he has behind the tender, so that he may be guided how to work his engine with due care and economy.

Express versus Goods Train Driving. The art of driving an engine is such a vast subject that it would be futile to attempt to convey any directions in a short article of this kind. We may say, however, that it is incorrect to suppose that a higher degree of skill is required to drive an express train. Every vehicle composing an express train is furnished with an automatic continuous brake, the weight behind tender is limited, the fuel is of the best, and the road is specially cleared for the express. Of course, there is an enormous sense of responsibility about the charge of an express, or, for the matter of that, every passenger train. Nevertheless, all practical enginemen will concur in the truth of the statement that goods and mineral trains which, with the increase of engine power have grown to loads of 60, 70, and sometimes 100 waggons, require more careful handling. With them the enginemen are handicapped by slack couplings and strictly limited brake power, which necessitates great finesse in negotiating the ever-varying gradients of the road, if couplings and drawbars are to be kept intact, and the train is always to be under perfect control, to pull up not only at appointed places, but also for signal checks. And the latter are of frequent occurrence in the working of goods trains.

The Driver on the Footplate. The driver's place on the footplate is in a corner, where he has the regulator, reversing gear, brake lever, and whistle under his hands, and commands as good a view as is possible through the window of the cab of the track and signals. The rule of the road prevails on British railways —trains run on the left; but it is a topsy-turvy arrangement that makes the driver occupy the coachman's place on the "off" or right-hand side. The pioneers of railways were responsible for this relic of the turnpike. Platforms and signals are on the left-hand side; the engine-driver has not to use a whip, and the guidance of his steed over the points is in other hands. Manifestly, the sensible arrangement therefore would be to place the driver on the left. One or two companies have effected this transposition. The London and North-Western long ago rearranged the engine gear for driving on the left, and the London and South-Western is following suit.

The driver is responsible for obeying the instructions of signals; his vigilance in this respect must never be relaxed, and overshooting or mistaking signals is considered about as serious an offence as a man can commit. The fireman has also to assist in keeping a look-out for signals when not otherwise engaged. Some companies make it a rule that the fireman is to stop firing when approaching an important junction or station in order to do this. However, looking into a blazing fire causes temporary blindness or colour blindness, hence there is a danger of firemen being unable to distinguish colours when necessary. On the London and South-Western Railway an important part of the footplate equipment consists of a small circular disc of purple glass, set in a metal frame. The fireman makes use of this appliance when looking into the firebox to ascertain the condition of the fire, the purple glass having the effect of neutralising the glare.

Enginemen's Links and Barracks. Drivers and firemen are arranged in what are termed *links*, meaning that certain men are kept to certain sections of the road. It is, of course, absolutely necessary that enginemen should be thoroughly familiar with the road on which they travel—the gradients, signals, sidings, stations, etc.—and this can be ensured only by restricting their field of work. The ideal, or, at any rate, simpler arrangement would be that enginemen should be able to return to their homes at the end of each trip. But this is far from being generally possible. There are what are termed "double home trips," "lodging turns," or "lodging-house jobs," which are specially favoured by certain companies, as they are supposed to yield more mileage in a given number of hours. Originally, "double home trips" were practically confined to the men working goods and mineral trains, but now the tendency undoubtedly is to extend the practice to passenger enginemen. Many companies provide splendidly equipped model lodging-houses or "barracks" at strategic points on their system for the accommodation of men who are unable to get back to their homes without working unduly long hours. The Great Eastern Company's barracks at Stratford, and those of the Midland at Kentish Town, are specially famous, and for some years past it has been the custom of the former company to supply all men who are detained therein over Christmas Day with a good dinner of old English fare. A man is paid for being in barracks 1s. 6d. in London and 1s. in the country per night. When there are no barracks each man is given a lodging allowance of 2s. 6d., and if lodged 18 hours or over 5s. is usually paid, although some companies do not allow the double rate for less than 24 hours. Some companies, however, have a list of approved lodging-houses as well, the landlords of which take in railwaymen for 1s. 6d. a night.

On "short trips," when an engine is not stabled, but waits in the yard for a few hours till the time arrives for starting on the return journey, the men may not leave the company's premises, and sometimes they may not even quit their engine without the authority of the district locomotive superintendent. The strenuous nature of modern railway business is evidenced by the fact that some companies "hustle" to the extent of employing such waiting train engines on shunting.

The End of a Trip. On returning to his own shed a driver hands over the engine to a stabler, and at once proceeds to the

office, where he makes out his returns for the completed trip. In these returns he specifies any irregularities, such as time lost, untoward occurrences, etc., and enters in a special book the character of any repairs he may consider necessary for the information of the foreman fitter. In any case, before an engine resumes work an examining fitter makes an independent investigation. The driver files the counterfoils of any water and coal tickets which he may have given to a foreign company, in the event of his having had to replenish those commodities when travelling off his own territory. At the stores his fireman hands back the sponge cloths, lamps, discs, flags, fog-signals, etc. Lastly, the two men repair to the time-office, where they hand in their keys and sign off. At the time-office they learn at what hour they are due to return to duty. Enginemen have different hours of duty nearly every day, in order to equalise the roster of turns and ensure them plenty of rest in between. The period for rest allowed between each trip is never less than nine hours.

Enginemen's Spells of Duty. Enginemen work either by the day or by mileage. Ten hours usually constitute a day's work, but with some companies it is eight hours, and with others, again, as many as eleven. Overtime is paid for, as a rule, at the rate of eight hours per day, and Sunday work reckoned at time and a half. When men work by mileage, 150 miles is almost everywhere conceded to be equivalent to a day's work on passenger trains, and 120 miles with goods, but mileage working is not often applied to the goods traffic. Thus, a Midland driver taking a passenger engine, say, from London to Nottingham and back (248 miles) receives pay for one day and six hours on the ten, but his number of trips per week are limited to four. Passenger train drivers seldom work more than four days, in the ordinary sense, per week.

Remuneration of Enginemen. The maximum pay of a passenger train driver—apart from bonuses and coal or oil premiums—is at the rate of from 7s. 6d. to 8s. per working day, while a first-class passenger fireman is remunerated with from 4s. 6d. to 5s. per working day. Enginemen are given a small annual clothing allowance, and leave with full pay for a certain number of days in each year, according to their length of service. Some companies do not pay their men while on leave. Owing to the high rents in London, enginemen residing in the metropolis are allowed a few shillings a week extra as rent money. Further, all enginemen are annually allowed one or two free passes on the railway, not only for themselves but for their wives and children as well.

Promotion from the footplate is of rather rare occurrence, but a really smart, well-educated, and trustworthy engineman may at least contemplate a field of advancement of fairly wide scope. He can rise to shed foreman or locomotive inspector, each of which posts carries with it a salary of £150 to £250 per year. The duties of an inspector are to investigate the running of engines, ride on the footplate with pass-firemen who are acting as drivers under examination, accompany royal and other high-class special trains, and report upon the trial trips of new locomotives.

Colour Blindness a Fatal Defect. In explaining the various grades of a footplate career we have not, perhaps, sufficiently emphasised the frequency and severity of the examinations for sight, both colour and distance. At every step of the ladder this test is imposed, and when a man becomes a fully-fledged driver it takes place periodically—namely, every two or three years. Few companies employ drivers over 60 years of age, and those that do so examine them annually. In any case, men over 60 are hardly ever allowed to continue in charge of express trains.

Washing Out Engine Boilers. One of the most important operations that takes place in engine sheds is "washing out" engine boilers. Every engine has its boiler washed out at least once, and more often twice, a week, when untreated water is used. The chief ingredients in boiler scale are sulphate of lime and carbonates of lime and magnesia, and a deposit of $\frac{1}{16}$th of an inch will cause an increased consumption of fuel of some 20 per cent., owing to the non-conducting character of the deposit.

The treatment is as follows: First, the smokebox [14] is cleaned of ashes, so that the plugs can be easily taken out, and no ashes find their way into the tubes. The engine is then placed over a pit, and the leaden wash-out plugs removed. Where hot water is used for cleaning, a steam pipe runs along the shed, conveying steam from a boiler to a high-pressure injector, which is equipped with flexible delivery connections of metallic hose piping and suitable nozzles for directing jets of hot water at high pressure through the different plug-holes of the boiler. Whether hot or cold, the higher the pressure of the water the better the result. Then the tubes have to be cleaned by raking them through with long, stiff wire rods, and streams of water must be directed among the tubes, stays, etc., to ensure the dislodgment of all loose pieces of scale. Finally, the glands are repacked, and the ashpan and damper put right.

The Breakdown Train. A breakdown train [15] is stabled at every running shed. It comprises tool vans, containing an assortment of jacks for lifting weights up to 40 tons, and all manner of instruments for clearing away débris and converting chaos into order. One of the vans, also, is equipped with ambulances and first-aid paraphernalia. In the centre of the train is a long eight or six wheeled truck, on which is mounted a powerful steam crane, whose boiler is always kept warm. The breakdown gang is furnished from the running-shed staff. It is divided into a regular and reserve gang. For ordinary jobs the services of the regular gang alone are requisitioned.

FORESTRY AS AN INDUSTRY

The World's Timber Supply. Its Possible Failure. Home-grown British Timber. An Industry of the Future. The Problem at Home and how it is Dealt with Abroad

By HAROLD C. LONG, B.Sc.

FORESTRY is a science which has for its ultimate object the discovery and application of such principles as will ensure the growth of the greatest amount of useful timber on a given area. The position of forestry, by which we mean here economic forestry, in Great Britain has long exercised the minds of some of our greatest and most enlightened landowners, members of Parliament, educational and commercial authorities, and many who are devoted to the subject for its own sake; but so far the results, though constituting an important beginning, are comparatively small.

In Germany, France, and some other European countries, forestry has long been treated methodically as an industrial science, and has received every attention. In fact, most continental countries are far ahead of Great Britain and Ireland in respect to the care of their wooded areas.

The splendid forest service in India may be said to have begun with the appointment, in 1856, as Superintendent of Forests in Pegu, of Dr. (now Sir) Dietrich Brandis, who eight years later was made Inspector-General of Forests for India. Since then the service has developed into a great organisation, dealing with some 200,000 square miles of forest lands, and producing a net revenue of about £600,000 per annum.

The World's Timber Supply. Some useful work is now being done in this country in instruction in forestry, and a scheme of instruction has been started in connection with the Forest of Dean. The Alice Holt Forest, in Hampshire, comprising some 1,800 acres, is also now being taken in hand by the Commissioners of Woods and Forests, and is in future to be managed on scientific lines, being also used as a demonstration area.

It is a well-established fact that many of the forest areas whence the chief supply of the British Isles is drawn are gradually becoming depleted. This is one of the most important and urgent reasons why close attention should be given to the question of providing an increased home-grown timber supply. According to M. Melard, Inspector of Forests in France, only seven countries are now able to supply large quantities of timber, these being Norway, Sweden, Finland, Canada, the United States, Austria-Hungary, and Russia. Increase of population and commercial development seriously threaten the available surplus of the three latter countries, the Norwegian supply is being dangerously reduced by a too free use of the axe, while the remaining sources of supply are quite insufficient. Forest lands have been rashly destroyed, it being forgotten—even if recognised—that no more than the annual production should be cut, and that it takes something like 80 to 100 years to produce timber fit for the sawyer. M. Melard believes, in common with some others, that a timber famine will begin before fifty years are past.

The Possibilities of the British Isles. For some years past a sum of over £25,000,000 per annum has been paid by this country for imported timber of all kinds, the major portion of which is coniferous, and, as experts agree, might be grown at home. The yearly value of the present utilised home-grown timber, chiefly used for estate purposes, cannot be even roughly estimated, but it is undoubtedly but a small fraction of our requirements, and yet we have far more than sufficient land to produce the necessary coniferous timber without a single acre going out of cultivation. It has been shown, on the highest authority, that there is in these islands a very large area of waste, heather, and rough pasture or land out of cultivation, amounting to 21,000,000 acres, a large proportion of which is suitable for profitable afforestation. According to Dr. Schlich about six to seven million acres would produce the whole of the timber (ordinary species) required which is now imported, and, with 21,000,000 acres from which to choose, the afforestation could undoubtedly be gradually accomplished.

The Waste Lands of Ireland. Although during the past thirty years there has been a steady increase in the area of woodlands in Great Britain, yet the progress is by no means rapid, while it is stated that in Ireland only 1½ per cent. of the acreage is under woods, 24 per cent. of the land area is uncultivated, and yet some 2,000,000 acres of the total waste land could be made available for afforestation. Professor Fisher, in a lecture on Forestry, given before the Royal Dublin Society, March 3rd, 1899, says: "Tenants and graziers who would oppose the planting of 2,000,000 acres of the waste lands of Ireland must be an extremely short-sighted people; the greatest of all wants in Ireland is an investment of capital of this kind, an investment which will yield an enormous return in affording labour to the people, and in supplying raw material for industries which cannot prosper without it, as well as timber for export, and for the improvement of farms and dwellings." On a different scale these words apply to Great Britain, the percentages of the woodlands to the total areas of England, Scotland, and Wales being about 5·1, 4·5, and 3·8 respectively.

Even where land of little or no value for any other purpose has been employed, the cultivation

of timber trees has brought excellent returns. On some estates in Great Britain the returns for a number of acres over a long series of years have averaged from 20s. to 30s. per annum, but the income is usually very much less, and, regular forest bookkeeping not being general, numerous statistics of cuttings are not available, while the production has not been so good as it would have been under proper management.

Examples from Other Countries. To take a German example (see Departmental Committee Report on Forestry, 1903), the average growing stock of 4,072 acres, in the Erzgebirge (Saxony), of which 93 per cent. was spruce, amounted to 2,128 cubic feet per acre in 1839, and to 3,276 cubic feet in 1893. The receipts were 48s. 4d. per acre, and the expenses 10s. 4d., the net receipts being no less than 38s. per acre per annum. Yet this very land was worth no more than 4s. per acre for agricultural or pastoral purposes.

It is maintained by Sir Herbert Maxwell that Scotch hill sheep pasture, which, as sheep pasture, yields only two or three shillings per acre, would, under correct management, yield a revenue of 37s. 6d. per acre. The same authority says (Journal of the Society of Arts, March, 1905): "It is estimated that there are 3,000,000 acres of woodlands of sorts in Great Britain and Ireland. In Belgium there are only 1,750,000 acres, yielding a return of £4,000,000 a year. At that rate British woodlands ought to yield £7,000,000 a year."

In Switzerland the Sihlwald, a forest owned by the city of Zurich, yields an annual return of about 32s. per acre. This area has been managed by the city for some hundreds of years.

In France the net annual yield from the forest area is approximately 10s. per acre.

In Great Britain the State woodlands amount to over 66,700 acres, or 2·2 per cent. of the whole area. In Germany, on the other hand, where examples of forest management form a feature of Government forests, there are some 35,000,000 acres, of which 33 per cent. belongs to the State, the whole being managed on a definite and scientific business basis for profit and instruction. In a similar way, but to a less pronounced degree, almost all civilised States own forests managed on modern lines, and, as we shall see later, many have forest schools.

An Idea for Municipalities. The planting of catchment areas by various local bodies having control over lands for water supply purposes might help considerably in the direction of afforestation. The Departmental Committee appointed by the Board of Agriculture in 1902 to inquire into and report upon British Forestry recommended that the attention of corporations and municipalities should be drawn to the advantages and profits to be derived from planting their catchment areas. It was pointed out that such planting would ultimately aid in the retention of water which fell as rain, and thus assist in regulating the water supply and in preventing floods, while at the same time forests would tend to the purification of the domestic water supply. The afforestation would naturally lead to monetary returns. The recommendations of the Committee have, with the assistance of the English and Scotch Local Government Boards, been brought to the notice of all the local authorities of England, Scotland, and Wales. The Corporation of Birmingham have allocated about 1,000 acres for plantations, to be planted principally with larch, Scots pine, and spruce. The Liverpool Corporation waterworks have about 600 acres of woodlands on a catchment area of over 20,000 acres and are still planting, having established their own nurseries in which to raise the young plants. Other local authorities are planting on a small scale or are considering the question. The water supply from wooded catchment areas is in general purer and clearer than it would otherwise be, reducing the expense of filtration, while it is not likely to silt up reservoirs.

This part of our subject would not be complete without some reference to the rating of woodlands and plantations, for the rates may bear an important relation to the afforestation of lands. Indeed, it is almost certain that some landowners have been dissuaded from establishing plantations on account of a misunderstanding of the rating.

Rates on Woodlands. The following extracts from a leaflet issued by the Board of Agriculture and Fisheries (*Leaflet No. 8, Assessments to Local Rates*) put the matter very clearly. In referring to the Rating Act, 1874, it is stated that:

"Under this enactment it is the land, and not the timber, underwood, or other produce of the land, which is made the subject of assessment. It would seem that if land used as a plantation or a wood, or for the growth of saleable underwood, is subject to common rights, it is exempt from the poor rate and other local rates. The method of estimating the gross estimated rental and rateable value of such woodlands is prescribed by Section 4 of the Act, and is as follows:

"(*a*) If the land is used only for a plantation or a wood, the value shall be estimated as if the land, instead of being a plantation or a wood, were let and occupied in its natural and unimproved state.

"(*b*) If the land is used for the growth of saleable underwood, the value shall be estimated as if the land were let for that purpose.

"(*c*) If the land is used both for a plantation or a wood and for the growth of saleable underwood, the value shall be estimated either as if the land were used only for a plantation or a wood, or as if the land were used only for the growth of the saleable underwood growing thereon, as the assessment committee may determine.

"Land of the kind described in paragraph (*a*) should be assessed as if it were divested of timber or wood of any description, and its value determined without taking into account any improvement which has been made, or of which the land might be capable. In other words, the land should be rated as if it were waste land."

The Influence of Forestry. A beneficial influence is also exercised in connection with the soil, climate, the erosion of hillsides, and protection from the force of the wind; in all these directions there can be no doubt that immense service is rendered by wooded areas. In the United States of America the necessity of forest preservation for the continued prosperity of the nation was keenly discussed and insisted upon by many authorities at the Forest Congress held at Washington in the first week of January, 1906.

Forest trees remove less food material from the soil than do agricultural crops, the major portion of the food supply being taken from the carbonic acid gas of the atmosphere [see CHEMISTRY]. For this reason, among others, forest crops may be grown continuously on the same soil over long periods of time. The system of coppice woods is, perhaps, the most exacting. Soils under forest management are also rendered more retentive of moisture, which can percolate more freely than on ordinary soils, while it is not so readily evaporated. Binding of light soils takes place under forest cover, while heavy soils are ameliorated and opened. The erosive effects of heavy rains are to a large extent obviated where there is a close canopy of trees, rain being successively retarded by crowns, stems, roots, and the covering of humus. The uses of afforestation in this connection are well seen on the mountain sides of Switzerland, France, etc., where the services rendered by woods in such positions in giving protection against avalanches and floods are invaluable. Under close canopy the soil is kept practically free from weeds.

The Climate and Forest Areas. The influence of forest areas relative to climate is often, perhaps, liable to exaggeration, the actual differences in temperature between cleared and afforested areas being in general but slight. But extensive forests undoubtedly tend to render the climate of a country more equable, the temperature of the air and soil being slightly lowered in summer and raised in winter. It has been stated that on the average of eleven German stations the July temperature of the surface soil in the forest was found to be 7° F. lower than that in the open field, whereas in December the forest soil was rather warmer than that in the open field. Forests also tend to increase precipitation of moisture.

Narrow strips of woodlands are frequently planted to afford protection not only to fields and orchards against cold and dry winds, but to exposed villages and towns. These "shelter belts," as they are termed, also serve as shelter for livestock, game, and wild birds. Such belts of trees are also utilised to break the force of high winds, and so protect the woodlands proper. Especially is this to be seen on certain open coast lines, where the wind-swept appearance of the marginal trees on the windward side of woods and forests is often well marked.

Labour and Forestry. In Great Britain the influence of forestry on labour is very small, but in some countries it is of vast importance. In the United States and Canada the lumber trade and allied industries give employment to a great number of workers. In Germany many industries depend entirely on the forests for their existence. The wages earned under forest work proper, and the industries dependent thereon, in Germany, run into many millions of pounds sterling per annum, while some 10 per cent. to 15 per cent. of the population are engaged in work connected with forestry. Among the numerous allied industries may be mentioned turning, matchmaking, wood-pulp manufacture, drum and cask hoopmaking, and the manufacture of shovels, shoes, barrows, etc. Compared with agriculture generally, forestry gives much less employment per acre, Schwappach stating ("Forestry," translation by Story and Nobbs) that in Germany arable farming employs one man for 10½ acres, while forestry requires only one man permanently employed for 308 acres. Yet more persons would be required per 1,000 acres of woodland than per 1,000 acres of hill sheep pasture, it being stated by the Departmental Committee [see Section 1] that whereas Scotch hill pastures quite capable of producing high-class timber appear to employ but one man to 1,000 acres, the same land if planted would require the services of one forester per 100 acres, quite apart from the men necessary to cut and remove ripe timber and those employed in the various trades arising from the proximity of forest lands.

Effects of Natural Agencies on Forests. In its turn, forestry is largely affected in any district by certain natural agencies which determine the character of the trees which may be planted with most advantage. It may briefly be stated here that the character of a forest area depends to a great extent on the soil and subsoil, and on aspect, elevation, and climate. The species of trees which will grow best under the same general management (after being established) will depend very much on such factors as those mentioned; the species, in fact, will differ accordingly as the land lies high or low, is open and bleak, or sheltered and mild, is porous or retentive of moisture, or is gravelly, chalky, clayey, or loamy. For example, the oak requires a fairly deep soil, while the spruce will do well on a shallow soil; the alder is suitable for very wet situations, while Scots pine occurs and flourishes on very dry soils; spruce grows at a greater elevation than almost any other of our forest trees, and poplar is found only at comparatively low altitudes. In other words, "locality"—meaning soil or climate in relation to tree growth—governs the species, and species largely determines the character of the wood or forest.

SENDING TELEGRAMS

Practical Telegraphy. How the Traffic is Handled. The Speed of the Telegraph. Sending and Receiving Messages

Continued from page 4886

By D. H. KENNEDY

Traffic Routes. Before dealing further with the instrument-room, it will be well to explain that the general system of dealing with telegraph traffic is closely analogous to that for railway passenger traffic. Small towns have lines to large towns, large towns have direct lines to all other large towns within a reasonable distance. Here it has to be remembered that as the distance increases the cost of providing and maintaining the line increases, but the sixpenny telegram is still the sixpenny telegram. Every large telegraph station is therefore a junction where messages change lines.

The route of a message is called its *circulation* and a good knowledge of circulation, and therefore, to some extent, of geography, is a desideratum for every telegraphist. It is, moreover, the special stock-in-trade of the youthful collectors.

Circuits. Now let us examine the arrangements of the *circuits* in the instrument-room. *Circuit* is the generic title given to any set of apparatus when in use for communication. In the centre, obviously for maximum accessibility, are the numerous London wires. There are eight or ten for commercial work, and three or four for receiving "News." Wires used exclusively for receiving Press messages from London are always called *news wires*.

One end of the room, let us say west of the London wires, is quite taken up with short distance local wires, while the east end is fitted up with wires to other large centres. We may call them *main cross-country* lines.

Just behind every receiving instrument there is a wire basket mounted on a pedestal rod, on which the telegraphists place the messages they receive; and again at the sending position for every town we see a narrow, deep little box, open at the top and at one end, into which the messages to be sent are frequently being placed. After this glance around, let us return to our learner. What are his sensations on coming into closer touch with the mystery of the electric telegraph?

Speed of the Telegraph. One novel and thrilling experience comes to every young telegraphist. It is the moment when he realises how complete is the annihilation of time by electricity. Even in the school he has speculated and experimented as to what was the actual interval between putting down the key and the response of the sounder; and if he *did* admit that it was too short for his powers of observation he mentally added that the distance was very short, and he resolved to repeat the experiment under other conditions when the opportunity should arise. Now it has come. He sees a telegraphist working on a circuit marked "Aberdeen." Here is a long wire, and he watches to note the interval between the Englishman's last signal and the first of the Scotchman's response. The sound of the key is still in his ears when the sounder is rattling out the reply. The learner mentally collapses. How long does it take to send a message some hundreds of miles? Merely the time necessary to signal it. He is quite stunned, and after slowly adjusting his mental conceptions he realises that telegraphy is practically instantaneous, and that the time consumed in the transmission of a message is all taken up in the handling and the formation of the signals.

He is now put in charge of a sounder circuit, working to a suburban office, and he has time to notice the methods adopted for handling the traffic so as to reduce delay to a minimum.

Messages. The messages handed in by the public are written on white forms with a big "A" in the left-hand corner. They are not always legible, and the counter clerk has to make them so. Messages received from one station to be forwarded to another are written on "B" forms—thin, yellow forms never seen by the public. Messages received at a station for delivery are written on "C" forms. These are in duplicate, and the under, or carbon, copies, go to the public.

All the writing is done with pencil, and both the "B" and the upper "C" forms are divided into five spaces per line, and one word must be written in one space, and no more. This facilitates counting, and prevents the dropping of a word.

When the telegram is handed in, the counter clerk inserts the "Code time," the "Office of Origin," and the number of words. It is immediately despatched to the instrument-room, probably by a pneumatic tube. In the instrument-room it is taken up by a collector and carried to the proper circuit. If other messages are not waiting, or in course of transmission, the telegraphist takes it up at once. He must first look at the address, and decide what the prefix will be. If it is to be delivered from the office he is working to, it will be prefixed "S." If it is to be sent on, it will be "X."

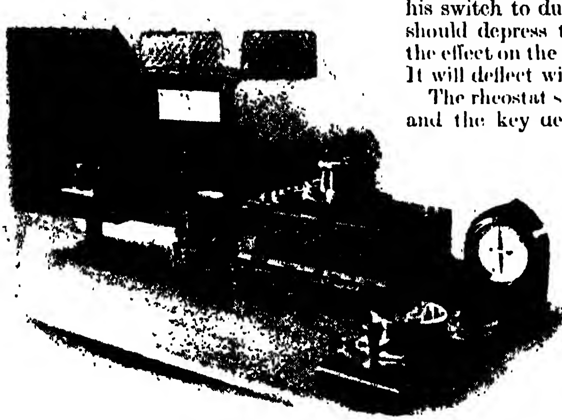
Sending a Message. When his first "A" form arrives, our new hand calls up the suburban office by signalling the prefix. In this case it will be "S," as suburban stations are never transmitting stations.

On *omnibus circuits* the station must be called by repeating the code of the station required three times, and then the code of the calling office. A *called* station replies by signalling its code, followed by the sign — — .

The sub-office signals — —. The message is then signalled in this order: Prefix, Code, Office of Origin, Number of Words, Address, Text of Message, Name from (if any), concluding with the understand signal . . . — .

The receiving telegraphist counts the words as he writes them, and immediately on the completion of the message replies by the acknowledgment signal . — . — . . The "time sent" is then inserted on the "A" form, together with the code of the distant station, and the initials of the sending clerk. The sent messages are placed on a hook under the wire basket, whence they are collected at intervals.

The School Sounder Circuit station had only two pieces of apparatus, but in actual practice a third is always present, namely a galvanometer [12]. A galvanometer is not absolutely necessary, but it is a very useful adjunct. Normally the needle remains vertical. When the key is depressed the needle should deflect to the *right*, and when signals are being sent it continues to oscillate backwards and forwards. Should it suddenly cease to do so, the inference is that the wire has become disconnected at some point. At other times, when calling fails to obtain a response from the distant office, it may be noted that the oscillation of the galvanometer needle is much more vigorous than usual. This is probably due to the fact that the insulation of the circuit has broken down at some point. In either case the telegraphist reports the fact to his superior, who will invoke the assistance of the test clerk. The complete designation of the circuit we have been dealing with is "Direct Sounder, Single Current."



10. DOUBLE-CURRENT DUPLEX CIRCUIT

The Relay. Direct sounder working is possible only on the very shortest lines. For all others it is necessary to employ relays. Relays [11] are electromagnets of special construction, sensitive to very small currents. The currents received from the distant office actuate the relay, which in turn controls the sounder. The working adjustment of the relay is made by means of the milled screw seen on the right side.

On single-current circuits the relay should be adjusted as follows. Turn the adjusting screw to the right (marking) until the sounder armature goes down, then turn back to spacing until the armature of the sounder rises. The relay is now in its most sensitive position for single-current working.

The Duplex. Next to the direct sounder, we find a circuit working to a much busier suburban office. It is of the same type, except for the fact that it has been modified to work "duplex."

In addition to the key, sounder, and galvanometer, there is a relay and a rheostat which has a movable top; also a switch for altering the arrangement from simplex to duplex, or vice versâ, as required.

The theory of the duplex system is dealt with in the electrical engineering section, but simple directions for adjusting a circuit to work duplex can be given.

Balancing a Single-current Duplex. The controlling office decides when duplex working is necessary, and instructs the other station by a service message. Both stations turn their switches from "simplex" to "duplex." The controlling office operator proceeds to "balance."

The rheostat is of the metropolitan pattern. The top, which is graduated 0, 25, 50, and so on, can be turned round so as to bring any desired figure opposite a pointer which is fixed on the side of the brass frame. Normally, the zero is at the pointer. After turning his switch to duplex, the telegraphist should depress the key, and observe the effect on the galvanometer needle. It will deflect widely to the left.

The rheostat should now be turned, and the key depressed at intervals. As the figures increase it will be found that the deflection to the left gradually decreases, and, finally, when the right point is reached, the depression of the key has no effect on the needle at all. If the rheostat be turned beyond this point the galvanometer needle will deflect to the right, the deflection steadily increasing as the figures on the rheostat increase. The highest figure on the rotating top is 225, but this can be supplemented by 300 and by 600, which are added by *withdrawing* plugs from their normal position between the brass blocks on the front of the wooden case.

The name of the unit of resistance to which these figures refer is the *ohm*. A useful mnemonic connecting the deflection of the galvanometer and the adjustment of the rheostat is given by the two words "Right, Reduce." When the controlling office has balanced, the same operation is performed at the "down" office, and working can then be commenced.

Duplex Working. Of course, two operators at each end are now necessary, and they must be fairly expert if the work is to proceed smoothly. Let us call the head office men A and Y, and the out-station men B and Z. A and B are at the keys while Y and Z are receiving. The latter are provided with long, narrow RD

slips on which they must write the "name to" of each message as received. When Y is ready, A gives — — ., and a similar signal is given B for his colleague. The senders then proceed steadily for quarter-hour periods, usually disposing of about ten messages of average length. If, say, Y fails to read a word, he informs A. A immediately signals . — . — — . —, giving the last word which Y has written. At the quarter-hour periods the names on the "R D" slips are counted, and totals exchanged, thus A will signal, "Total, ten Brown," and B thus, "Total, nine Jones." The figures refer to the number of messages received during the quarter-hour, and the name is that of the addressee of the last message. If these are correct, each gives . — . — . ., and work is then resumed for another quarter-hour. If the total be incorrect, the names on the acknowledgment slip are signalled, and the missing name found and accounted for.

The galvanometer indications should be properly understood. As already stated, when signals are being sent in only one direction, the galvanometer at the sending station remains vertical. At the receiving station it deflects to the right when a *mark* is being received, and, of course, oscillates backwards and forwards under the influence of a series of signals. Should the line become disconnected, the depression of the key causes the galvanometer needle to deflect to the left vigorously. On the other hand, vigorous deflections to the right indicate that the insulation of the circuit has failed at some point.

Main Line Circuits. Now let us look at some of the longer sounder circuits—the main cross-country lines. These are all worked on the *double-current* system. The main difference to the operator is the substitution of the light single-current key by the heavier double-current pattern [10].

The double-current key is provided with a switch marked, "Send, Receive." When working, the handle must be turned to the appropriate position. It follows that on double-current simplex circuits, once a message has been commenced, the sender cannot be interrupted by the receiver, as in single-current working. Any repetition must therefore be obtained after the completion of the message.

11. POST OFFICE STANDARD RELAY

What has been said as to galvanometer indications in the case of single-current working applies equally to the double-current system, if the difference between the two methods is kept in mind. In single-current working, the signals are made by successive impulses of current, which traverse the circuit in the same direction, and in the interval between successive signals no current is flowing. In double-current working, instead of the "no current" interval for spacing, the key is arranged to send spacing currents opposite in direction to the marking current. The observant telegraphist will note that the space deflection is to the *left* and the "mark" to the *right*. The latter, of course, is in agreement with single-current working.

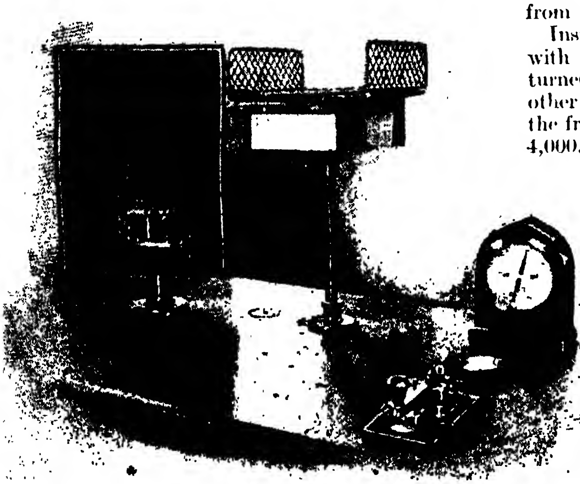
Balancing a D-C Duplex. To duplex a D-C circuit, the procedure is similar to the S-C case, with the following slight modifications. The key switches at both stations are turned to "send," and left so permanently. The galvanometer needle, instead of balancing in the centre, will take up a position about 40 divisions to the left. The "Right Reduce" rule holds good. The rheostat is larger than the metropolitan pattern. This style is called *rheostat* "*C.*" It can be adjusted to any figure, advancing from 0 by 10 to 8,430.

Instead of a rotating top, it is provided with two radial arms. One of them can be turned from 0 to 400, advancing by 40; the other from 0 to 4,000, advancing by 400. On the front there are three brass plugs marked 4,000, 20, and 10. Thus, to make up 6,670, we have:

Brass plug withdrawn from front	4,000
One radial arm turned to front	2,400
,, ,, ,, ,, ,,	240
Brass plug withdrawn from front	20
,, ,, ,, ,, ,,	10
Total	6,670

The balancing should be carried out in the methodical manner already described.

The Condenser. The large wooden box on which the rheostat



12. DIRECT SOUNDER WITH GALVANOMETER

is placed is a *condenser*. At one end there are half a dozen brass plugs. The capacity of the condenser is increased by *inserting* the brass plugs so that they connect two adjoining brass segments. The segments are marked 2, 1, ·5, ·25, and, again, 2, 1, ·5. By inserting various plugs, it is therefore possible to vary the capacity from ·25, advancing by ·25 to 7·25. The unit of capacity to which these figures refer is called the *microfarad*. To adjust the capacity, depress the D-C key, and observe if there is any effect on the sounder just at the moment of depression. If a dot be formed, the capacity must be increased till this effect disappears. If, on the other hand, no dot be formed on depressing the key, but just when it rises, then the capacity of the condenser is excessive, and must be reduced.

Fault Indications. It should be mentioned that in the event of the line becoming disconnected, the signals sent on the key at each station are given out by the sounder, but reversed, while a sudden breakdown of the insulation of the line will have the effect of causing the sounder at each station to repeat the key signals, or, in telegraphist parlance, one "gets their own marks." The great bulk of the main cross-country telegraph work in this country is done on the double-current duplex circuits, and every effort is made to provide a sufficient number of circuits between towns to carry the traffic without delay. The delay in each office is limited to ten minutes. In any cases where this is exceeded the sending telegraphist must state the cause on the back of the form.

Roundabout Routes. It is, of course, obviously deducible from this that the time taken to transmit a telegram is proportional to the number of offices through which it has to pass, and this is approximately true. From this fact, and the circulation arrangements already described, it sometimes curiously results that two places which may be quite near geographically are very badly situated telegraphically. One such case may be instanced.

Two villages on a main line of railway running east and west are four miles apart. They have no direct communication. One of them is connected to the eastern terminus of the railway, viâ one intervening office, and the other to the western terminus of the rail, viâ two transmitting offices. The main terminal offices are connected, so that a telegram from one village to the other has to pass through five transmitting offices. It need scarcely be added that such telegrams are very rare, or better arrangements would be made.

Traps for the Unwary. Frequent transmission is to be avoided, not only in order to save time, but also to avoid inaccuracies. Every effort is made by the department to secure accuracy, and mistakes are always traced home, if possible, and the misdoer punished or cautioned. But pitfalls are numerous, and the most careful clerk trips occasionally. Probably the majority of the errors are due to bad writing, but the following examples show what care is necessary to avoid errors in signalling. Compare the following pairs:

Cash —·—· ·— ··· ····
Cases —·—· ·— ··· · ···
Bad —··· ·— —··
Dead —·· · ·— —··
Satin ··· ·— — ·· —·
Sateen ··· ·— — · · —·
Calls —·—· ·— ·—·· ·—·· ···
Calais —·—· ·— ·—·· ·— ·· ···
Hall ···· ·— ·—·· ·—··
Half ···· ·— ·—·· ··—·

One example of an error due to indistinct writing may be given, because it is both true and amusing. The head of a syndicate controlling provincial music-halls was considerably mystified by a telegram from a provincial manager, asking him to "send two good twins on Monday." He was, no doubt, much relieved when, on inquiry, it transpired that "turns" had been, in transit, turned into twins, and that artistes, not infants, were wanted.

PICTURE FRAMERS

The business of a picture framer is often conducted profitably on agency lines, all orders being sent as received to the wholesale moulding manufacturers, detailed instructions being given with the picture, carefully packed, the finished work being in due course returned ready to be handed over to the customer, or, maybe, without the glass, this being cut and fitted by the shopkeeper. The manufacturers supply numerous sets of samples of mouldings, corners, etc., each sample numbered to facilitate the selection and ordering of their goods, and marked with prices from which usual trade discounts are allowed. In this method of conducting the business little is wanted beyond samples of mouldings, mount boards, show-room display (as described below), and a tape measure.

Common "window glass" is of the same quality as that used for cheap picture frames, and the sale of window glass often proves a profitable side line to the picture framer. If the business be conducted on agency lines, this side line may still be adopted, and glass inserted into frames on receipt from the maker. The proper use of a glazier's diamond is easily acquired. A baize-covered table reserved for glass cutting prevents breakages.

Sale Shop. The sale shop may be fitted with the usual counter, under which several long shallow drawers for engravings, etc., will be useful; also some shelving for fancy goods, alternated with plain wall spaces for the display of pictures, frames, and other goods.

In convenient recesses there may be upright divisions for the storage of mouldings in the case of practical trade being chosen. Mouldings are usually in 9 ft. to 12 ft. lengths, and require the full height. In the cheaper kinds of "German" gilt mouldings, or the plain oak, both natural colour and stained, the enamelled and other cheap fancy mouldings, as well as the largely used gilt "slips"—plain flat, bevelled, or hollow moulds, usually inserted as an inner frame next to the picture—a large variety and a fair stock is generally maintained.

Fancy frames, such as ovals, rounds, Oxfords, and "swept" frames, may be bought ready-made from the wholesaler advantageously. Among this class should be set down Masonic frames containing emblems of the craft. These are in fairly regular demand.

Indispensable to a good framing business is the sale of pictures, especially of engravings, etchings, or other good reproductions of popular works of art, that may be sold at from 1s. 6d. to half-a-guinea each, with a good margin of profit. Another class of goods finding regular sale is that of artists' materials [see page 894].

A special attractiveness always attaches to the exhibition of *original* oil paintings, water-colour drawings, etc. These are generally obtainable on "sale or return" from artists of small renown, who allow a suitable commission. These, if really good work, sell better when displayed without frames, and an order for framing may be secured at the same time.

How to Take Framing Orders. It is generally found that the customer has no preconceived idea of suitable styles for framing various styles of pictures, though he has probably decided on a limit to his expenditure. The first business of the salesman is, therefore, to acquaint himself with the usual styles of framing adopted for definite classes of pictures, and, knowing these points, he should ascertain his customer's idea of price, and display the kind of frame or samples of mouldings suitable to meet the case.

For general guidance, the following leading points may be carefully noted, though individual preferences may call for occasional deviation.

Oil paintings are usually framed in gold, or best imitation gold, without any "mount," the painting coming directly under the rebate of the moulding or slip. As a rule no glass is used over oil paintings. The use of a plain slip greatly improves the effectiveness of an enriched moulding. Ornamental corners over enriched mouldings add to their rich effect, but, especially in best gold work, plain mouldings, void of such addition, are generally preferred.

Water-colour drawings are generally "mounted" either by being pasted down (by the edges only) upon a white or tinted board large enough to provide a wide margin all round, or this margin is provided by a "cut-out" mount with an opening a trifle smaller than the picture, which is then secured by touches of paste (at the corners only) on to a larger sheet of paper, and the cut-out mount laid over both to display the picture in recess. The latter is the better style, and is charged at higher rates. Various tinted mounts, from greys to pale primary tints, are occasionally more appropriate than pure white. A sheet of glass is always placed in front of water-colour drawings, as they lose much of

their colour value if exposed to air and moisture, which also rot the paper. For best qualities, a colourless glass, specially made, is obtainable.

Prints, engravings, etchings, photographs, needlework, certificates, and all such subjects, may be treated in the same manner as water-colours.

Frames. For water-colours, white enamel and gold mouldings, or enamel with a gold slip next to the mount, or plain gold of neat and light, rather than rich or heavy patterns, are in the best taste. The plain "slip" is often placed under the glass, preventing contact between the glass and the picture.

For photographs, etchings, engravings, and other black-and-white or monotint pictures, a plain oak frame, polished or unpolished, natural colour or stained, made up with a plain gold slip under the glass, maintains the quiet dignity of the picture as a contrast to the gaiety of highly-coloured work, which may be enhanced by more elaborate framing.

"Swept" frames are peculiarly adapted to ancestral portraits, old engravings, and pictures by old masters. These are the old-fashioned heavy gold frames in which ornate corners are joined by scrolled curves.

Best Gold Frames. These, being executed with real gold leaf laid perfectly level and finished with either matt or burnished surface, by various methods requiring apprenticeship or long practice, may with advantage be sub-let to expert gilders who work for the trade.

If the beginner wishes to acquire the necessary proficiency to execute his own gilding, he must prepare for it by special practice, in which Scott-Mitchell's book on "Practical Gilding, Bronzing, and Lacquering," may be of service. (Price 3s. nett. Trade Papers Publishing Co., Ltd.)

Mounts. Wide margins may redeem a small picture from appearing commonplace.

In mounting prints, etchings, etc., sometimes it is desired to display the "title" (printed on the lower margin of the picture), though some object to this because the first proofs in good works of art contain no descriptive title. The customer's preference should be ascertained beforehand on this point, and, if required, a small opening may be cut in the mount, carefully adjusted to the position of the title. Rounded or pointed ends to this opening add to the neatness of finish.

When taking orders for framing with "mounts," it is economical to adhere to definite fixed sizes in which the mounting boards are usually supplied. These are as follows (in inches): 10 × 8, 12 × 10, 15 × 11, 19 × 12, 22 × 16, 24 × 9½, 24 × 19, 26½ × 16½, 26½ × 19½, 30 × 11, 30 × 22, 33½ × 16½, 39½ × 26½, 40 × 30. Comparatively few orders will come for larger sizes than 30 × 22. When cutting out mounts for large-sized pictures, the panel cut out from the board should be kept clean for probable use in mounting smaller work.

Measuring. The measure of the mount when ready for framing is called the "glass measure," and that is the measure always recorded as the *size to work to* in making the frame. When a gold slip is used, this is made first and the larger frame fitted round. Hence, in measuring for frame moulding, due allowance must be made for these points, which in some cases may mean considerably increased cost, especially in case of English gold frames. A safe method when calculating the value of frame moulding required is to add four times the width of the moulding to the total of glass measurement. The extreme outside of the frame is the measurement to be charged for, because the irredeemable waste of corners cut away cannot be overlooked. Also note that the usual lengths of picture mouldings (from 9 ft. to 12 ft.) will often be just too short or too long to "cut up" without waste pieces at the ends, which may be of no further use. The latter point may sometimes affect the recommendations of the salesman as to size of frame to adopt, especially in cheap kinds of work. Oval, circular, swept, Masonic, and Oxford frames are best ordered to given sizes from the wholesaler.

Prices. A reliable method of pricing is to total up the prime cost of materials, such as mouldings, mounts, glass, eyelets, etc. (allowing for necessary waste), and multiply that total by three, which will be, as a rule, the fair selling price, including average cost of making up and a reasonable profit of 25 to 30 per cent. This system is specially applicable when "German" mouldings are used. It may be called into service for real English gold work by adding the price of gilding to the former total, at the rates given below.

Oil gilding in genuine English gold leaf is usually charged 9d. per foot run for first 1-in. girth or part of an inch, and 6d. per foot run for each additional inch girth. Matt and burnish gilding is charged double the rates of oil gilding. Cost of gilding, if put out to the wholesaler or to the expert who works for the trade, will be from three-fourths to two-thirds the prices named; while if the work be done in the framer's own workshop by competent employees, the cost may sometimes not exceed one-half the price chargeable. But, as already mentioned, the work of the gilder is a distinct trade, and unless a competent workman be employed, or very considerable practice be obtained on correct lines, there may be sufficient waste of the precious metal to create a loss instead of a profit.

Repairs to old frames before regilding usually constitute an extra charge. They may require the services of a practical frame-maker, though the aspirant may learn the customary methods from Scott-Mitchell's book on gilding already mentioned.

Workshop. Whenever convenient, it will be found most profitable to make frames on one's own premises. The mouldings are all made with a rebate ready to receive the picture, etc. To describe the making of an ordinary frame in brief would be:

"Cut the necessary four lengths (two exact pairs) from the mouldings, each length with its ends cut at an angle of exactly 45 deg., without chipping the surface or other damage, and fasten the ends together with glue, adding screws or brads for permanent security. Insert the

picture (with glass and mount when required), and make up the back with back boards of thin cut pine, covered with brown paper carefully pasted over all to the edge of the frame. Panelled backs replace the thin back boards for best work."

Tools. To facilitate this apparently simple process there are scores of mechanical contrivances without which no business can be done profitably. They are inexpensive, and from the extensive variety offered to the trade the following list is compiled with the double object of economy and efficiency:

Mitre Block. This is a large tablet of wood, surmounted by a smaller block of hardwood, fixed so as to leave a margin on the tablet on which to lay the mouldings for cutting into required lengths. A mitre block costs from 5s. upwards.

Shooting Board. A similarly-built tablet for the convenient use of a plane to make the mitred ends perfect before gluing them together; value, 5s. upwards. Some tool-makers supply this and the preceding tool combined; value, 9s. upwards.

Mitre Plane. A smoothing plane specially designed for "shooting" the mitres by sliding in a rebate on the "shooting block"; value, 6s 6d. upwards.

Tenon Saw. A fine steel saw, specially gauged for sawing picture mouldings; value, 5s. 6d. upwards.

Cramping Machine. A table with long arms crossing it diagonally, X-shaped over the top, in which slide four corner grippers, controlled by a handled screw. The frame is placed on this cross immediately after gluing up the corners before the glue is set. By turning the screw handle the four corner grippers close in upon the frame simultaneously, and by uniform pressure in all directions secure the accuracy of the square. The glue then cements the corners securely in their true positions, and before releasing the cramps each corner may be permanently fixed by driving screws or brads, care being taken to keep clear of the face of the mouldings. These machines are now almost indispensable to the trade, and are made in various sizes. A suitable size for general use is known as No. 2 (Lawson's patent), and will cramp any size of frame from 4 in. by 3 in. up to 4 ft. by 3 ft; value, £2 6s. Extended sizes are obtainable, but seldom required.

Two Wood-cutting Chisels. For trimming; value, 2s.

Oilstone. For sharpening tools; value, 2s. 6d.

Oil-can. Value, 6d.

Cutting Board. For laying mounting boards upon while cutting out. This has to be of well-seasoned wood, well bound, to prevent warping, and must be large enough for large-sized mounting boards. A most useful size and quality is 36 in. by 30 in.; value, 10s.

Steel Straightedge. Bevelled and rule-marked, for mount cutting, 3 ft. long; value, 6s. 6d.

Mount-cutting Knife. Value, 2s. 6d.

T-square. Adapted for glass cutting and for mount marking, 3 ft. long; value, 2s. 6d.

Glazier's Diamond. For glass cutting; 8s. 6d.

Glass Pliers. For blunting corners of glass squares, and for snapping off narrow strips after cutting; value, 3s.

Glue-pot. For melting glue; value, 3s.

Glue-brush. Value, 6d.

Paste-brush. Value, 6d.

Hammer, Panel-pins (fine nails), Military Brads, Screws (fine and light), Screw-eyes, Nail-punch, Bradawls (various sizes), and usual tool-boxes.

From the above list it will be seen that a moderate workshop outfit can be obtained for less than £7.

There are other labour-saving contrivances, such as mitre-cutting machines, mechanical mount-cutters (42s. and 24s. respectively), and heavier machinery for large factories, to be power-driven, at correspondingly higher prices; but the list enumerated above will fulfil all workshop requirements of a moderately good retail business.

Stock of Mouldings. It will generally be found wise to stock a variety with small quantities, say, two or four lengths of each kind, according to cost, to start with, as these goods are easy to replace. German mouldings are cheap and good, ranging from 3d. (½-in. slips, common quality) to 5s. per length of 9 ft., the latter for wide and deep mouldings of best quality, the average cost for most saleable sizes being from 1s. 6d. to 2s. per length. Mouldings "in the white," ready for the gilder's art, may, with advantage, be stocked to a limited extent at first if making up own frames, and sent to the gilder afterwards. These are of better quality than the German mouldings, and cost slightly more. Glass, thin cut pine for back boards, and stout brown paper, complete the needs of the framer.

Capital Required. To a sum of £7 for workshop outfit, add £10 for mouldings, £5 for glass, back boards, and sundries, £10 for pictures and fancy goods to start the show-room display (see periodical market lists), and a total of £32 is reached. Allowing a sum of £8 for show-room and window fixtures, sign board, etc., if the beginner starts with the comparatively small capital of £50, a working margin of £10 would be left in hand, which would be sufficient if prospects were good.

PICTURE POSTCARD DEALERS

Like its near relative the Christmas card, the picture postcard originated on the Continent, and from very small beginnings rapidly developed into a flourishing business long ere it took hold of the British public. But to-day there is not a town or hamlet in the United Kingdom where the picture postcard has not penetrated.

Local views are, of course, the primary subjects, stock of which it is safe always to keep; but every conceivable sphere has been exploited to provide a novelty, and not a day passes without some new design being produced. It goes without saying that there has been a steady and distinct advance in the artistic quality of the work produced.

Stock to Buy. Although in every town of any considerable size there are one or two shops where nothing but cards are sold, the sale of picture postcards is not confined to any trade, but may be undertaken by anyone who has a shop or a window to show them, and no special training is necessary for the sale of them. The terms on which the cards are bought are advantageous to the retailer. As a rule, he can purchase good saleable cards at a discount of 33⅓ per cent., and if in good quantities, at 50 per cent. The most popular selling lines are the penny and twopenny, and these can be bought—and first-class work they are—at 8s. and 16s. a gross. Every now and again, however, the dealer will have from some publisher the offer of a surplus stock of cards which have fallen flat on the market, and he may be tempted by the apparently exceptional value offered - sometimes a tenth of their supposed value. He may be induced to buy, and may do well with them, even supposing he may fail to clear them. But the chances are that he will very soon find that the transaction has resulted chiefly in the transference of stock from the cellars of the publishers to the shelves of the retailer, who, as a rule, has sufficient remainders of his own to satisfy the most ambitious.

Local Views. At one time it was a very good idea to get up a set of local view cards, confined entirely to one dealer. These, of course, cost more than if they had been selected from the stock of the wholesaler, as the retailer had the photographs to provide, or pay for, and, as a rule, had to take a fairly large quantity. Now, it would be a mistake to do this. The quantity necessary to secure the restriction is generally too large for most districts; and so many houses have views of nearly all the principal places of interest in the neighbourhood that a much better variety can be obtained, and at a much lower price, by simply selecting from stock. It is not necessary to order large quantities of any single card—you can always send repeat orders, and new views can be added as they come out. Quite a good trade can be done by arrangement with printers, whereby customers' own photographs for private circulation can be printed on postcards. This trade is fairly profitable, and has the special recommendation that there are no "remainders" or bad stock. Again, if the dealer be himself a "knight of the camera"—and who is not, nowadays?—he can utilise his accomplishment in some interesting local event, print off his cards, and sell them while the incident is still fresh in the memories of his customers. There is no need to make suggestions here, as each district will readily supply its own incidents.

Stock to Avoid. The picture postcard has come to stay. It may readily be added as a valuable adjunct to almost any business, especially to that of the fancy stationer, who will find in it more than a compensation for the decrease in the sale of notepaper. For there is no doubt that since the advent of the picture postcard letter writing has to a large extent gone out of fashion.

Now let us give a word of warning. In order to retain and develop this business, which is at once a source of pleasure to the customer and of profit as well as pleasure to the seller, all dealers should beware of allowing anything vulgar, indecent, or suggestive of indecency, to creep into stock. There have been and there are such cards on the market, and there are dealers vile enough to engage in the traffic. The British public is clean minded, and will on no account tolerate this. Nothing will more quickly kill this business than the publication and sale of such filth. The Stationery Trades Association is aware of this fact, and, we are glad to note, has taken up a strong position in regard to it. It rests with dealers themselves to be vigilant in stamping it out, and they will find that they have, as a rule, loyal allies in the magistrates and police throughout the country.

PLUMBERS

The business of a plumber is one in which scientific knowledge must be wedded to mechanical skill. The days when mechanical skill was all or nearly all of the plumber's qualification are passing swiftly. Mechanical and physical science, the principles of sanitation, ventilation, and water supply, and more than a smattering of chemistry, are elevating the "trade" into a profession, and the increasing appreciation of the requirements of sanitary science is bringing to the expert plumber some of the recognition which is his due.

Apprenticeship. Apprenticeship formerly lasted seven years, but for some time there has been a tendency towards its curtailment. Five years is now not uncommon. When apprenticeship in the workshop is united to technical and scientific instruction in the evening, the present-day five years' apprentice emerges much better equipped than the former seven years' man. Premiums are common in the trade, but not universal. They vary from £5 to £50, and the wages from 2s. 6d. to 5s. per week during the first year to from 10s. 6d. to 20s. during the last year.

Associations of Plumbers. For some years two bodies have been striving to lead the members of the plumbing craft in Great Britain—the Worshipful Company of Plumbers in London, and the National Association of Plumbers with headquarters in Hull. The former body are to be congratulated upon being one of the few London livery companies who are now taking an interest in the craft from which they derived their origin; but on account of the manner in which they have sought to secure ruling powers over the trade their efforts have been regarded with cold neutrality by sanitary and other representative bodies who might have furthered their aims. Opposition also has been strong, and the tide of battle seems to be favouring the National Association of Master Plumbers, composed of practical men who know what they want, and who are more likely to lead the plumbing trade into professional recognition. The Association

was formed in 1895, and registered two years later. The objects of the original society, briefly stated, are:

(a) To improve the status of the trade by schemes of education for employers, operatives, and apprentices, and to act in conjunction with any or all of the existing educational authorities for the purpose.

(b) To establish an official organisation having authority to represent the craft of plumbing, and managed by persons *bona fide* in the trade, to act on behalf of the trade in its relation to the Government, county councils, municipal and other local authorities, associations of architects, and all other institutions having any connection with the plumbing trade.

(c) To organise and to bring into existence local associations or branches of the national body for the purpose of dealing more readily with matters of a purely local character, and generally to create and maintain a brotherhood and community of good fellowship amongst all engaged in the trade.

The association is being reconstructed as we write, and is acquiring additional powers. It is proposed to give it a new title—the Institute of Plumbers—and to raise it to the dignity enjoyed by the Surveyors' Institute, the Institution of Civil Engineers, and the Sanitary Institution. The Board of Trade is, at the moment, considering the proposed constitution.

The new institute will have power to deal with examinations in plumbing, but in the meantime it co-operates with other associations in a joint examination scheme, syllabus of which is appended.

Technical Instruction. Instruction in plumbers' work may be had at technical schools and institutions throughout the kingdom, and the fees are merely nominal. Examinations are held annually at the schools where instruction is imparted, and certificate awards are made by the examiners of the City and Guilds of London Institute (Department of Technology), South Kensington.

Students who compete successfully in the written examination receive a certificate in the "Principles of Plumbing." Those who pass in both the written and the practical sections are awarded a certificate for "Plumber's Work." Students are recommended to attend a two years' course of instruction before presenting themselves for the preliminary examination, and those who consider themselves competent may enter for the ordinary grade examination without having attempted the more elementary part.

Registered Plumbers. Examination by the Plumbers' Company secures the qualification of "registered plumber," but this City company has decided to cease holding examinations. Most of the master plumbers who hold the certificate of registration have, however, secured it by "testimonial" and not by examination. It is probable that the examination of the City and Guilds of London Institute, mentioned above, will entitle to the degree—if it may be called so—of registered plumber. It may be added that the wearer of the title "registered plumber" possesses no specific privileges above his fellow who has not earned the right to the title. The title which may be assumed by plumbers who shall have passed the examination of the new Institute of Plumbers will be *member* or *associate* or *certificated* plumber.

EXAMINATION IN PLUMBING BY CITY AND GUILDS OF LONDON INSTITUTE.

PRELIMINARY EXAMINATION.

[Annually, in April. Fee, 1s.]

The preliminary examination is written only.

1. Workshop arithmetic, geometry, and drawing.
2. Elementary science for plumbers.
3. Alloys, solders, etc.
4. Workshop appliances and the principles of their action.

ORDINARY GRADE.

[Annually, in April. Fee, 1s. 6d.]

Written and practical.

1. Elementary science for plumbers.
2. Drawing for plumbers.
3. Properties and uses of materials.
4. Mechanical appliances and the principles of their action.
5. External roof work.
6. Hot water apparatus.
7. Sanitary appliances in common use, and the principles of their action.
8. Drainage.
9. Practical test in marking out and cutting off sheet lead; in bending pipes of from 1¼ in. to 3 in. in diameter; in joining lead pipes with wiped soldered joints, and in bossing lead.

HONOURS GRADE.

[Annually, in May. Fee, 5s. If the written examination only is taken, the fee is 1s. 6d.]

Written and practical.

1. *Water.* Qualities and properties of water from deep wells, shallow wells, springs, and other sources, water storage, filtration, general distribution, and arrangement of services in buildings, flow through pipes, loss of head, and retardation by bends and branch pipes.

2. *Plans and Specifications.* Preparation of plans and specifications for general plumbers' work and house drain construction, in compliance with the local sanitary authorities' by-laws and regulations.

3. *External Roof Work.* Details of covering domical and turret roofs, finials, Mansard curbs, making plain and ornamental rain-water pipes and heads, lead burning.

4. *The Warming of Buildings.* Heating by hot water and steam, high and low pressure, and hot air. Amount of heating surface required for rooms and buildings of different sizes. Principles of heating water for domestic use by steam heaters, etc.

5. *Sanitary Appliances.* Their arrangement and position in dwelling-houses, hospitals, and public buildings. Principles of construction. Methods of automatically removing grease from traps, and flushing public conveniences and drains. Entry of tidal, storm, and other waters into basements of buildings, and the prevention of same.

6. *Ventilation.* Ventilating apparatus for apartments in dwelling-houses and public buildings in which sanitary fittings are fixed. Systems of mechanical ventilation, and methods for washing and purifying air, ventilating stoves, etc.

7. *Drainage.* Principles and construction of house drainage with disconnecting and inspection chambers, gullies, interceptors, and other traps. Ventilation of drains and soil-pipes, etc. Drain testing by water, smoke, chemical substances, and air pressure. Simple methods of sewage disposal for isolated country houses.

8. *Practical Test.* Bending lead pipes of all sizes; joining them by wiped soldered joints without the use of lamp or gas-jet, or by lead burning, in such positions as would occur in practice; bossing lead to a given form, and any other piece of plumbing work. Practical tests are held locally only if five candidates enter. If less than five enter, special arrangements are made.

The Plumber in Business. The business of a plumber is not one demanding a large capital, unless it be attempted on an ambitious scale and with large stock of material. Nowadays, many plumbers' businesses are run from an office only, without workshops or warehouse accommodation. It is becoming common to do all plumber work on or in the buildings in course of construction or under repair, and the plumber merely draws upon the manufacturer or plumber's merchant for supplies as he requires them, and returns any material left over, the workmen employed providing their own manual tools.

A business run on these lines is possible only in a city or very large town. The country and provincial plumber must have his shop fitted with benches and some shop tools. Even the city plumber who does a jobbing trade must also have his shop and warehouse.

The jobbing trade, being the most remunerative, should be cultivated. The price got for labour represents a large profit upon its cost. The wages of workmen vary from 6d. per hour in some country districts to 11d. per hour in London, and their hours from 47 in London to 56½ in some country towns. The price charged for labour, even in towns on the lowest scale, is seldom less than 10d. an hour, and in London a charge of 1s. 6d. an hour is not uncommon. The profits on material are also good from 33⅓ to 100 per cent. on cost prices—when the work is ordinary jobbing, so that the plumber with even only half a dozen men in his employ may make a very good thing out of his business.

Estimate Work. New work is seldom secured otherwise than by competitive tender, and in most districts such work is cut down in price until profits are bare or non-existent. The new man must take a hand in this game of "beggar-my-neighbour" if he would establish himself. He has the advantage that in his eagerness to make a business he will work hard himself, and exercise a stricter supervision than his competitor claiming earlier establishment. Thus, he may be able to make a profit when the firm in a larger way could not come out of the job with a profit. On the other hand, he may be under the disadvantage of not being familiar with the practice of the architect or clerk of works, who may put him to expense by the arbitrary enforcement of useless clauses in the specification.

A non-remunerative job may often be made to pay by the *extras*, and a knowledge of the habits of an architect in adhering to the details of his specification is worth having when tendering for work under his charge.

Allies of Plumbing Proper. The term *plumbing* has come to be wider in its scope than the mere working in lead, and house sanitary fittings, which was the origin of the name. It is usually allied to gas fitting, and hot water fitting, and sometimes to the installation of hydraulic plant, to the work of an electrician, and to tinsmithing. It is probable that from the various tradesmen engaged upon the installation of sanitary, ventilating, and heating apparatus, a new profession—that of the domestic engineer [see page 2218]—will be evolved.

The Merchant Side of the Business. Development of the merchant side of the plumber's trade is usually wise, particularly since the trade in incandescent gas fittings began to assume its present large dimensions. The plumber who keeps no front shop neglects an important means of feeding the working department, and allows to go to other shopkeepers trade which he might easily have. In such things as sanitary fittings, the best method of display is to have a showroom arranged with samples of the best style of lavatory basins, baths, and closets, with water supply connected up. These samples should meet the demands of modern ideas on the subject of sanitation. The sum of £50 plus the labour would pay for fitting up a very fine show-room, say, two baths—one of the shower type—three or four lavatory basins, a similar number of closets, and perhaps a foot bath. A tiled floor, and walls of tiles, or of "Emdeca," will add to the expense, but may be worth it, and will make a handsome sanitary show-room sure to attract custom. The tile fitting can be done in his slack hours by any workman sufficiently expert. From the roof should be suspended some samples of gas pendants, and brackets should be mounted on the walls. It is unnecessary to carry heavy stocks of sanitary and gas fittings.

Stock of cisterns, faucets, unions, and plumber's brass work must, of course, be held in a fully equipped plumber's business. In the sale shop and windows the public should be shown the latest things in gas lighting. Excellent use is sometimes made of tiny models of sanitary fittings in the window. The competition of the gas companies—municipal or otherwise—may qualify the wisdom of stocking gas fittings upon a heavy scale, but gas mantles and other accessories of incandescent gas lighting can be sold freely in spite of all the competition which companies and corporations can bring.

Buying. The plumber who keeps stock of plumbing materials can usually do better in his purchases than the mere "office" plumber. He is not tied to the merchant so much, and can draw many of his supplies from the manufacturers, thereby securing keener prices. The terms offered by both merchants and manufacturers differ. When the standing of the plumber is known to be good, he can usually get three months' credit, or should he pay monthly or at shorter date—always an advisable course when it is possible—he will secure better terms.

Gas Cookery. A department which at one time gave promise of developing to the benefit of the plumber is that of gas cooking and heating stoves, but the policy of hiring these appliances and of fitting them free of charge, which has been adopted by gas service companies, has killed whatever promise there was. Therefore, except in a few exceptionally favoured districts, the plumber is wise in leaving this department severely alone, reserving his energy for matters more likely to be remunerative.

Acetylene Plant. The scale and installation of acetylene lighting plants offer scope for the enterprising plumber in the provinces. The work needs a good knowledge of the principles of acetylene generation apparatus and supreme care in its fitting. The man who makes himself an authority on the subject has at command a means of making good profits. There is not, for the work, the competition which prevails elsewhere. The prospect of securing business from the owners of country mansions and farmhouses is very good if energetic efforts be made to obtain it. These efforts may be made in the distribution of circulars, in personal visits, and by the exhibition of acetylene apparatus at local exhibitions. The purchaser of a plant becomes a constant customer for carbide of calcium, the storing of which, however, requires a knowledge of the legal provisions governing its sale.

Work for Public Bodies. Some municipalities, large institutions, and local educational authorities offer the work of keeping their property in sanitary repair for public tender. To estimate for such a work is a pure gamble. A severe winter may involve in a heavy loss the plumber who secures it, and a favourable year may enable him to come out of the contract fairly well. The wisdom of entering the competition for such work depends upon several conditions. If the plumber be a man of very small capital, he will do well to refuse to look at it. There may be circumstances when it is politic to risk the loss, but even this is questionable.

Textbooks. In recommending textbooks for plumbing students, we cannot do better than enumerate the works of reference suggested by the Department of Technology of the City and Guilds of London Institute: "The Plumber and Sanitary Houses," by Hellyer (Batsford. 12s. 6d.); "Standard Practical Plumbing," by Davies (Spon. Vol. i., 7s. 6d.; Vol. ii., 10s 6d.; Vol. iii., 5s.); "Building Construction," by Mitchell (Batsford. 5s. 6d.); "Treatise on Warming Buildings," by Hood (Spon. 15s.); "Hydraulics," by Box (Spon. 5s.); "Hot Water Supply," by Dye (Spon. 3s.); "Pump Construction," by Bjorling (Spon. 5s.); "Plumbing," by Hellyer (G. Bell & Sons. 5s.); "Domestic Sanitary Drainage," by Maguire (Kegan Paul. 12s.); "Plumbing Practice," by Clarke (Batsford. 5s.); "Metal Plate Work," by Millis (Spon. 9s.); "Hydrostatics and Pneumatics," by Magnus (Longman. 1s. 6d.); "External Plumbing Work," (1896), by J. Hart (Scott, Greenwood & Co. 7s. 6d.); "Water Supply," by Thresh (Rebman. 7s. 6d.); "Plumbing and Sanitation," by Davis & Dye (Spon, 55s.); "Hints to Plumbers," by Hart (Scott, Greenwood. 7s. 6d.); "Pumps," by J. W. Clark (Batsford. 3s. 6d.); "Hydraulic Rams," by J. W. Clark (Batsford. 2s.).

POSTAGE-STAMP DEALERS

In stamp dealing it is practically impossible to know every stamp issued, but a general acquaintance with the postal emissions of all countries is a necessity. It may be assumed that a young man desiring to enter the stamp trade has had his thoughts turned in that direction by a familiarity with stamp collecting as a hobby. Knowledge gained from forming a collection of his own will stand him in good stead in the business. If the prospective dealer has not this experience of stamps, he will have to start collecting judiciously, bearing in mind that the collection he is forming will ultimately become his stock, and ought to yield a substantial interest on the money invested in it. He will get his elementary knowledge from the various primers sold, along with which he must study the priced catalogues issued by other dealers, and watch the fluctuations in the prices, not so much of individual stamps as of classes of stamps.

Assistants in Small Shops. If the beginner has a moderate knowledge of stamps, a position might be obtained as an assistant in an established firm. These openings in the highest class firms are extremely rare, however, so it is likely he will have to be content with serving a small dealer at a remuneration of 20s. to 30s. a week in order to gain experience in the handling of stamps. A warning may be urged here that he should not allow himself to be led away by the lack of business method displayed by many small dealers. He had better spend his evenings after work in studying bookkeeping, and the systems of card indexing, advertisement writing, and, where possible, in attending displays of fine collections at the meetings of the local philatelic societies.

Shop or Office? In England, most of the stamp businesses have shop premises, although a very large portion of their work is done by correspondence. A few highly successful ones are conducted postally from private addresses. In America, the businesses are mostly carried on from offices upstairs—many of them necessitating a journey in an "express elevator" to reach them. One Boston firm has met with considerable success in employing a travelling salesman, who visits private collectors, customers of the firm, all over the United States and Canada, taking with him selections of the finest things in stock at the time.

The Cheap Packet and Approval Sheet Trade. There are three distinct classes of stamp trade on which one may embark, according to capital and knowledge of the subject on the part of the intending dealer. The trade in packets and low-priced approval sheets, or the "boy trade," can be started with a very small amount of stamp knowledge, and only a few pounds of capital. The profits are high, but the business is not great. Doing this class of business postally from one's home address, a capital of £10 would suffice for a start. One main feature of this business is that the packets—which must contain good value—are the chief means of introducing approval sheet business.

Capital and Profits. In this class of trade a third of the £10 capital might go to the purchase of stamps for retailing at ½d. to 1s., and a quantity of cheaper stamps for enclosing in packets. Another third should go towards

supplying the dealer with a stock of ruled and spaced approval sheets, small envelopes for packets, gummed hinges for mounting the stamps on the sheets, and a few other trifling requisites. A portion of the remaining third should be devoted to one or two small advertisements in papers which reach the class of customers whom the dealer is trying to interest.

Stamps for retailing at ½d. on cheap approval sheets may be had from wholesalers at from 4d. to as much as 1s. 6d. per 100. Stamps to sell at 1d. and 2d. each are about double and treble respectively in wholesale price. The wholesale rate on stamps for retailing above 3d. and 4d. each do not yield quite the same profit, but they represent better returns. The profit on this trade should work out at not less than 40 per cent.

The Small Shopkeeper. To start a small shop entails a considerably larger capital. It could be done with from £50 to £75. The nucleus of the stock of stamps is generally the collection formed by the proprietor before entering the trade, a portion of the monetary capital going to purchase small wholesale lots for making up into packets and for making a window display. A stock of accessories in the way of albums, handbooks on stamp collecting, tweezers for handling stamps, gummed hinges for mounting specimens, and other goods will be required. Select a small shop on the shady side of the street if possible, as the colours of some stamps—violets, purples, blues, etc.—fade quickly if exposed to excessive light, and much good stock may be spoiled. Another important thing to consider in taking a shop is to get it in a good business quarter—where much foreign business is conducted—so that you will get opportunities of buying good stock cheap and first hand. Clerks and business men will often look in with stamps for sale, and in this way you may pick up some good things and sell them to other dealers, or keep them in stock for your own customers. Small dealers often get rare stamps in this way for which they have no customers, so they sell them to a dealer who has customers for them. It pays the small dealer to get a quick turnover by selling in this way, and the man with the customer for the rarities can command a very high profit, as much as 400 to 500 per cent. in many cases.

In the stamp trade successful buying is as important as successful selling. It is more difficult to get good stamps than it is to sell them. A dealer should get into touch with correspondents all over the world who will supply him with stamps direct. Advertisements in papers with foreign circulations will help to form such a connection.

Have a Speciality. The small shopkeeper will find it worth his while to have a speciality. That is to say, that while not neglecting to keep a representative general stock of the world's stamps (that is, as representative as his capital will allow), he should also make a special feature of one country or small group of countries. He should thoroughly master the study of the stamps of the country or group selected, and stock them well. In this way he will come into contact with customers who are forming specialised collections of that country, and his sales to these collectors should be considerable.

The Question of Prices. With regard to prices, there are certain priced catalogues of dealers' stocks issued annually, or at slightly longer intervals, which have come to be recognised as reflecting the approximate values of nearly every stamp known. These catalogues are extensive and valuable works of reference, and are indispensable to every dealer. The catalogues are published by big firms with heavy expenses for large and centrally-situated shops and highly-salaried staffs, and these have to be paid for by the sale of the stamps at good prices. Proprietors of small shops, with but trifling expense for paid assistance, can afford to sell a very large number of stamps at less than catalogue prices. The small dealer will have to decide what discount he can allow off stamps according to the prices he has to pay for them in the first place. New issues, and current unused stamps, cannot be sold much, if at all, under catalogue quotations, as there is usually only 10 per cent. above face value charged upon them, and the cost of importation and handling has to be deducted from this 10 per cent.

Stamps to Stock. In Great Britain, the class of stamps which must chiefly be stocked by the small dealer are old English stamps and British Colonials. Probably about 75 per cent. of a small dealer's customers will be collectors of British Colonial stamps only. Unfortunately, the old trade in foreign stamps (as distinct from Colonial issues) is not as it used to be. An American dealer will have to stock both the United States (with Colonial possessions) and British Colonies. Hawaii, Cuba, Porto Rico, Philippines, Guam, Panama, and South American States are in good demand in the United States, as also are the issues of the Haytian and Dominican Republics.

The Importance of Condition. An all-important point for the dealer with a medium-class trade is to see to the condition of his stamps. A thorough philatelist insists on absolute perfection in every stamp purchased. The colour must not have been faded or the paper stained. No particle of the perforated edge may be missing, and if the stamp has been through the post, the fastidious customer will want it only if it has a light or clearly impressed postmark, and not an inky smudge. If unused, the gum on the back should be in its original untouched state. There is little or no sale for damaged or soiled stamps.

The High-class Business. To conduct a high-class stamp business a large capital is required; though, of course, with persevering hard work and a little daring, such a trade might easily grow out of the beginnings described in the case of the small shop proprietor. The first-class firms all hold very extensive stocks, large portions of which must necessarily lie idle for years. They also keep deposits with a number of foreign postal departments to secure a good supply of new issues as they come out.

Advertising is another big item here, as the firm's name has to be kept constantly before the minds of the stamp-collecting public.

Stock, Premises, and Staff. In addition to the more comprehensive stock of stamps, he will require a more varied assortment of albums, handbooks, and other accessories. His shop fittings will be more elaborate, and the shop will be situated in a thoroughfare frequented by the well-to-do. A private office in which the manager can interview important customers, and transact "deals" which require diplomatic secrecy until effected, will be necessary. A shop manager at £3 to £5 a week, and a shop assistant at £1 to 30s., will probably be required for counter sales. A staff of girls, at 15s. to 25s. each per week, will be employed making up neat, attractive-looking packets for sale from 1s. to £15. Clerical assistance will also be required.

Stock Keeping. Most leading dealers have wholesale stocks, and can supply wholesale as well as retail. Heavy stock of common stamps may be warehoused, but stocks of used or unused good stamps, if laid away for a rise in value, will have to be deposited in a safe vault. The general stock is kept in big stock books, supplied with shelved strips in which the stamps are all classified. From these big stock books the shop counter and approval books (usually one and the same, counter books being sent out on approval when first made up) are compiled at intervals as required.

Approval Books. These books will contain stamps of individual countries, and each book will have to be made up by men who have knowledge of the particular country. Payment for such work, if done at home, varies from £1 to £3 per book for the smaller countries, and £5 to £10 for the more important ones. A book when made up, with notes pointing out the special features of the stamp, will be priced by the head of the firm, or another responsible member of the staff, and the book will be sent to the most important customer known to be interested in the stamps of the country. He will pick out the "plums," the book will then be sent to another, and so on. Or if there are no specialists in that particular country's stamps on the firm's lists, the book will be placed in the safe, and produced whenever required for counter sales.

Following Up Rarities. The proprietor of a high-class business must be keen in following up the scent when an important collection or a great rarity is for sale. If a firm sell a £1,000 stamp, even on commission terms at 10 per cent., it is a good deal, and brings credit and advertisement to the firm. A collector is greatly influenced in favour of a dealer if the latter secures for him a specimen for which he has hunted everywhere else in vain. The leading dealer must devote his best energies to tracing and securing the rarities. Such stamps need never be put into stock. As soon as they are found, there are purchasers eager for them to complete their collections. The special fancies of every customer of note will be familiar to the dealer, so that he knows where to place every uncommon variety as soon as it turns up. In fact, a card index should be kept of collectors' addresses and the countries in which they are interested, what their collections contain, and what they lack. Want lists will be solicited from all collectors, and must be executed as far as possible when they come in, and the remainder filed and indexed to supply at the first opportunity.

Trade Discounts. If one dealer send to another for a stamp which the first wants for a customer, he is generally allowed a discount of 10 per cent. This is also the discount allowed on a large sale on commission, while a similar transaction in a small way would be worth 25 per cent.

POST OFFICE SUB-AGENTS.

A distinction must be drawn between a district office, a branch office, and a sub-office. The first two are completely under Government control. The whole of the office is devoted to postal work, and the wages, hours of labour, and holidays of the employees come under the regulations of the Postmaster-General. For particulars of this branch of the Civil Service see "The Post Office Service" [page 2807].

A Sub-office. We are here, however, dealing with a different kind of postal work—that of a sub-office which is under a district office, and is undertaken by a shopkeeper as an addition to his ordinary trade. Such a combination offers distinct advantages to him. It introduces customers, who, when once on the premises, take the opportunity of making purchases. Then, the profits reaped from the postal department are by no means to be despised.

Naturally, certain businesses are tabooed by the authorities. In villages the office is frequently located in the shop of a general dealer or draper, but in towns or surburban districts those most favoured are chemists, stationers, confectioners and grocers, and sometimes, though rarely, bakers. A post-office, for obvious reasons, is seldom granted to a man holding a licence for the sale of wines and spirits. Occasionally the grant is withdrawn; it would be so were gambling or betting known to take place in the shop. Only two months' notice of withdrawal of the grant is given, and no compensation or pension is forthcoming.

The Grant from Government. The method of procedure followed by a shopkeeper wishing to add a post-office to his or her business is to send to the authorities a petition signed by the local residents. Such a petition would be available for signature in the shop, and would naturally indicate the need for, and the advantages of, such a grant. In a growing neighbourhood several such petitions may be received almost simultaneously. Inquiries are then made, and the shop most suitable, from the point of view of position and character of trade, is then chosen.

Commissions. At first sight the coveted distinction may appear a somewhat empty one, when one finds that a postmaster in a village may get the small salary of £10 or £12. A certain busy grocer in a surburban district is allowed the

somewhat nominal "responsibility" salary of £48, increased later to £50; but he gets a good commission on certain sales—in the case here referred to £200 a year—out of which, however, he has to pay his staff. The postmaster has no information as to the working out of commissions on his business. That is all calculated in the head office, to which accounts are sent every day to be worked out by the clerks employed there. The result may not be called in question by the postmaster.

The items on which commissions are reaped are telegrams, postal-orders, savings bank transactions, and money-orders. The commission is at the rate of one penny on every telegram forwarded or received. On postal-orders it is now paid once a year, at £1 per 1,000. On money orders it is one penny on each order, and the same holds good of savings bank transactions.

A sub-office may be knocked up to send a telegram after closing hours, on which there is an extra fee of 2s., or more, out of which a messenger has to be paid to fetch the clerk, the clerk paid for coming to telegraph, and probably porterage paid for delivery at the other end. Therefore, the margin of profit is in this case small, though to the public 2s. seems a high fee.

Express letter work is naturally undertaken only by an office open for telegraph work, and the Government reaps the benefit of the sale of extra stamps. The sale of stamps, by the way, which involves most work in a post-office, brings absolutely no profit, nor is there any commission on letters or parcels.

The postmaster, on undertaking postal work, signs a bond, under which he is responsible for a certain amount, all of which he runs the risk of losing; but the step is necessary as a guarantee of his financial soundness.

Assistants. In a sub-office one, two, or three assistants may be necessary, whose salaries, unlike those of fellow-workers in a Government office, vary very much, not merely according to the amount and value of their work, but according to the liberal-handedness or stinginess of the postmaster. Applicants are certainly more likely to apply for posts in a neighbouring office attached to a grocer's shop, where the three clerks have their meals, but sleep at their own homes, and receive respectively 18s., 16s., or 12s. a week. Three clerks to a sub-office is a generous allowance. The hours of work average nine a day, but are in some cases 12. Leave of absence is arranged by the chief clerk. The usual holidays are Sundays, Christmas Day, and Good Friday, in addition to a fortnight in the summer.

The clerks take it in turn to be away on Bank Holidays. They get no pension or wedding-present, as clerks in Government offices do.

Telegraph boys and postmen are all under Government control, except in a country office, which is hardly worth having.

How to Enter a Post-office. A girl desirous of becoming a clerk in a sub-office has no competitive examination—in fact, no examination whatever to encounter. She comes into the office as a learner without salary. If she proves capable, after a time she receives a small salary. Every branch of the work has to be mastered by her. Advertisements for such learners will frequently be found in, for instance, the "Christian World." The sub-agent is not allowed to take premiums with his employees. In a country office the junior clerk may be wanted to keep the books of the business or perform housework; not, however, in a London sub-office. She occasionally assists in a light business when the postal work is slack; but all such additional work is discountenanced by the officials, who sometimes institute inquiries respecting this matter.

It will be readily understood that it is an advantage to a postmaster to employ one or more members of his own family in the post-office, especially in country districts. The daughters often naturally slip into such vacant posts.

Fittings. The rear end of the shop is a favourite place for conducting post-office business. Here is a counter usually wired off above, with two or three drawers underneath, and space for stationery stores, two or three stools, pigeonholes at the side for papers, and scales for weighing parcels. The scales are supplied by Government, and are marked with the broad arrow. Fitted to the wall on the public side of the counter are compartments, with ink, pens, and blotting-pads for the use of the public. Letter boxes are also affixed outside. £20 covers the initial expenditure.

Telegraphy. This is an important part of post-office work, requiring considerable gumption, knowledge, nerve, and energy as well as physical strength when the work is continuous. A learner takes, on an average, two years to master the Morse code thoroughly. The code is put into her hands to be studied; then other clerks send messages to her, as opportunity offers. Occasionally one learner interchanges messages with another, a plan which has disadvantages. In many sub-offices, telephones are now found. This subject is dealt with in a separate article.

London sub-offices have sorting offices in a separate building, the sorters being Government employees.

Books of Reference. All necessary information concerning new rules, or alterations in old ones, is supplied to the sub-office for the information of the clerks. Guide-books for reference are forwarded in abundance once a quarter, as well as "rule-books" concerning telegrams, money-orders, and details of office work, so that all information is ready to hand. This is an important matter in a busy office, as anyone will agree who notices the stream of questions which the public put to the post-office clerks. Post-office servants are sworn to secrecy, and have to promise not to open letters, delay their delivery, divulge the contents of telegrams, or give information about another customer. A formal declaration has to be made at the police-station.

THE HOSIERY INDUSTRY

The Growth of Hosiery. Yarns and Fabrics. Hand Knitting. The Knitting Frame; Its Details and Methods of Working

Continued from page 4502

By W. S. MURPHY

WOOLLEN cloth caps were worn by the peasants of Northern Europe, and of England and Scotland, before the Norman Conquest, and knitted wool gradually and quietly superseded the woven cloth. The first historical record of which we can find trace is in the Act of Parliament, dated 1488, during the reign of Henry VII., in which the price of knitted caps is stated to be 2s. 8d., about 9s. of our money. During the following century knitting was frequently mentioned in legislation, and in the famous Statute of Labourers, passed in 1563, the hosiers are classed among the craftsmen whose contracts were to be regulated by that Act. The great Churchmen and Royal personages of Europe had set the fashion of covering the lower limbs with hose, at first of cloth, and later of knitted silk, and the Royalty and nobility of England followed suit. Howell, in his "History of the World," states that Henry VIII. ordinarily wore cloth hose, "except there came from Spain, by great chance, a pair of silk stockings."

From the high importance which the Court chroniclers seemed to give to the gift of a pair of silk stockings to Edward VI. by Sir Thomas Gresham, those commodities must have been rare and costly at that time. We may take that gift, however, as marking the end of the mediæval age of the industry. During the reign of Edward's sister Elizabeth the modern era began—the age of invention, of machinery, of vast industrial expansion.

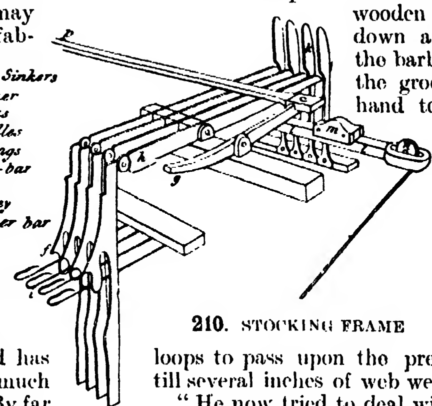
Hosiery Yarns. The hosiery industry uses many classes of woollen, worsted, merino, cotton, and silk yarns. During the past thirty years important changes have taken place in the yarn department. Before the period indicated, thick worsteds, five-ply and over, were the staple yarns of the popular stocking trade. Merinos were almost wholly mixed cotton and wool. The cottons most favoured were soft and thick. Silk, both thrown and spun, was in very small demand. Fancy hosiery had almost gone out of fashion. Between 1870 and 1900, however, a vast change occurred. Fine merinos of pure wool, formerly reckoned too costly for hosiery, came into use; cotton yarns of the finest counts and the highest quality became common; silk hosiery once more revived; fancy hosiery regained its hold on the popular market. All over, the demand for hosiery has increased enormously, and the desire for good quality has grown in even greater proportion. Silk stockings, socks, and other articles of underwear, are largely worn by members of the upper, middle, and professional classes, both male and female. In the fancy hosiery trade the change is equally well marked. No design is too fanciful to command a sale, though good taste, combined with bold originality, is surer of a permanent hold than mere eccentricity. The artistic pleasure in wearing dainty and pretty things for personal satisfaction, not for display, has spread into all ranks of society. Woollen hosiery has also come into larger demand because of the higher standards of life which obtain among the labouring classes. These are facts which should be observed by the worker in the hosiery industry. Supplying a personal need, he should pay very particular attention to the changes in personal need and taste prevailing among large classes of the community.

Fabrics. The range of articles made by the hosiery industry is very great. Between 5,000 and 6,000 articles are regularly manufactured and sold. Stockings, socks, shirts, vests, pantaloons, pyjamas, petticoats, caps, baby-hoods, jerseys, bonnets, gloves, mittens, slippers, and a vast number of other things of many varieties and classes employ the hosiery workers. On the one side, the hosier comes into close competition with the lace manufacturer, and on the other side he encounters the cloth weaver. In most cases it is difficult to say which is the invading party, the spheres of all three shading so gradually into one another.

Hand Knitting. Knitted fabrics are formed by a single thread, linked loop into loop, and may be made with two wooden pins or metal wires, named *needles*. Suppose we watch a knitter at work. First the basis must be formed. Holding the end of the worsted firmly against the needle in the left hand the knitter makes a loop on the right-hand needle like a running knot, and lifts it on to the left-hand needle. As many loops are made as there are stitches in the breadth of the fabric. Having got this foundation, the knitter inserts the right-hand needle into the end loop on the left-hand needle, passes the thread over the point of the inserted needle, with which she draws it through in the form of a loop, while slipping the first loop off the wire, thus making a loop or stitch. She works along the whole row in this way, and at the end we find that the right-hand needle has taken on all the thread, and now carries a row of stitches and a row of loops. The bared needle, which is always the working one, should be transferred to the right hand, and the loop-covered needle taken into the left hand. Again the knitter inserts the bare needle into the top loop on the left-hand needle, passes over the thread, draws it through as before, slipping the stitch thus formed on to the side of the row of stitches already made, forming another row of stitches

and another set of loops on the wires. When this row is completed, you can see clearly the beginnings of a knitted fabric, formed by the linked loops of a single thread.

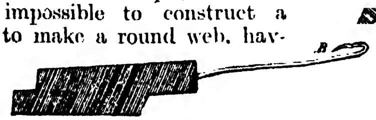
Styles and Qualities of Knitting. There are numerous styles of knitting; but two methods form the basis of most of our hosiery production. These are known among knitters as "plain" and "purl." Plain is the stitch we have just seen, and purl is the reversal of the same. One of the supreme merits of knitting is the facilities it affords for any shape or form being made without any seam. A seamless round web, shaped as a stocking or shirt, may be made with four wires. Knitted fabrics, being constituted of one thread continuously looped, and having neither warp nor weft, are soft, flexible, and elastic, lie close to that part of the body for which they have been made, and retain their shape after much wear.



210. STOCKING FRAME

Invention of Knitting Frames. William Lee, M.A., of Calverton, in the county of Nottingham, is entitled to rank among the very few original inventors the world has seen. Originality in invention is much rarer than most people suppose. By far the greater number of even the greatest inventors were merely improvers of mechanisms already existing. James Watt transformed the steam engine; but there were steam-engines working before he was born. With William Lee the case was quite different. No knitting machine had ever been constructed or even thought of, so far as we can gather, before he made the stocking frame [210]. He had to form the idea, and work it out in practical shape without one ray of guidance from past experience. Gravener Henson, in his "History of the Frame-Work Knitting and Lace Trades," thus describes Lee's method:

"The web of a stocking is knitted by hand, on three or four long pins, of a row of loops, and in a round shape; it seemed to Lee impossible to construct a machine to make a round web, having as many needles as loops in the circumference of the hose. Pondering on the difficulty, he one day saw his mistress knitting the heel, using two needles only; one held the loops, while the other was employed in making a new series. It struck him he could make the web flat, or in a straight line of loops, and when thus made, join the selvage by seaming them together and thus make it round. He was thus led to the idea of throwing a thread across a long elastic hook, the point of which would be pressed down into a hole in the stem of the wire, and thus loop at pleasure. He bored the holes, and tried to insert the point, but though he could make the loop on the wire, since called a needle, it would not slide easily over the inserted point. At length he thought of the groove instead of the hole. . . . In his first attempt at looping he inserted firmly into a piece of wood a dozen of these needles, eight to an inch, fixing this piece of wood upon a wooden framework, and endeavoured to make a succession of loops upon them by hand, which he finally accomplished, knitting on this row of hooks a pair of garters in this manner.



211. PRESSER BAR AND NEEDLE

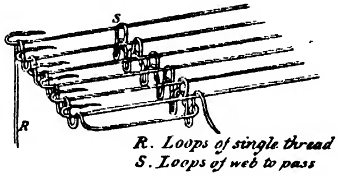
"The next point needed was to form and fix a wooden bar [211 A] to press down at one movement all the barbs of the hooks into the grooves, using the one hand to bring forward the loops, while he put down all the beards into the grooves with the other. So, by passing the row of loops over the beards and the heads of the needles, he formed row after row of loops to pass upon the previously-made rows, till several inches of web were produced [212].

"He now tried to deal with the single thread with which his web was to be made, so as to gain a sufficient length of yarn on each loop, and so to form a succession of loops across a series of needles [210*i*] placed in a straight line. . . . This, after many efforts, was effected in the most ingenious manner by the construction of what are called the jack and sinker. The jack [210*h*] is a lever working freely on a wire, upon which it is balanced. In Lee's frame these were of wood, one to each needle, and the whole row of jacks were kept in place by working in a comb. In the round head of the jack is a slit from which the sinker hangs and works perpendicularly. The sinker [210*f*] was made by Lee from a thin plate of tin, and is shaped by passing between the needles so as to carry down as much thread as will form a loop between each pair, then to carry them forwards under the needle beards and close to their heads; and after the presser had placed the points of the beards in their grooves the sinkers brought forward the web of loops already formed, and passed it over the last row formed, then took the work back to the stems of the needles ready for a new course. . . .

"The jacks, when the sinkers were attached, were lighter behind than in front, so he placed a row of light springs [210*k*] at their tails to hold them from falling forwards, except when wanted to form a fresh row of loops. Then they, following the thread thrown by the workmen each way, were forced down in rotation by an iron instrument of suitable shape, called a slur cock [210*m*], which, pulled by a string attached to treadles, runs backwards and forwards on a bar [210*l*], and by striking against the jack tails in succession, causes the hissing sound heard in framework knitting."

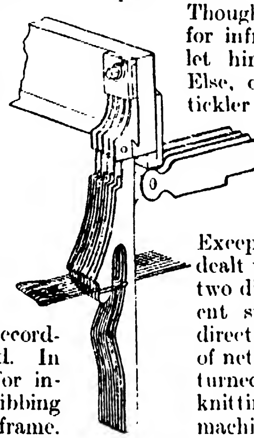
Fixed Sinkers. Aston, an apprentice taught by Lee, devised a frame which had one fixed sinker between every movable jack-sinker, and double the number of needles, thus doubling the gauge and capacity of the knitting frame [213].

Tuck Presser. Invented about 1740, the sliding tuck presser is a thin bar of iron attached to the frame presser, its lower edges grooved so as to lift some of the loops over the heads of the needles, while letting others remain, till the ordinary presser comes and passes the whole range of loops over the heads of all the needles.



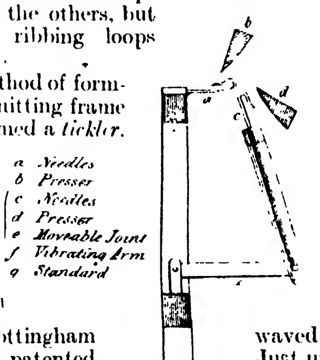
212. LOOPING ON NEEDLES

Ribbing Appliance. The tuck presser gave the knitter a certain power of changing the action of the needles, and this suggested further development. In 1758, Jedediah Strutt, of Derby, invented an appliance which solved the problem of ribbing, and opened up the way for a succession of inventions which revolutionised the hosiery trade. Strutt's apparatus [214] consists of an iron machine hung in jointed arms, *f*, in front of the ordinary frame. The needles, *a c*, in this apparatus are similar in form to those already in use, but the frame needles are set horizontally, while those of the ribbing appliance are placed almost perpendicularly, so as to work in between the former. The number of needles fixed in the added machine is regulated according to the number of loops to be reversed. In working one "purl" and one "plain," for instance, there are as many needles in the ribbing apparatus as there are on the knitting frame. When the knitting-frame needles have had their heads pressed, the needles of the ribbing machine are brought by its swinging motion in between them, penetrating those loops which are to form the ribbing, which, being passed under their beards, are reversed; then, being pressed again by the pressers, *b d*, the loops pass over the needle heads with the others, but with the visible part of the ribbing loops showing the opposite way.



213. FIXED SINKERS

Many Inventions. A method of forming fancy patterns on the plain knitting frame was by the use of a long wire named a *tickler*. With this the weaver shifted the loops according to the pattern. To make this automatic would effect a saving of labour. A poor stocking maker of Mansfield, named Butterworth, hit on a practical solution of the problem, and, by one means or another, John Morris, a Nottingham hosier, obtained possession, and patented the idea in 1764. Morris's specification runs: "For making by a machine to be fixed to a stocking frame, eyelet holes, or network, having an additional row of frame tickler needles." This machine is worthy of special attention, because it shows the first step towards the development of the lace loom. Felkin thus describes it: "The tuck presser and ribbing apparatus were combined. The tuck presser brought the loops to be shifted to the needle heads; and, in order to make the eyelet holes, these were removed by a short, flat-pointed tickler fastened to a bar. These ticklers covered the beards, pressed them into the grooves, and then took off the loops, and by a side movement placed each of them on the next needle on either side, leaving a series of fast holes below the next course of loops."



214. STRUTT'S MACHINE

Improved Tickler. A. Else, an ingenious inventor, devised an apparatus to regulate the tickler's action on a sliding bar, doubling the speed of the machine patented by Morris. Though Strutt might have sued Morris for infringement of his patent rights, he let him alone; but Morris pursued Else, on the ground that the improved tickler was an infringement of his tickler patent, won the case, and annexed the improvement.

Hand Knitting Frames. At this point we must leave the story of hosiery invention. Except in a few particulars, afterwards dealt with, the course of invention took two directions not cognate to the present stage of our inquiry. The one direction was towards the development of netting and lace frames; the other turned directly to transforming the knitting frame from a loom into a machine, ultimately to be driven by power motors. In our study of the hosiery factory, the latter part of the outline of the vast subject is glanced through. Meantime, our interest is in the hand frames. By adding on to Henson's description of Lee's frame the improvements enumerated, we can obtain a fair view of the general character of the various hand frames now in use; but we purpose making ourselves thoroughly sure of an understanding of the machine by viewing the principal details in order.

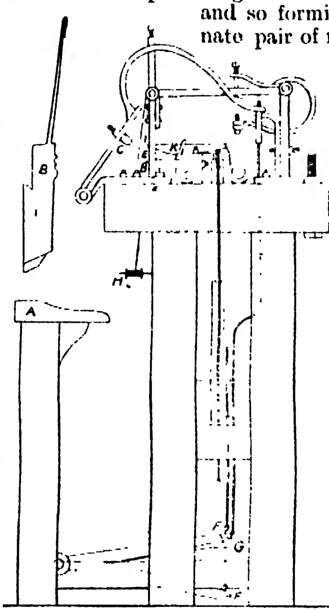
Needles. Two forms of needle may be taken as typical of the whole class—these are the bearded and the latch needles. Lee's needles were wires, peculiarly hooked. The hook was turned straight at the head, but the sharpened point was given a waved curve, which was called the beard. Just under the curved point the stem of the hook was grooved so as to admit the point of the needle when pressed down and to form a solid loop of steel. The form of this needle has been improved, the beard being straighter and easier to press down, thus obviating the risk of splitting the threads.

The latch needle, invented by M. Townshend in 1858, does away with the need of a presser bar, and is very useful in many kinds of modern frames. Instead of the curved beard, which is pressed into the groove, this needle has a hinged latch, or pin, with a fork at its point. The pin is hinged into the stem of the needle just below the point of the hook, with which it forms, when closed, a solid loop of steel. As the thread comes into the hook it throws back the latch. As it approaches to pass over the hook, the loop throws the latch into position and so passes over clear.

Sinkers. The function of the sinkers is to depress the threads for the formation of the loops. Originally the stocking frame had only one set of sinkers; but as we have it at present there are two sets—the jack sinkers and the frame sinkers. The former depend singly on levers, or jacks; the latter are fixed in a frame bar. Sinkers are thin metal plates, shaped like broad hooks with round points, which gently form the loops on the threads.

Jacks. The long levers which hold and move the sinkers are named jacks. They are actuated by springs driven by the slur cock.

Slur Cock. Along a bar under the jacks runs a small block named the *slur cock*, which, as it passes, lifts the jacks and so depresses the sinkers. The to-and-fro motion of the slur is imparted by a pulley at the side.



215. HAND KNITTING FRAME

Locker and Bar. When the sinkers have formed the loops, the locker [210*g*] is brought forward to fix them in position. The bar [210*p*] extends along the back of the frame, to be out of the way of the rest of the mechanism.

Pressers. There are different forms of presser. On the common hand frame the presser is a strong bar extending above the needles At the moment the loops are passing over the needles the bar is brought down to depress the beards and form the hook into a smooth loop The pressers on the rib hosiery appliance have a similar action.

Mountings. Ribbing apparatus, ticklers, brocade cylinders, and various other appliances for the making of fancy figures are fitted on to the knitting frame, and are technically described as *mountings*. These mountings are very numerous and varied in character.

Treadles. On the common hand frame there are three treadles. Two, one right and one left, are for bringing down the jacks; the centre treadle brings down the presser bar.

Working the Old Hand Frame. These parts are supported in a strong framing of wood, and at the centre is the weaver's seat [215*a*] Taking up his position, the weaver throws his thread, *h*, over the hooks by hand. Pressing the right foot on the treadle, *f*, he brings the slur along under the jacks, *k*, forcing down the sinkers, and so forming the loops between every alternate pair of needles. Then he brings the lead sinkers, *e*, down on the loops, to divide the loops over all the needles, locking up the jacks at the same time with the thumbs, and equalising all the loops by these combined movements. He brings the loops thus formed to the needle heads, *b*, throws up the frame with the help of the strong central spring, presses the centre treadle, *g*, to bring down the presser bar, *c*, carries the web over the needle heads, and lets the presser rise. Lowering the frame to the point at which the noses of the sinkers can catch in the work, he draws the web gently back. Finally, the knitter allows the frame to resume its balance, holding his thumbs firmly on the thumb-plate the while. When the frame has returned to its normal position he lets go, and begins another course.

Cottage and Factory. The use of the hand frame has greatly decayed, and the factory threatens to absorb the whole hosiery industry. On this fact Mr. Mundella, a well-known authority, passes the following judgment: "Notwithstanding the growth of the factory system, there is still a use for some thousands of the old hand frames; and the framework knitters, with their free choice of work hours, their independent position, their healthy life in rural villages far from the tyranny of the factory bell and the noise and unnatural conditions of modern manufacturing towns, preserve some traces of the days before the tall chimneys claimed human beings as mere details in a vast machine They may only be a survival, but perhaps they may maintain an old tradition until the dawn of a coming time when some motive power other than coal and steam shall restore to our toilers in many trades the conditions of life and work which the factory system has destroyed."

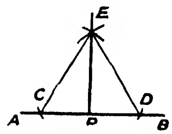
By HERBERT J. ALLPORT, M.A.

Proposition 15. Problem

To draw a straight line perpendicular to a given straight line at a given point in it.



First Method. Let AB be the given straight line, and P the given point in it.

Construction. From AB cut off any two equal parts PC and PD.

With centres C and D, and any radius greater than CP, draw two arcs cutting at E. Join PE. Then PE is ⊥ to AB.

Proof. Join CE, DE.

In the △s CPE, DPE,

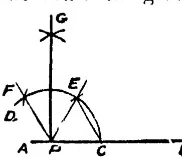
CP = DP, PE is common to both △s,

CE = DE, since they are radii of equal ⊙s.

∴ ∠CPE = ∠DPE (*Prop.* 7).

∴ each of these ∠s is a right ∠ (*Def.* 8).

Second Method. Let AB be the given straight line and P the given point.



Construction. With centre P and any radius, draw an arc CD. With centre C and the same radius cut this arc at E, and with centre E and the same radius cut the arc at F. From centres E and F, with any radius greater than half EF, draw two arcs cutting at G. Join PG. Then PG is ⊥ to AB.

Proof. Join PE, PF, CE.

The △ PCE is equilateral, since its sides are radii of equal ⊙s.

∴ △ PCE is equiangular (*Cor. Prop.* 5).

But the three ∠s of the △ make 180° (*Prop.* 14).

∴ ∠CPE = ⅓ of 180° = 60°.

Similarly, it can be shown that ∠EPF = 60°.

But ∠EPF is bisected by the straight line PG (*Prop.* 8).

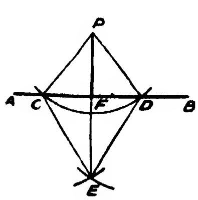
∴ ∠EPG = 30°.

∴ ∠BPG = 60° + 30° = 90°,

i.e., PG is ⊥ to AB.

Proposition 16. Problem

To draw a straight line perpendicular to a given straight line from a given point outside it.



First Method. Let AB be the given straight line, P the given point.

Construction. With centre P, and any radius great enough to reach a point on the other side of AB, draw an arc cutting AB at C and D. With centres C and D and any radius greater than half CD, draw two arcs cutting at E, on the other side of AB from P. Join PE, cutting AB at F. Then PF is ⊥ to AB.

Proof. The △s CPE, DPE can be proved equal in all respects (*Prop.* 7).

∴ ∠CPF = ∠DPF.

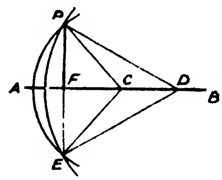
Hence, the △s CPF, DPF have two sides and the contained ∠ of the one equal to two sides and the contained ∠ of the other.

∴ they are equal in all respects (*Prop.* 4).

∴ ∠PFC = ∠PFD.

∴ PF is ⊥ to AB (*Def.* 8).

Second Method. Construction. In AB take any two points C and D. With centre C and radius CP, describe an arc. With centre D and radius DP, describe an arc cutting the first arc at E. Join PE, cutting AB at F. Then PF is ⊥ to AB



Proof. The △s PCD, ECD are equal in all respects (*Prop.* 7).

∴ ∠FDP = ∠FDE.

Hence, the △s FDP, FDE have two sides and the contained ∠ of the one equal to two sides and the contained ∠ of the other.

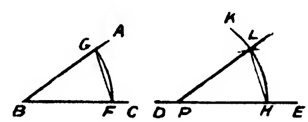
∴ ∠PFD = ∠EFD (*Prop.* 4).

∴ PF is ⊥ to AB (*Def.* 8).

Proposition 17. Problem

At a given point in a given straight line, to make an angle equal to a given angle.

Let P be the point in the straight line DE at which an angle is to be made equal to the given ∠ABC.



Construction. With centre B and any radius, describe an arc cutting AB and BC at G and F.

With centre P and the same radius, describe an arc HK, cutting DE at H.

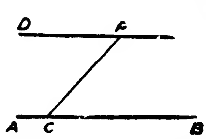
With centre H and radius FG, draw an arc cutting the arc HK at L. Join PL. Then ∠EPL is equal to the given ∠.

Proof. Join FG, HL. Then the △s BFG, PHL are equal in all respects (*Prop.* 7).

∴ ∠ABC = ∠LPE.

Proposition 18. Problem

Through a given point to draw a straight line parallel to a given straight line.



Let AB be the given straight line, P the given point.

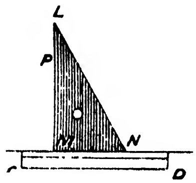
Construction. In AB take any point C. Join PC. At the point P in the straight line CP

make, by the construction of Prop. 17, the $\angle$DPC equal to the $\angle$PCB, and alternate to it. Then DP is $\parallel$ to AB.

Proof. Since the straight line CP meets the two straight lines DP, AB, and makes the alternate angles equal,

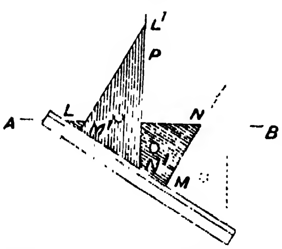
$\therefore$ DP is $\parallel$ AB (*Prop.* 11).

Note on Drawing Perpendiculars and Parallels. In practical work, perpendiculars and parallels are not drawn by using the constructions given in Propositions 15, 16 and 18. A set-square is used instead. This is simply a right-angled triangle, cut from thin wood, or other suitable material.



Suppose AB is a given straight line, and P a point through which we wish to draw a straight line $\perp$ to AB. If we place a straight ruler, CD, along the line AB, and put one of the perpendicular edges of the set-square against it, we can then slide the square along the ruler until the edge LM passes though the point P. By drawing the line LM we get the perpendicular we required.

There are two objections to this method. The one is that the corner M of the set-square gets rounded, through constant use. The other is that it is difficult to get the point of the pencil right up into the corner formed by the ruler and set-square at M. It is therefore much better to proceed as follows:



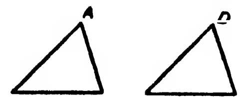
Place the *longest* edge of the square along the line AB, and put the ruler up to one of the other edges. Next, holding the ruler firmly, turn the square about the corner M, into the position shown by the dotted lines. We have thus turned the square through a right angle, and the edge LN is therefore at right angles to its former direction. Hence, if we now slide the square along the ruler until its long edge passes through the point P, *i.e.*, into the position L′M′N′, we can draw the perpendicular required.

Proposition 19. Theorem

If two triangles have two angles of the one equal to two angles of the other, and a side of the one equal to the corresponding side of the other, the triangles are equal in all respects.

If two $\angle$s of one Δ are equal to two $\angle$s of another Δ, it follows that the third $\angle$s of the two Δs must be equal. For the sum of the three $\angle$s of a triangle is equal to two right $\angle$s (*Prop.* 14).

Let, then, ABC, DEF be two Δs in which the $\angle$s A, B, C are respectively equal to the $\angle$s D, E, F, and the side BC = the side EF.



It is required to prove that Δ ABC = Δ DEF in all respects.

Proof. Place the ΔABC on the ΔDEF, so that B falls on E, and BC along EF. Then, since BC = EF,

$\therefore$ C must fall on F.

And since $\angle$B = $\angle$E

$\therefore$ BA must fall along ED.

And since $\angle$C = $\angle$F

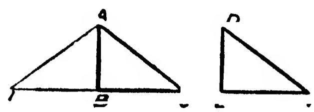
$\therefore$ CA must fall along FD.

$\therefore$ the point A, which is the intersection of the lines BA, CA, must fall on the intersection of the lines ED, FD, *i.e.*, on the point D.

$\therefore$ ΔABC coincides with the ΔDEF, and is equal to it in all respects.

Proposition 20. Theorem

If the hypotenuse and one side of a right-angled triangle are respectively equal to the hypotenuse and one side of another right-angled triangle, the triangles are equal in all respects.



Let ABC, DEF be two right-angled Δs, in which the $\angle$s ABC, DEF are right angles, the hypotenuse AC = the hypotenuse DF, and AB = DE.

It is required to prove that the Δs are equal in all respects.

Proof. Place the ΔDEF so that DE coincides with the equal side AB, and F falls on that side of AB away from C. Let F′ be the new position of F.

Then, since $\angle$s ABC and ABF′ are right $\angle$s.

$\therefore$ BC and BF′ are in a straight line (*Prop.* 2)

$\therefore$ AF′C is a Δ, in which AF′ = AC.

$\therefore$ $\angle$AF′B = $\angle$ACB (*Prop.* 5),

i.e., $\angle$DFE = $\angle$ACB.

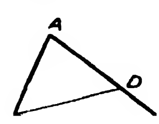
$\therefore$ in the Δs ABC, DEF,

$\angle$ABC = $\angle$DEF, $\angle$ACB = $\angle$DFE, AB = DE.

$\therefore$ the Δs are equal in all respects (*Prop.* 19).

Proposition 21. Theorem

If one side of a triangle is greater than another, the angle opposite to the greater side is greater than the angle opposite the less.



Let ABC be a Δ, in which AC is > AB.

It is required to prove that $\angle$ABC is > $\angle$ACB.

Proof. From AC cut off AD = AB. Join BD. Then, since AB = AD,

$\therefore$ $\angle$ABD = $\angle$ADB (*Prop.* 5).

But the exterior $\angle$ADB of the ΔBCD, is > the interior opposite $\angle$DCB (*Prop.* 10).

$\therefore$ $\angle$ABD is > $\angle$ACB.

Still more, therefore, is $\angle$ABC > $\angle$ACB.

ACIDS

Appliances and Processes in the Manufacture of Sulphuric, Nitric, and Hydrochloric Acids

Continued from page 4416

By CLAYTON BEADLE and HENRY P. STEVENS

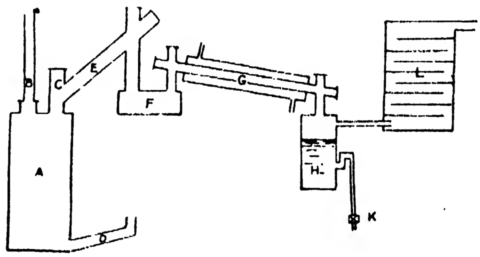
Sulphur and Brimstone. This substance is usually associated in our minds with fire and the nether regions. The popular superstition has some foundation in fact, as brimstone is found in the neighbourhood of volcanoes. Sulphur or brimstone is the main constituent of perhaps the most important of all chemical substances—namely, *sulphuric acid.* It occurs in nature as native sulphur in certain parts of the world, particularly Southern Italy, where it is sometimes extracted in a rather primitive manner. The sulphur ore, when poor in sulphur, is made into a heap, and the heat derived from burning a part of the sulphur melts the rest, which runs out and is collected. Such a process is, of course, very wasteful, but has the advantage of simplicity and cheapness. A better plan is to supply the heat by burning fuel and to allow the molten sulphur to collect.

Various Sulphur-recovery Processes. In other processes the sulphur is melted out by treating with a hot liquid, such as a saturated solution of calcium chloride, or by using superheated steam. All these processes are based upon the principle that the sulphur melts, leaving the earthy material behind. A recent adaptation of this process has been made use of to obtain sulphur from deposits in the State of Louisiana. In the neighbourhood of Lake Charles City there is a large deposit of sulphur under a layer of shifting sand, and 200 ft. to 250 ft. below the surface. The sand formed, until recently, an impassable barrier to the sulphur deposit, and all attempts to freeze the sand, a method which at other times has given satisfactory results, proved in this case unavailing. However, Frasch has recently patented and developed a method in which super-heated water, at a temperature of 166° C. is forced down into the sulphur deposit through a steel tube, and the molten sulphur forced up another tube placed inside the former (German Patents, 461429, 461430, 461431).

Sulphur can also be distilled, and it may pay to treat rich ores in this manner. The vapours are condensed and form *flowers of sulphur* if the cooling chamber be large and the temperature not allowed to rise too high, otherwise the sulphur melts. Molten sulphur run out and cast into blocks is known as *roll sulphur.* Distillation, however, is usually resorted to for refining sulphur.

Besides native sulphur, the element can be obtained from certain sulphides, particularly that of iron, known as *iron pyrites,* which occurs abundantly in various parts of Europe. This substance, if heated, parts with rather less than half of its sulphur, but the process is not used to a large extent for obtaining sulphur. Pyrites are more suitably employed for producing sulphur dioxide, as we shall presently see. Sulphur may also be obtained from coal gas by-products, such as the spent oxide from the gasworks. Here, again, it is better to prepare sulphur dioxide rather than sulphur from such sources. Sulphur can also be obtained by a number of processes from alkali waste, which consists largely of sulphide of calcium.

Carbon Disulphide. We have just mentioned this substance as a suitable solvent for sulphur. It is also largely used as a solvent for other substances. It is prepared by passing vapour of sulphur over red hot coal or charcoal. Vertical retorts are used constructed of cast iron, or earthenware, glazed inside [shown diagrammatically at A, in 1]. The lid



1. CARBON DISULPHIDE PLANT

of the retort is provided with two openings—one, B, for the introduction of fresh charcoal, the other, C, for leading off the vapours to the condenser, while the sulphur is introduced through an opening at D at the bottom of the retort. This opening is fitted with a tube sloping gently upwards, down which the sulphur runs, and is vaporised on flowing into the retort. The vapour passes up through the mass of charcoal, whereby the larger quantity is converted into carbon disulphide. The vapours leave the retort by a wide tube, E, sloping upwards, in which the sulphur condenses and flows back again into the retort, while the carbon disulphide, which is far more volatile, passes on into another vessel, F, in which any residue of sulphur is deposited. The vapours are condensed in a suitable condenser, G, and the liquid is collected in a receiver, H, and may be drawn off through the cock, K.

Any vapours of carbon disulphide which escape condensation are absorbed in a vessel, L, containing shallow trays filled with a vegetable oil. The crude carbon disulphide which still contains a small quantity of sulphur, is purified by distillation. When large quantities are taken,

such as five tons at a time, the distillate is collected in several portions ; that which comes over first contains most of the evil-smelling constituents. Sometimes the crude product is distilled over caustic soda, which holds back sulphuretted hydrogen and other impurities.

In place of caustic soda, certain metallic salts which react with sulphides, such as copper sulphate or chloride of lime, will serve the purpose. Thus, 100 parts of crude material may be treated with two or three parts of dry copper sulphate, and then redistilled over a fresh quantity of the same substance.

Carbon disulphide, or *bisulphide*, as it is sometimes called, is a colourless, very volatile, and heavy liquid, which has usually a very repugnant odour, due to the presence of small quantities of sulphur compounds. As already stated, it is an excellent solvent, and will dissolve elements such as phosphorus, iodine, bromine, chlorine, and sulphur, and a great variety of organic substances, such as rubber, camphor, fats, and grease of all kinds.

Care must be taken to avoid inhaling the vapours, as it is of a very poisonous nature, and would probably find a much wider use were it not for this circumstance. As it is, it is very largely employed in a number of industries for extracting fat and grease. It is also used in rubber factories [see INDIARUBBER] and for making viscose [see PAPERMAKING].

Sulphur Dioxide. The preparation of sulphur dioxide from native sulphur, pyrites, spent oxide, or other sources, is the first stage in the manufacture of sulphuric acid.

Spent oxide is a mixture of about equal parts of oxide of iron and of sulphur. In the neighbourhood of large towns, where much gas is burned, it is plentiful, and forms a good material for making sulphur dioxide. Brimstone is practically free from arsenic, and gives the purest product ; spent oxide is somewhat inferior, and pyrites, which always contains much arsenic, yields the lowest-grade acid. The brimstone, pyrites, or spent oxide, is heated in a small furnace, with the admission of sufficient air to combine with the sulphur to form sulphur dioxide. As a rule, rather more air than is necessary must be admitted into the furnace, and the process must be regulated so that as little sulphur as possible vaporises and sublimes unchanged. Owing to the excess of air present, some of the sulphur combines with more oxygen than is required to form the dioxide so that it becomes contaminated with sulphur trioxide (or sulphuric anhydride), SO_3.

Since the air contains only one-fifth part by volume of oxygen, the strongest gas produced cannot possibly contain more than 20 per cent. of sulphur dioxide. As a matter of fact, it does not usually contain more than 15 per cent. when burning sulphur, and only 8 per cent. when burning pyrites. In working with sulphur and spent oxide it is easy to avoid using a large excess of air, but with pyrites a larger excess is necessary in order to effect a thorough roasting of the material. In the manufacture of sulphuric acid, this is of little importance, as an excess of air always has to be admitted into the chambers, sufficient to oxidise the sulphurous to sulphuric acid. On the other hand, when preparing sulphites or a solution of sulphur dioxide in water, an excess of air should be avoided. Large quantities of acid calcium bisulphite are prepared for the manufacture of sulphite cellulose [see PAPERMAKING], and here also an oven which will produce sulphur dioxide gas with as small a percentage of free oxygen as possible will have the advantage. Liquid sulphur dioxide is often supplied in "syphons" [2].

2. SULPHUROUS ACID SYPHON

Brimstone and Pyrites Burners. The ovens for burning sulphur (brimstone burners) and spent oxide are comparatively simply constructed. They consist of a tray to contain material placed in a furnace, composed of an iron retort in the form of a long box provided at one end with well-fitting doors for charging, the other end leading to the flue. These doors have ventilating holes which can be opened or closed at will. In this way the supply of air can be satisfactorily regulated and the formation of sulphur trioxide avoided.

Pyrites burners are provided with a grate formed of bars on which the material is placed. Besides the lumps there is always some fine powder or "smalls," for which special furnaces have to be provided. In some works, when pyrites are burnt for preparing sulphite liquor the gases are led through a Kellner filtering tower, which contains lumps of limestone, so that the sulphuric acid is retained by the limestone as calcium sulphate. The tower is washed out from time to time with water.

Sulphuric acid has a greater tendency to be formed in the burners if moisture be present. If the temperature of the oven should get too high, some sulphur will be sublimed unchanged, and block the outlet pipes and flues, so that care must be taken to see that the furnace does not get too hot. This may be done partly by avoiding an excess of air, and partly by cooling the furnace. We can cool the furnace by placing a water-jacket round it, or else by playing a jet of water on to it. The colour of the burning sulphur is an indication whether the right amount of air is being admitted, as the sulphur should burn with a pale-blue flame tipped with white. If the furnace gets too hot, yellow-brown clouds of sulphur vapour make their appearance.

In some plants, that part of the sulphur which is not burnt straight away, but sublimes, has an opportunity of burning in an intermediate chamber before the gases are led away. In this manner the drawback common to most sulphur burners where the sulphur sublimes if the temperature gets too high may be avoided. In another plant a continuous supply of molten sulphur is burnt by subliming it and introducing air to burn the sulphur vapours. The sulphur dioxide then passes through a chamber loosely packed with bricks in which any sublimed sulphur deposits. The great disadvantage in working pyrites burners lies in the

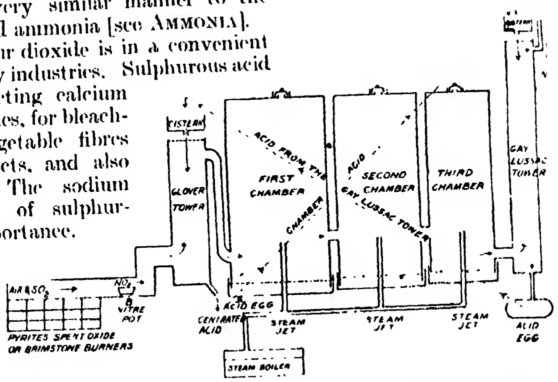
formation of much flue dust, which is carried along by the gases. Long settling chambers where the dust is deposited are necessary. In some plants the chambers have baffle plates, which effectively hold back the finely divided particles suspended in the current of gas.

Sulphurous Acid and Sulphites. The gas is led through a small quantity of water, which soon becomes saturated and no longer absorbs the sulphur dioxide but retains small quantities of sulphuric acid. The gas then passes into towers filled with coke, over which water is allowed to trickle, the excess of nitrogen escaping into the air.

For the preparation of liquid sulphur dioxide it is necessary to have the gas free from nitrogen, for which purpose a saturated solution of sulphurous acid is heated in a leaden retort. The sulphur dioxide which escapes is passed through oil of vitriol, which retains the moisture, and then on to a compressor, where it is condensed to a liquid in a very similar manner to the preparation of liquid ammonia [see AMMONIA].

This liquid sulphur dioxide is in a convenient form for use in many industries. Sulphurous acid is used for extracting calcium phosphate from bones, for bleaching all sorts of vegetable fibres and animal products, and also for disinfecting. The sodium and calcium salts of sulphurous acid are of importance.

Sodium bisulphite is prepared by saturating a solution of soda with the gas. The bisulphite ($NaHSO_3$) is converted into normal sulphite ($Na_2SO_3 7H_2O$) by adding to it a solution of sodium carbonate in the correct proportion. [For calcium and magnesium sulphites see PAPERMAKING.]



3. PLANT FOR MAKING SULPHURIC ACID BY CHAMBER PROCESS

Sulphuric Acid. It is considered by some that the manufacturing activity of any country may be very closely estimated by its consumption of sulphuric acid. It is perhaps the most important of chemical substances, and the basis of many important industries. There are two methods of manufacture termed respectively the *chamber* and *contact* processes, both of which are worked on a very large scale in this country. The contact process is comparatively new, but is likely to supersede the older chamber process.

We shall consider the chamber process first. We have already shown how large quantities of sulphur dioxide and sulphurous acid may be prepared by burning sulphur or spent oxide, or by roasting iron pyrites. The whole process of the conversion of this substance into sulphuric acid lies in the addition of one atom of oxygen to the molecule of sulphurous acid ($H_2SO_3 + O = H_2SO_4$). Sulphurous acid solution in contact with air is slowly converted into sulphuric acid, but the process is too slow and cumbersome for manufacturing purposes. It has long been known that the higher oxides of nitrogen give up oxygen to sulphur dioxide, converting it into sulphur trioxide, which on contact with water produces sulphuric acid. This is the chamber process in a nutshell.

The lower oxide so formed reforms the higher oxide by contact with air and is again reduced with formation of more sulphuric acid. The oxide of nitrogen acts merely as a carrier without itself undergoing any permanent change. Theoretically, then, a very small quantity of oxides of nitrogen is sufficient to convert an unlimited quantity of sulphurous into sulphuric acid provided sufficient air and water be present. In practice, however, there is always a loss of oxides of nitrogen, as will be seen shortly. The chemical changes may be represented thus:

SO_2	+	NO_2		H_2O		H_2SO_4		NO
Sulphur dioxide		Nitrogen peroxide		Water or steam		Sulphuric acid		Nitric oxide
	$2NO$	+	O_2		$2NO_2$			
	Nitric oxide		Oxygen from the air		Nitrogen peroxide			

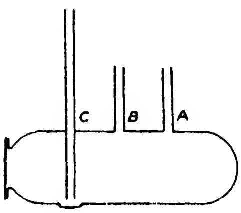
Fig. 3 illustrates the formation of sulphuric acid in the chamber process. Sulphur dioxide (SO_2), obtained by burning pyrites, spent oxide, or brimstone, reacts with higher oxides of nitrogen (NO_2), obtained from nitre, to yield sulphur trioxide (SO_3) and the lower oxide of nitrogen (NO). The sulphur trioxide (SO_3) combines with the water (H_2O) from the steam to form sulphuric acid (H_2SO_4), while the lower oxide of nitrogen (NO) combines with the oxygen (O) from the air to form the higher oxide of nitrogen (NO_2), ready to give up this oxygen again to a further quantity of sulphur dioxide with the formation of more sulphuric acid, and so on indefinitely.

Working Processes. Having now explained the principle of the "chamber" process, we will shortly describe the construction of the plant [3] and its mode of working.

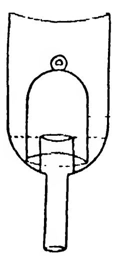
The flue gases from the sulphur or pyrites burners are brought into contact with oxides of nitrogen evolved from pots containing nitre and sulphuric acid placed in the flue, whence they pass together into a series of "lead chambers," supported on a woodwork frame and resembling boxes without bottoms. They stand in large leaden trays sealed by a water joint as shown in the figure. They have to possess a certain cubic capacity for every pound of sulphuric acid produced. Steam jets supply the water necessary to complete the reaction. The sulphuric acid condenses and collects at the bottom of the chamber from which it is drawn off.

The escaping gases consist of atmospheric nitrogen and unconsumed oxygen and steam. They hold mechanically some quantity of oxides

of nitrogen and sulphuric acid. If allowed to escape they would pollute the atmosphere and add to the cost of production through waste of the valuable oxides of nitrogen. To avoid this loss they are conducted to the bottom of the "Gay-Lussac" tower [see **3**]. This tower is usually cylindrical, and built of lead like the chambers. It is filled with coke and provided at the top with a cistern to hold "chamber acid." This acid collects in an oblong vessel under the chamber, termed an acid "egg" [**3** and **4**], whence by air pressure it is forced up to the cistern in the top of the tower. Thence it finds its way through a number of "lutes" [**5**] fixed in the lead roof of the tower, and, trickling down over the coke, absorbs and carries with it the greater portion of the nitric fumes contained in the ascending current of gases. A means must now be found for freeing the acid from the oxides of nitrogen and conveying the latter into the chambers for further action on the sulphur dioxide. This is effected by means of a "Glover" tower, which is built on a similar principle to the Gay-Lussac tower.



4. ACID EGG



5. ACID LUTE, OR DRIP

The sulphuric acid containing the oxides of nitrogen is forced up into the cistern at the top of the tower, and as it descends it meets the hot flue gases from the pyrites burners, with the result that the sulphuric acid gets heated, and most of the oxides of nitrogen and some of the water are driven off and carried along with the flue gases. It will be seen, then, that the sulphuric acid in the Glover tower not only gives up its oxides of nitrogen, but, at the same time, is concentrated, while the steam and oxides of nitrogen are carried together into the chambers.

Chambers. Most works possess at least two, but usually not more than four of these chambers. The chambers, of course, vary in size according to requirements and output. They are connected together by leaden flues, the last chamber being connected with the Gay-Lussac tower. As already explained, there must be plenty of room in the chambers for the sulphur dioxide, nitrogen oxides, and steam to react with one another before they reach the Gay-Lussac tower. Of course, the faster the gases are fed into the chambers the larger the chambers must be built.

Avoidable and Unavoidable Losses. In any manufacturing process, the actual chemical changes which take place are never exactly represented by the theoretical chemical equations; and in the manufacture of sulphuric acid these chemical reactions are never quite complete, so that a certain proportion of sulphur dioxide and nitric oxides which is not dissolved in the Gay-Lussac tower escapes and is lost.

It is a question for the manufacturer of sulphuric acid whether it will pay him best to increase his production by feeding in the gases faster, and losing a larger proportion, or going to the expense of building and up-keeping larger chambers. In France a method known as *forced working* is employed. The amount of nitric fumes carried away from the chambers is considerable, but the plant is provided with extra large Gay-Lussac towers to counteract this. As just stated, the lower oxide of nitrogen, nitric oxide (NO), is not dissolved in the Gay-Lussac tower, but only the higher oxides, so that to prevent loss of oxides of nitrogen we must have a plentiful supply of air in the last chamber. This will ensure the conversion of any of the lower into the higher oxides before reaching the Gay-Lussac tower. For this purpose sufficient air must be admitted with the other gases, and the excess of air necessary will vary with the circumstances—that is, as to whether the sulphur dioxide is got by burning sulphur, spent oxide, or pyrites, and in the last case, whether rich or poor ore. From the equations we have already given it will be seen that enormous quantities of sulphuric acid can be made with only the smallest quantity of oxides of nitrogen, but in practice the action is too slow unless larger quantities of nitre are used.

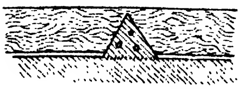
Working Conditions. It will be seen that the design and working of the sulphuric acid plant necessitates careful control and experience in using the right proportions of ingredients if the process is to work economically.

To give some idea, it may be stated that under the most favourable circumstances, working with plant which is in efficient repair and using a good class of pyrites, the supply of gas during the twenty-four hours must not exceed ten to eleven times the volume of the chambers when using three to four parts of nitre for every hundred parts of sulphur burnt. Under these circumstances, perhaps 1 to 2 per cent. of sulphur dioxide will escape conversion into sulphuric acid. To put it into other words, for every pound of sulphur burnt daily we must allow 16·2 cubic ft. of chamber space. If we economise the nitre, and use only 2·5 to 3 parts per 100 parts of sulphur, we must allow instead 19·8 cubic ft. In many works anything up to 25 cubic ft. may be found. By the method of "forced working" just spoken of, only some 12 cubic ft. are allowed.

Chamber Construction. The construction of chambers varies considerably. Of course, the larger the contained space per square foot of lead sheeting the better, so that the ideal chamber would be spherical.

In practice, chambers are usually made rectangular in form, using as few, and making them as large, as possible. A good method is to make the first chamber much the largest—say, two-thirds of the whole—as it is here that most of the chemical action takes place. The second chamber may have a capacity of two-ninths of the whole, and the third one-ninth. The weakest acid collects in the last chambers, so that they should be built each standing a little higher than the first, the weaker acid running down to the first chamber. The substance of the sheet lead, of which the

chambers are made, is in most cases somewhere about 6 lb. to the square foot. Sometimes the first chamber is built of heavier sheet, as the temperature is higher, and, in consequence, the wear of this chamber is greater. The lead is attached to a wooden scaffolding by tongues [6].



6. LEAD TONGUE FIXED TO A WOODEN BEAM

Chambers are connected by tunnels, which interfere least with the draught when they lead out of the bottom of one chamber into the top of the next; otherwise they are near the bottom, as illustrated.

Testing Progress of Operations. The whole process has to be carefully controlled. For this purpose instruments very like rain gauges are placed on the floors of the chambers. The rain of fine drops of acid is caught as it descends in the chambers. These "tell-tales" are provided at the bottom with a syphon from which the acid "drips" are collected. By taking the specific gravity of these "drips," and also of the bottom acid—namely, that which has collected on the bottom of the chambers—the progress of the reaction can be followed, and the supply of sulphur dioxide, nitric fumes, and steam regulated in accordance.

Chambers are also provided with glass peep-holes, so that the colour of the nitric fumes can be judged. Reference to the Pure Chemistry course will show that the lower oxide of nitrogen, nitric oxide (NO), is colourless, but when it combines with oxygen it forms the higher oxide, nitric peroxide (NO_2), which has a deep orange red shade. If the contents of the last chamber are pale yellow or colourless, it shows that there is either an insufficient supply of nitric fumes or else that there is not enough oxygen to convert them into the higher oxides. In the former case more nitre must be burnt, and in the latter more air let in. It is essential that the nitric fumes should be thoroughly oxidised before they reach the Gay-Lussac tower, as the higher oxides only are absorbed there.

Chamber Acid. The strength of the acid which collects on the bottom of the chambers will depend partly upon the amount of steam supplied. If the acid gets too strong—above 125 Tw., which equals s.g. 1·625—it begins to dissolve large quantities of the oxides of nitrogen, and not only would there be a loss of this valuable substance, but the acid would begin to act vigorously on the lead of the chambers. To avoid undue corrosion the acid is drawn off a little below this strength.

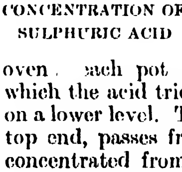
Acid cocks are very liable to get out of order, and it is usual to draw off the sulphuric acid (chamber acid) by means of a syphon. As the acid frequently has to be concentrated, some makers find that it pays them to allow the strength to rise to 140 Tw., the increased value of the acid compensating for the loss due to the corrosion of the chambers.

Gay-Lussac and Glover Towers. For the Gay-Lussac tower to do the work of recovering the oxides of nitrogen efficiently its capacity should be not less than 1 per cent., but preferably nearer 2 per cent., of the capacity of the chambers. The same applies to the Glover tower. The latter is usually built shorter and broader, and of heavier lead, often lined with firebrick, as the gases which enter it are very hot, and consequently have considerable action on the walls. It is filled with lumps of flint, as the coke used in the Gay-Lussac tower might catch fire if the supply of steam or acid were accidentally cut off. It is said that a considerable amount of sulphuric acid is formed in this tower—sometimes as much as 10 per cent. or 15 per cent. of the whole. In this way it acts as an extra chamber, besides concentrating the chamber acid, which trickles down it from the cistern on the top, and freeing it from the nitric fumes, which are carried on to the chambers. Gay-Lussac towers are sometimes built up of perforated acid-proof earthenware plates, which take the place of the coke. These plates are moulded so that a little pool of acid collects over each hole and drops through on to the plate below. This construction is more effective than towers filled with lumps of coke. These so-called *plate-columns* have also been used to replace chambers, and in some works alternate chambers and plate columns are employed. The latter are said to be ten to twenty times as effective as the former.

Concentration. Acid as concentrated in the Glover tower is impure. If pyrites acid, it contains arsenic and iron from the flue dust of the pyrites burners, also some oxides of nitrogen and lead sulphate from the walls of the tower and chambers. The arsenic can be got rid of by passing sulphuretted hydrogen through the acid, when it is precipitated as a sulphide, or by heating it with a little common salt, when the arsenic chloride, being volatile, is driven off.

To get rid of the oxides of nitrogen a little ammonium sulphate is added. The nitrates and nitrites of ammonia formed are decomposed when the acid is heated.

Having got rid of the nitric fumes the acid can be concentrated in lead pans to 145-150 Tw. When stronger, the acid goes for the pans, and for final concentration some more resistant material must be chosen. Glass and porcelain have the disadvantage that they are liable to crack and break suddenly, and cause much loss of acid, while platinum is very much acted upon, and the wear of the vessels is a very serious item in the cost of the process. In Webb's plant [7] porcelain pots provided with hoods are used, and the concentrating operation is continuous—that is to say, 20 pots or so are set in a line on a brick oven; each pot is provided with a lip, from which the acid trickles into the next pot, placed on a lower level. The acid flowing in weak at the top end, passes from pot to pot, and flows out concentrated from the bottom one. The acids, concentrated to 94 per cent. to 95 per cent., can be obtained absolutely free from water, either by adding to them some fuming sulphuric acid



7. CONTINUOUS CONCENTRATION OF SULPHURIC ACID

to convert the water into sulphuric acid, or by freezing the liquid, when the mono-hydrated acid (acid with one molecule of water) separates out.

Contact Process. We have explained the chamber process for making sulphuric acid; we now come to the second commercial process, which works without chambers. Although in some respects simpler, it is complicated by the fact that special precautions have to be taken to ensure the purity of the flue gases from the sulphur or pyrites burners. This section need not be studied except by the more advanced student and those who are anxious to acquaint themselves with the very latest methods for making sulphuric acid.

Reference to the course on Inorganic Chemistry will show that one of the methods of preparing sulphur trioxide is to pass a mixture of oxygen and sulphur dioxide gas over platinised asbestos, heated in a glass tube. $2SO_2 + O_2 + 2H_2O = 2H_2SO_4$. Sulphur trioxide, when dissolved in water, gives sulphuric acid, and the question naturally arose, Could this principle be applied to the manufacture of sulphuric acid? Early experiments in this direction seemed to show that the action is only partial when the sulphur dioxide and oxygen are much diluted with nitrogen, as would be the case in practice, where air would replace oxygen in the experiment mentioned above. We may, perhaps, mention here that the original discovery is due to Davy, 1817, and the first real attempts to apply it on a manufacturing scale, to Phillips, 1831 (British patent 6096). It was soon found that a number of conditions would have to be carefully complied with if the process was to be successful.

In the first place, the gases must be dry, and all dust and other impurities carefully excluded. The flue gases leaving the pyrites burners contain about 6 per cent. excess of oxygen over that necessary for the conversion of sulphur dioxide into sulphur trioxide. Knietsch has patented a successful process now working at Ludwigshafen on the Rhine. He found, in the course of his early experiments, that an excess of air had no influence on the oxidation process. His first experiment was made with artificial gases, and with such success that he soon began experimenting with the actual flue gases. These he led off from pyrites burners, through long tubes to deposit dust, and then dried them with sulphuric acid.

Contact Poisons. It was soon found, however, that the platinised asbestos, or *contact substance*, as it was called, began to lose its power, and no improvement was obtained by cooling the gases or further filtration and washing with sulphuric acid. This entailed a considerable amount of experimental work. Eventually, a number of laboratory experiments showed that certain elements are extremely injurious to the action of the contact substance—in particular, arsenic, mercury, and phosphorus, the last-named owing, perhaps, to the arsenic it contained. A number of other metals, such as antimony, bismuth, lead, iron, and zinc, were also found to clog up, and mechanically envelop the contact mass when introduced in large quantities. However, arsenic is the most troublesome "poison," not only because 1 to 2 per cent. on the weight of the platinum entirely destroys its activity, but arsenic is contained in all flue dust from pyrites burners. Moreover, the contact substance once "poisoned," it is difficult to effect a cure.

Having now discovered the cause of failure, it remained to find a remedy.

Prevention Better than Cure. Even the purified flue gases were found to contain a finely divided whitish mist of sulphuric acid, which could not be precipitated. The method eventually employed for purifying the gases consisted in gradually cooling them by leading them through a long dust flue and a set of lead pipes so that their temperature was reduced 100° C., and then through a series of mechanical washers, which were found more effective than washing towers, to retain the sulphuric acid. The gas is then dried over strong sulphuric acid and subjected to an optical and chemical test before going further. In the optical examination a layer of gas is viewed through a tube several feet in length to see if it is free from dust and mist.

In the chemical examination a current of the gas is passed for 24 hours or more through water, and the water tested for arsenic by the Marsh test [see ANALYTICAL CHEMISTRY]. Great care has to be taken to see that sulphuric acid does not condense on the iron flues on its way from the burners, as a certain amount of arsenuretted hydrogen is produced, owing to the liberation of hydrogen by the action of acid on the iron pipes. Arsenuretted hydrogen is a gaseous substance, and, once formed, would be carried on to the contact substance and rapidly poison it.

In the pyrites kilns there is always some very finely divided sulphur, which, under ordinary circumstances, is carried forward by the flue gases. This sulphur, as it would contain traces of arsenic, has to be got rid of by some means or other. It was found that directing a jet of steam into the kilns aids the combustion of the sulphur dust, and also brings about the condensation of any sulphuric acid present, so that the coolers do not become encrusted with solid impurities in combination with sulphuric acid.

By close attention to the foregoing details, it is possible to produce mixed gases on a commercial scale, and, in quality, free from traces of arsenic and other contact poisons.

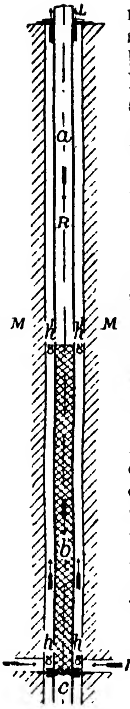
How the Heat Reaction is Controlled. When sulphur dioxide combines with oxygen to form sulphur trioxide, a very large amount of heat is evolved. This is in accordance with the equation ($SO_2 + O = SO_3 + 32{\cdot}2$ calories). A calorie is the unit for measuring quantities of heat. Put in other words, sulphur dioxide and oxygen combine to form sulphur trioxide, while at the same time 32·2 units of heat are produced, so that the sulphur trioxide formed is much hotter than the sulphur dioxide and oxygen before they entered into combination.

The reaction between the sulphur dioxide and oxygen in the presence of the contact substance takes place only when the gases are hot enough

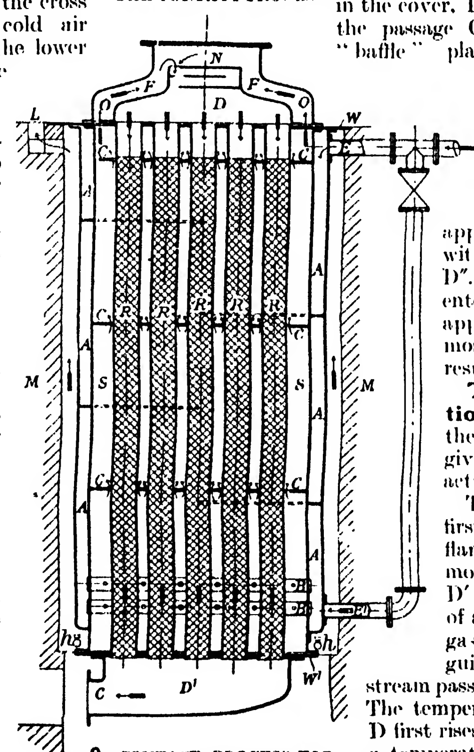
at the start—that is, when raised to a sufficiently high temperature. The heat produced by the chemical union of the already heated gases may be so great as to raise the mass to a bright red heat, and so prevent the permanent formation of sulphur trioxide, which tends to dissociate at very high temperatures. At the same time the iron parts of the apparatus are quickly destroyed by the action of the sulphur compound, and the efficiency of the contact mass is also reduced. This, of course, is due to the reverse action, the sulphur trioxide being broken up again into sulphur dioxide and oxygen, the reaction taking in both directions as shown by the arrows ($SO_2 + O \rightleftarrows SO_3$).

The Plant Described in Detail. It is, therefore, necessary to cool the contact substance, and in the early form of apparatus this was accomplished by means of a current of air. The plant for this purpose is shown in **8**, according to patent No. 15947, 1898. In a brickwork structure, or an iron tube, M, is fixed a tube R, leaving a space between the outside of the tube R and the inside of the brickwork of tube M. The two portions, *a* and *b*, of the tube R serve different purposes and may consequently differ from one another in length and diameter, and both parts can be replaced by a number of tubes. The one part, *b*, is occupied by the contact substance (indicated by the cross lines), and is cooled by cold air entering by the inlet *n*, at the lower end of the outer tube. In the other part, *a*, of the inner tube, the gases containing the sulphur dioxide, which enter at the upper end, are heated to the temperature necessary for the reaction.

When beginning the operation, the whole apparatus is first raised to the temperature necessary for the reaction by heating by means of gas flames, *h*. Then, if concentrated gases are used after the reaction has once begun, further heating is unnecessary, because the air cooling the contact mass absorbs heat and transfers sufficient heat to the other portion, *a*, of the tube containing the sulphur dioxide gases, to allow of the necessary reactions taking place in the contact mass *b*. The stream of air can be regulated by means of adjustable updraught openings, L, in such a way that the contact mass in the part *b* is constantly maintained at the temperature most favourable for the



8. SULPHURIC ACID BY THE CONTACT PROCESS



9. CONTACT PROCESS FOR SULPHURIC ACID MANUFACTURE

reaction. When the gases contain but little sulphur dioxide, the air, which is somewhat heated by its cooling action, is further heated by means of the gas flames, *h'h'*, so that the gases flowing in through the part *a* of the tube get more strongly heated. The gases, which now contain sulphur trioxide issuing from the contact mass in the part *b*, leave the apparatus by a pipe, *c*.

An Improved Method. Instead of using air for cooling the contact mass, it is much more economical to use the flue gases themselves. They thereby become heated up to a temperature sufficiently high for the reaction to begin. This apparatus is shown in **9**. It will be noticed at once that we have here a battery of five tubes instead of one, and that the whole of the tubes are filled with the contact mass. In order that the cooling gases may pass as closely as possible in contact with the walls of the tubes which contain the contact mass, there are inserted at intervals a number of partitions, C, C, extending across the chamber S, sufficient space being left for the gases to pass through close to the walls of the inner tubes, R, R, as indicated by the small arrows.

The gases should be thoroughly mixed before they pass into the contact mass, in order to equalise their temperature. This is done by means of mixing apparatus, N, fitted in the cover, D, the gases passing up the passage O F and between the "baffle" plates as shown. The strength of the current and the temperature of the cooling gases is regulated by noting the readings of thermometers fixed in various parts of the apparatus, and especially within the covers D and D″. Analyses of the gases entering and leaving the apparatus show when the most favourable practical result is being obtained.

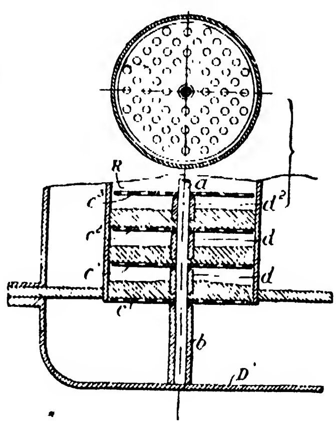
The Plant in Operation. In order to explain the mode of action we may give an instance taken from actual working.

The apparatus is heated first (say, by means of gas flames at *h'*), until a thermometer in the upper cover D′ indicates a temperature of about 300° C. Then the gas flames are extinguished, and the whole gas stream passes into the apparatus A. The temperature within the cover D first rises. When it has reached a temperature favourable for the reaction, a valve in the upper part

of the apparatus is opened, so that a part of the gases may enter directly, as shown by the arrows. The gases entering and leaving the apparatus are analysed to determine their contents of sulphur dioxide, and in this way we can see how the plant is working.

To Regulate the Temperature. About two-thirds of the entire gas current passes in at the entrance A to the chamber S surrounding the inner tubes R, and one-third directly into the top cover D. The temperature, which becomes uniform owing to the action of the mixing chamber N, in the cover is about 380° C., while the thermometer in the lower cover D′ indicates about 234° C. In this actual case, taken from experimental practice on the factory scale, a conversion of from 96 per cent. to 98 per cent. of that theoretically possible has been obtained while making from 40 to 50 kilogrammes of SO_3 per tube in 24 hours. The conversion can be increased to 99 per cent. if the gas be permitted to remain longer in the presence of the contact substance.

Filling the Contact Substance into the Tubes. The method of packing the tubes with platinised asbestos so that the gases shall come thoroughly into contact with the mass without having their flow too much impeded is seen in the next diagram [10]. A central iron rod, *a*, passes up the axis of the contact tube R; surrounding the bottom end is the short tube *b*, on which rests the perforated plate *c*. On this sieve plate is heaped the platinised asbestos, and then another short piece of tube, *d*, is fitted on to the rod *a*. This is followed by a second sieve tube, *c′*, carrying its layer of platinised asbestos; and then another short piece of tube, *d′*, followed by a third sieve plate, c^2, and so on.



10. SULPHURIC ACID BY CONTACT PROCESS

Instead of asbestos as a carrier for the platinum, a mass can be used prepared, for example, by heating barium chloride with ammonium sulphate. These substances interact and form barium sulphate and ammonium chloride, and, on heating, the ammonium chloride is driven off, leaving a very porous mass of barium sulphate. Further, an economy in the platinum can be effected by conducting the operation in two stages—thus, whereas 100 parts of platinum would in one operation yield 97 per cent. of the theoretical quantity of sulphuric anhydride, 15 parts of platinum would yield 80 per cent. If, now, this 80 per cent. be removed by absorption, the remaining 20 per cent. could be subjected to the same treatment, yielding eventually $80 + \frac{(20 \times 80)}{100} = 96$ per cent. yield of theoretical.

Spent contact substance may be regenerated by passing the vapours of hydrochloric acid mixed with some inert gas through them until all impurities are removed.

Sulphuric Acid from Sulphur Trioxide. The absorption of the sulphur trioxide or sulphuric anhydride with the formation of sulphuric acid is not so simple a process as it would seem. It is extremely difficult to dissolve sulphur trioxide completely in water or dilute acid. As one kilogramme of sulphur trioxide liberates 500 calories when dissolved in water, 300 calories when dissolved in 66° Bé sulphuric acid, it would seem that the best plan would be to have a continuous arrangement with a number of absorbing vessels, and to pass the gases through them in one direction and the current of water in the other, so that the strongest gas passes into the strongest acid, while the gas from which practically all the acid has been removed passes through pure water. Such an arrangement, on the same principle as Webb's sulphuric acid concentrating apparatus already described, does not work in practice, as there is much loss of acid owing to a whitish mist carried away in the current of gases. It is found, however, that a very strong acid, 97 to 98 per cent. (H_2SO_4), absorbs sulphuric anhydride immediately and completely, so that the absorption can be carried on in a single absorbing apparatus which is fed continuously with water or dilute sulphuric acid to maintain the strength at 97 to 98 per cent. (H_2SO_4).

Sulphuric Acid in the Atmosphere. We should not omit to mention that large quantities of sulphuric acid are produced quite unintentionally, the whole of which finds its way into the atmosphere. All coal contains larger or smaller percentages of sulphur due to the pyrites in it, and when burnt, whether on the domestic hearth or under a steam boiler, or in other manufacturing operations, the sulphur is oxidised to sulphurous, and eventually sulphuric acid. All the acid derived from house coal escapes up our chimneys into the air.

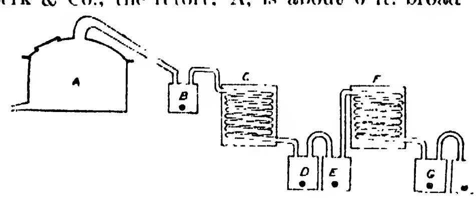
Combustion of a ton of coal produces about 68 lb. of strong sulphuric acid, and taking, say, the amount of coal raised annually in the United Kingdom, as 250,000,000 tons, of which we burn three-quarters ourselves, the atmosphere of Great Britain is contaminated with 5,700,000 tons of strong sulphuric acid per annum. A cubic yard of strong oil of vitriol weighs approximately 1·4 tons, so that the foregoing amount of sulphuric acid would occupy 4,000,000 cubic yards, sufficient to fill a canal eight yards broad, two yards deep and 115 miles long. This appalling quantity of sulphuric acid produced unintentionally by the coal we burn is more than twice as much as we manufacture for industrial purposes. Fifteen per cent. of the coal raised in Great Britain is burnt in our houses, so that a very large proportion of the enormous quantity of sulphuric acid

mentioned is produced by coal burnt for domestic purposes. All this acid poured into the atmosphere cannot but affect the buildings of large towns. It is carried down by the rain and dissolves away the surface of stone work, corrodes iron, and brings about decay generally. The whole subject was very fully gone into by Dr. Angus Smith many years ago, but very little has been done since then to mitigate the evil.

Fuming Sulphuric Acid. This acid consists of ordinary sulphuric acid with sulphur trioxide dissolved in it. It was originally made at Nordhausen, in Germany, by distilling green copperas (crystallised sulphate of iron) which had been exposed to the air. The acid collects in the receiver, while oxide of iron, or *colcothar* [see PAINTS], remains in the retort. Nowadays it is made by the contact process already described; obviously this should prove the most rational method of manufacture on a large scale. It is used in the colour industry.

Nitric Acid. We have already explained how nitric acid is prepared for the manufacture of sulphuric acid. Some manufacturers use ready-made nitric acid. It is prepared by distilling Chili saltpetre [see MANURES] with strong sulphuric acid from iron retorts. It is a very curious thing that nitric acid, when weak or moderately dilute, rapidly dissolves iron, but has little or no action on the metal when it is strong. The iron retorts are sometimes arranged so that the whole of them, including the upper part, is kept heated, in order that no acid condenses on the metal cover.

In the Valentia plant [11], as adopted by Berk & Co., the retort, A, is about 6 ft. broad



11. VALENTIA NITRIC ACID PLANT

and 4 ft. deep. The acid is distilled off under diminished pressure (say two-thirds of an atmosphere). The acid fumes are led into suitable condensing arrangements made of porcelain or glazed earthenware, and consisting of a series of Woulff bottles, that is to say, earthenware bottles, with two tubulars or flanged holes in the top. Each bottle is connected up with the next by means of an earthenware tube in the shape of an inverted U luted into the holes. From the retort the fumes pass into a Woulff's bottle, B, to condense any sulphuric acid carried over. The temperature here is too high to condense any nitric acid. Next comes a "worm," C, in which a good deal of acid condenses. The "worm" is an earthenware tube, corkscrew shaped and surrounded by cold water. Much of the nitric acid condenses in the worm and collects in two Woulff bottles, D and E. What escapes condensation passes through a second worm, F, and a long series of Woulff bottles, G, the last of which contains water to hold back any remaining traces of acid.

The quantity of sulphuric acid taken is some 30 per cent. in excess of that theoretically required in accordance with the equation, $2NaNO_3 + H_2SO_4 = Na_2SO_4 + 2HNO_3$ in order that the resulting nitre cake (sulphate of sodium) may remain sufficient fluid to be run out of the retort when the operation is over. It is utilised for making "salt cake" [see below]. The stronger the acid used for decomposing the nitrate, the stronger the nitric acid produced.

Pure nitric acid decomposes rapidly when heated, so that the crude product is always contaminated with red fumes. These consist of oxides of nitrogen such as are used in the chamber process. These red fumes condense with the nitric acid in the first bottles, and are easily driven out of the acid by a current of air. From what has been said it will be understood that the strongest nitric acid cannot be distilled unchanged. Strong nitric acid has a specific gravity of 1·42 and contains about 70 per cent. of pure acid. The very strongest and purest acid has a specific gravity of 1·5, that is to say, it is half as heavy again as water, and contains over 90 per cent. of pure acid. The strongest acid is used for making guncotton, smokeless powder, and other explosives.

Hydrochloric Acid and Salt Cake. Hydrochloric or muriatic acid is a combination of hydrogen with chlorine, and is used in considerable quantities in the preparation of chlorine, bleaching powder, and for pickling iron in the manufacture of galvanised sheets. Although in itself of considerable importance, it is formed as a by-product in the manufacture of alkali. The raw material consists of common salt, which is a compound of the metal sodium and chlorine. When decomposed with sulphuric acid the chlorine is liberated as hydrochloric acid gas and the sodium is left combined with the sulphuric acid as sodium sulphate. The operation is carried out in a special salt cake furnace, consisting of a pan to contain the salt covered with a brick hood or dome, with a tube leading out of it for carrying away the hydrochloric acid gases.

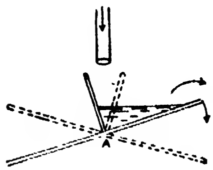
In this pan the operation carried out is represented in the main by the following chemical equation:

$NaCl$	$+ H_2SO_4 =$	$NaHSO_4$	$+$ HCl
Common salt	Sulphuric acid	Acid sodium sulphate	Hydrochloric acid

Sulphuric acid, sp. gr., about 1·7, such as comes from the Glover tower, is run into the pan, and the decomposition promoted by a fire underneath.

Absorption of the Gas. The reaction takes place with considerable violence, and torrents of gas are given off. These gases are led into towers filled with coke, similar in construction to the towers used in the chamber process for the manufacture of sulphuric acid, except that in this case water, and not sulphuric acid, trickles down from a cistern above. The water from the cistern flows into a trough which, as soon as full, tips over and discharges water automatically into the tower, and then re-fills

automatically and discharges again [12]. It is found in practice that an intermittent discharge is better than a continuous one. Two or three of these towers stand together, and when gas is not absorbed in one tower, it passes on, and is absorbed in the next. The Alkali Act sets a limit of ·2 grain per cubic foot for the amount of acid which may be allowed to escape into the air.



12.
WATER DISTRIBUTOR AT TOP OF HYDROCHLORIC ACID ABSORBING TOWER

Although hydrochloric acid is very soluble in water—the latter dissolves some 500 times its own volume of the gas—its absorption in the towers is not such an easy process as would at first appear. The gas is not given off evenly and uniformly during the reaction, but the greater part of it comes off with a rush at the beginning. At this time the absorbing power of the towers is taxed to the utmost. Then the gases are hot and require cooling, and they are also diluted with large volumes of inert gases, such as air—all which circumstances render it more difficult to ensure complete absorption in the towers. At the bottom the concentrated muriatic acid is drawn off.

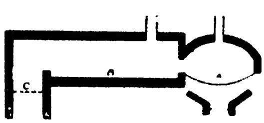
Open and Close Roasters. When the reaction in the iron pan, A, is complete, which will be in the course of an hour or so, the solid mass is raked forward on to a brick floor in another part of the furnace, B, where the heat is greater; here the reaction is completed, the mass being stirred up from time to time by a workman with a long iron crowbar, to prevent it from caking or crushing on the hearth.

The chemical reaction may be represented thus:

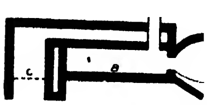
$NaHSO_4$	+	$NaCl$	=	Na_2SO_4	+	HCl.
Acid Sodium sulphate		Common salt		Neutral sodium sulphate		Hydrochloric acid.

But in practice the two reactions take place simultaneously, and cannot be sharply separated from one another. A small excess of sulphuric acid is often taken, over and above that actually required to produce the decomposition.

This part of the furnace is differently constructed, according to the purity of the product required [13 and 14]. If the salt cake be wanted for making alkali, the ordinary reverberatory furnace, or *open roaster*, is employed [13], where the flames and hot gases from the fire on the grate, C, play over the surface of the material on the hearth, B. If a purer and whiter product is wanted, such as is used by glassmakers and wood pulp boilers, a muffle furnace, or *close roaster*, is used [14], one in which the flames and hot gases do not come directly into contact with the material, but play round the firebrick box, B, in which the salt is contained. It is usual, in this case, to use a slight excess of sulphuric acid; the gases given off are not so pure as in the first part of the process. They are carried away and the acid absorbed in separate towers.



13. OPEN ROASTER



14. CLOSE ROASTER

One hundred parts of salt yield something like 116 to 120 parts of salt cake.

Mechanical Furnaces. Many inventors have devoted themselves to the construction of mechanical furnaces in the place of the roasters just described, to economise labour and fuel, and to avoid the risk of breaking the pans. The most successful of these is Mactear's, which consists of a revolving circular bed or pan into the middle of which the salt and acid are continuously fed. Over the bed is a fixed arch, the fire passing between them. The pasty mass gradually spreads towards the outer edge of the pan and stirrers carry it to the circumference, where it falls off the edge, collecting in a trough underneath, whence it is carried away. The salt-cake round the edge of the pan forms a lute and prevents the escape of hydrochloric acid under the pan, flues above being provided to carry it off. As the process is perfectly regular, the hydrochloric acid is given off in a continuous stream.

Salt Cake Without Sulphuric Acid. By the Hargreaves and Robinson process, salt is decomposed by a mixture of gases from the pyrites kilns—chiefly sulphur dioxide and air—without the direct intervention of sulphuric acid. The gases, mixed with steam, are led into cast-iron cylinders containing salt, when the following reaction ensues:

$2NaCl$	+	SO_2	+	O	+	H_2O
Common salt		Sulphur dioxide		Oxygen		Steam
	=	Na_2SO_4	+	$2HCl$		
		Sodium sulphate		Hydrochloric acid.		

In order that the reaction may be complete, a series of iron cylinders is provided, and the fresh gases are led first into the cylinders in which the salt has already been exposed for some time to treatment, finally reaching those freshly filled with salt, when the gases are nearly exhausted. Special precautions are necessary to allow of free passage of the gases; the salt is moistened with steam, pressed into cakes, and dried. In this state it is fed into the cylinders, the whole operation being conducted mechanically.

Properties of the Acid. The commercial hydrochloric acid is a fuming liquid, generally coloured yellow by the iron it contains. This iron is derived from the pans. Its purity will generally depend upon the purity of the sulphuric acid used to discompose the salt. If pyrities acid has been employed, the hydrochloric acid will contain arsenic. The common muriatic acid contains from 30 to 32 per cent. of hydrochloric acid gas.

Continued

THE MAKING OF WROT IRON

Finery Methods. Puddling. Modified Processes. Rolling Mills. Rolling Special Sections

By A. H. HIORNS

THE production of malleable iron from pig iron is divisible into two classes—the ancient or finery methods and the reverberatory or puddling methods, although the reactions are similar in both cases.

Finery Method. The graphite first passes into combined carbon and is then converted into carbonic oxide by the oxygen of the blast directly or indirectly by the action of oxide of iron dissolved in the slag. At the time of fusion the foreign elements begin to be rapidly oxidised. The silica unites with the oxide of manganese, together with some oxide of iron, and forms the slag. The ferrous oxide (FeO) of the slag acts as a vehicle for oxygen, uniting with the oxygen of the air and is converted into the magnetic oxide (Fe_3O_4). This coming into contact with impure iron oxidises the iron itself, being converted into FeO. After a time the slag becomes neutral, and is in part removed; then fresh basic and hammer slag are added. To complete the operation the iron in masses is lifted up to the twyer level in order to oxidise the carbon thoroughly. The white-hot mass of iron, which is of a spongy consistency, is then taken to a heavy hammer and compressed to a slab, termed a *bloom*. The subsequent treatment of the bloom varies in different countries. In Italy the partially-refined mass is taken out and cooled with water, then broken up and reheated sufficiently to allow the iron and the slag to cake together, when it is again removed. In the third stage the above mass of iron is reheated with a rich slag until it is practically refined.

Charcoal Iron. In South Wales a superior quality of tin-plate iron is made from the best pig iron in a charcoal finery. The pig iron is first partially refined in a special hearth, termed a *refinery*, and then treated in charges of 3 cwt. in the finery. The bloom of refined iron is then shingled and drawn out into a bar under a lever hammer. This bar is nicked, broken and made into bundles, then reheated and welded under a hammer and rolled into sheets. Before finishing, the sheets are annealed, pickled to remove scale, and rolled cold into sheets.

Materials for Wrot Iron. In the above finery methods white cast iron is more suitable for conversion into wrot iron than grey iron, since it does not pass directly into the liquid state, but assumes, when near its melting point, an intermediate pasty mass, which is favourable for the more effective oxidising action of the air and slags. Grey iron, on the other hand, requires a higher temperature for fusion and becomes very liquid, and in a deep hearth sinks below the level of the blast, becomes covered with slag, and is completely protected from the action of the air; the refining is delayed with the consequent expenditure of extra fuel and labour. For this reason grey iron was first converted into white iron in the refinery. In former times hearth refineries were called *bloomeries*. The reheating or welding fires were termed *chafferies*.

The old finery is a rectangular hearth, formed of cast-iron plates lined with charcoal, the bottom being exposed to the air. Three sides are vertical, while the remaining side slopes outwards. The blast is supplied by a single twyer. The fuel is charcoal. In the Lancashire hearth the blast is heated to about 100° C., and used at a pressure of 1 lb. to 1¼ lb.

Reverberatory or Puddling Process. The method of dry puddling in a reverberatory furnace was developed by Cort in 1784. The furnace bottom was dished out and lined with sand, which became glazed over with slag during the working. In later years the bottom was covered over with oxide of iron, formed by oxidising scrap iron in a strongly oxidising atmosphere. Each operation was composed of three periods—fusion, rabbling, and forming the blooms—white or refined iron being used. About 4 cwt. of refined iron were charged into a hot furnace, and partially melted in half an hour, forming a pasty mass, which was then stirred with iron tools to bring all parts under the influence of oxygen. As the impurities were removed and passed into the slag the iron became less fusible, requiring the temperature to be raised. The particles of refined iron were then collected into balls by the puddler, which were taken to the hammer and subsequently rolled. The reactions are similar to those of the finery, and the same kind of iron is used.

In 1830, Hall found that by using old furnace bottoms, which contained much oxide of iron, as a material for lining his puddling furnaces, the process was shortened and the preliminary fining in a refinery could be dispensed with. This caused the old brick furnace to be discarded and to be replaced by a frame of air-cooled iron plates. This was lined with calcined tap cinder (bulldog), which is still partially used. This method is characterised by the complete fluidity of the pig iron, and grey iron may be used.

The Puddler at Work. When the furnace is charged, the door is kept closed and the fires made up. When the iron is softened, the puddler, by means of an iron bar termed a *rabble*, moves the unmelted portions into the centre of the furnace and increases the temperature of the fire. When the whole is melted, it is rendered uniform by stirring and the damper lowered until the surface is covered with slag. In order to cause the slag to react on the molten metal, the whole is well stirred. The slag is also made more

basic by the addition of hammer slag and mill cinder. The oxide and silicate of iron react on the combined carbon, forming carbonic oxide, which by its rapid escape causes a rapid commotion in the metal, which is said to *boil*. The action is facilitated by constant stirring. As the carbon diminishes, the action becomes less violent, the iron begins to separate—termed *coming to nature*—in bright spots, which gradually collect together. This reduced iron is subjected to a final heat to separate the fluid cinder. The iron is then collected into balls of about 80 lb. each. These balls are separately lifted by tongs to a table in front of the door and dragged or carried to a shingling hammer or squeezer to consolidate the iron and to remove the slag. The process, therefore, includes the following operations:

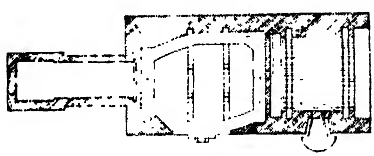
1. Melting the pig iron with or without preheating.
2. Addition of oxidising materials.
3. Removal of carbon by oxidation at high temperatures.
4. Consolidation of the refined iron into balls.

The excellence of the iron produced will depend on the kind of pig iron used and a high temperature during the boil, for if the temperature be too low the reducing action of the carbonic oxide prevents the complete liberation of carbon, and hard, steely iron results. The slag is essentially a silicate of iron containing many of the impurities originally present in the iron, and is termed *tap cinder*.

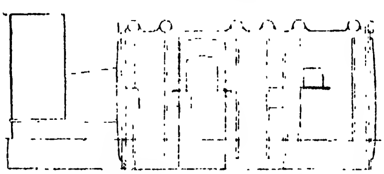
Yorkshire Method of Fettling. The celebrated brands of iron known as Bowling and Lowmoor are made by a process intermediate between that of the dry method and the wet method. Cold-blast pig iron is used. This pig iron is first treated in refineries, the plates of metal thus obtained being reheated and charged hot into the puddling furnace, where a high temperature is used. The metal, being free from silicon, is soon refined, and the balls of iron produced are shingled into blooms or "noblins" about 12 in. square and 2 in. thick. They are then broken, the most fibrous and least crystalline ones being selected as the best iron. These are piled, reheated, and welded into billets, and after again being reheated are rolled into bars. The success of the operation lies in using good pig iron and using only the best of the puddled blooms. It is uniform in quality, and stands several times reheating and welding without deterioration.

Puddling Furnace. The modern puddling furnace [34 to 36] is a single-bedded reverberatory, with a low, flat roof, generally sloping from fireplace to flue. The fire-bridge and the flue-bridge are formed of hollow castings encased in firebrick; the bed is likewise formed of iron plates robatted together; and the sides consist of hollow iron castings. These hollow castings are kept cool by the circulation of air or water through them. The laboratory, or working part, is about 6 ft. long and 4 ft. wide, tapering towards the flue-bridge. The grade area varies from one-third to one-half that of the laboratory. The bed is lined with broken slags, hammer scale, and red oxide of iron, or puddlers' mine, and the sides with bulldog, all being well rammed down, which is termed *fettling*. The whole of the brickwork is cased with side plates of iron, united by flanges and bolts and bound with tie-rods.

34. SECTION OF PUDDLING FURNACE



35. PLAN OF PUDDLING FURNACE



36. ELEVATION OF PUDDLING FURNACE

In Cleveland burnt pyrites (*blue billy*) is used as a fettling. The working door is on the same side as the fire-hole, and is made of firebrick, set in an iron frame; it is suspended by a chain attached to a counterpoised lever. A flue is generally provided for each furnace, and communicates with its own chimney or passes into a boiler for utilising the waste heat. The flue slopes down towards the stack, its sectional area being about one-fifth to one-seventh that of the fireplace. The draught is usually regulated at the top of the chimney by a damper, which is moved by a hanging chain. Two men are required for each furnace—the puddler and the under-hand. About six heats are worked off in 12 hours, the charge being about 4 cwt. to $4\frac{1}{2}$ cwt. The smaller amount refers to grey iron, and the larger to a mixture of white and grey iron. The loss of weight between the pig iron charged into the furnace and the puddled bars is about $1\frac{1}{2}$ cwt. to 2 cwt. per 22 cwt. of pig metal, or from 7 to 10 per cent. The coal required is about 20 cwt. to 22 cwt. per ton of puddled bars. The fettling materials required in a turn of 12 hours are from 6 cwt. to 7 cwt. of bulldog and from 2 cwt. to 3 cwt. of puddlers' mine, in addition to the mill-scale added to the charge.

Fettling. The fettling used in puddling furnaces is of three varieties, depending on the quality of the pig iron employed. It may be classified as *fusible*, *moderately fusible*, and *infusible*. The fusible kind is a silicate of iron containing some magnetic oxide. Hammer-slag is the material used for this purpose. It is regarded as a flux, and the object is to yield a fluid bath into which the grains of iron may trickle and become purified during the melting-down stage, and thus hasten the operation. The

amount of slag required is about one-sixth that of the pig iron used. The moderately fusible kind is used to form the sides of the furnace. It must have a higher melting point than the pig iron, and melt only as the temperature rises, so as to nourish the iron at the later stages of the refining. Bulldog and similar material which contain much ferric oxide are used for this purpose. Bulldog is calcined tap cinder, the calcination being conducted in open heaps or in kilns. This fettling is used for ordinary varieties of iron, but for the best brands of wrought iron a more infusible fettling is employed, such as purple ore or blue billy. The infusible fettling consists of ferric and magnetic oxides, such as hæmatite and pottery mine, used in compact lumps.

Pig Iron for Puddling. White pig iron is sometimes employed for puddling, especially on the Continent, for making sheet iron, as the sheets are less liable to black streaks of slag. White iron works more quickly than grey, as it contains less silicon and manganese, but it gives a smaller yield of puddled iron per ton of pig iron used. The iron chiefly used in England is No. 4, which is a strong and close-grained grey pig-iron. As already mentioned, the fettling used depends on the quality of the pig iron, for if much silicon and phosphorus are present a more infusible fettling is required. Such irons are said to be "hungry." They require more time, more fettling, make the slag too thin, and tend to yield a brittle bar iron. A little phosphorus is an advantage, as it increases the yield of iron and prevents the cinder from getting too thick towards the end of the operation, which would produce red-shortness. The presence of manganese is an advantage, since it covers the carbon, delays its removal, gives greater fluidity to the slag, and helps to remove phosphorus and sulphur.

Special Furnaces. In Anderson's furnace the end and crown of the fireplace are made with a double wall of bricks forming an air passage between. The air in passing through this becomes heated and thus supplies hot air to the furnace; it also serves the purpose of keeping the outside walls cooler. This system is employed in the North of England for ball and mill furnaces. Double furnaces are also employed and consist of two furnaces placed back to back with the dividing wall removed. They have the disadvantages of unequal working of the men and the greater difficulty of working with larger masses of metal.

Mechanical Puddling. Many attempts have been made to introduce mechanical puddling tools in order to lessen the enormous manual labour expended in hand puddling, but with little success. Such tools are arranged so as to be capable of a compound motion over the bed of the furnace. The rabble is supported in a stirrup connected with a lever actuated by overhead mechanism, and by means of a fast and loose pulley can be put in or out of gear at will.

Revolving Furnaces. The best form is that of Danks, which consists of an iron cylinder with conical ends, 4 ft. long and 5¼ ft. in greatest diameter. On the inside are twelve ribs to keep the fettling in position. The cylinder is encircled at each end with a roller-way, which rests on anti-friction rollers. One end is open to the fireplace and the other opens into an elbow-shaped movable flue leading to the chimney. The fireplace is provided with an air-blast pipe placed below the grate, and also small twyers for introducing air at the fire-bridge. The furnace is lined initially with a mixture of crushed ore and lime; then on this there is laid a lining of iron ore and hammer slag, into which, when soft, lumps of hard ore are thrown. The charge consists of pig iron with 20 per cent. of cinder, and as this melts the furnace is revolved, the action being the same as in the ordinary puddling furnace. The process is automatic, and the puddled iron is collected into a large ball ready for the hammer.

Gas Puddling Furnaces. By the use of a gas furnace a higher temperature can be obtained than by using solid fuel. Of such furnaces that of Siemens is one of the best. It is of the ordinary regenerative type, and it possesses the advantage of having the temperatures more under control, and an oxidising, reducing, or neutral atmosphere can be obtained at will.

Treatment of Puddled Iron. This consists of shingling, or hammering, and rolling. Squeezers are also used instead of the hammer. The white balls of puddled iron are taken to the hammer or squeezer to expel slag, to weld the iron into a compact mass, and to confer a shape suitable for rolling. The tilt hammer is used for small work. The helve hammer was universally employed for heavy work, but has been largely replaced by the steam-hammer. This is now used both for shingling and welding. It is a simple direct-acting machine, and takes but little room compared with the cumbrous wheel work of the old helve. The force of the blow in shingling is generally required to be light at first, and with the steam-hammer the force can be varied with the work to be done.

Another advantage is that the hammer always works parallel with the piece under operation, which is not the case with helves, the hammerman having to use thickness pieces to overcome this difficulty. Both sides of the steam-hammer are also accessible for working. It consists essentially of a vertical high-pressure engine with an inverted cylinder. The piston rod is attached to a heavy block or *tup* moving between guides on the inner faces of the standards, which form part of a massive cast-iron framing. The ordinary hammer is double-acting, the steam being exhausted above and below the piston. The hammer varies in weight from 30 cwt. to 60 cwt., but the force of the blow is, to a great extent, independent of the mass of the hammer head.

Squeezers are of two kinds—lever and rotatory. In the former a movable upper jaw is actuated by a crank and connecting rod attached to one end. The rotatory squeezer consists of a

cylindrical casting, the inner surface being studded with teeth. Within this also revolves a cylinder similarly studded and placed eccentrically with regard to that of the outer casing. The ball is carried forward along a gradually narrowing path and compressed to smaller dimensions.

Rolling Mill. The rolling mill for puddled iron contains two sets of rolls—the roughing and the finishing rolls. The roughing rolls are usually 5 ft. long, and about 20 in. in diameter, forming a series of gothic and diamond-shaped grooves between them, diminishing in size from right to left. The larger grooves are gothic shaped and roughened, so as to lay hold of the iron more effectually; the smaller ones are diamond shaped. The distance between the rolls is regulated by the screws and the connection between them is established by means of the cogs attached to the ends. The journals or necks of the rolls run into metal bearings, which are supported in cast-iron frames or housings. The finishing rolls are arranged in housings similar to the roughing pair, but have rectangular channels instead of the diamond grooves. These channels diminish in size from right to left. The two sets of rolls are generally connected together by heavy couplings keyed tightly together. The two rolls of each pair revolve at the same speed, which in the roughing rolls is about 70 revolutions per minute, and in the finishing rolls about 90 per minute when separate.

The bloom of iron is first passed through the largest groove of the roughing rolls, then lifted back over the top roll, turned one quarter round, and passed through the next smaller hole. This operation is repeated until the bloom is reduced to a square bar small enough to enter the flat grooves of the finishing rolls. In this pair the process of reduction is continued until a puddled bar of the desired thickness is obtained. Puddled bars may have ragged edges and a rough surface, and for the production of good bars they are cut up, piled, reheated and welded.

Reheating. Bars and slabs of iron obtained by shingling and rolling puddled iron require to be refined if best malleable iron be desired. They are cut up into short lengths, arranged in faggots or bundles, then reheated and welded by hammering and rolling. The reverberatory furnace for reheating is somewhat similar to the puddling furnace, but the bed is flat, with a slight slope downwards towards the flue, so that the liquated cinder flows out at the flue bottom and is termed *flue cinder*. Ordinary reheating furnaces are relatively inexpensive to erect and are easily worked, but are extravagant in fuel, while the waste due to oxidation is considerable. On this account gas-fired furnaces are largely used with consequent saving of fuel and diminution of oxidation.

Mill rolls are classified according to their shape into:

1. Flat or plain rolls for sheets and plates.
2. Grooved rolls, for bars, angle and channel iron.

For the production of sheets and plates requiring a fine surface chilled rolls are used. The *mill rolls* or *mill train* for rolling merchant iron also consists of two sets—the billeting or roughing pair and the finishing pair. The rolls are provided with tightening and adjusting screws for keeping them accurately in position.

Rolling Small Sections. In rolling small and light sections, which are difficult to keep from distortion while hot, a fore plate and guide jaws are added to the arrangement so as to keep the section straight. In two-high trains revolving constantly in one direction, it is necessary to return the work over the roll after each pass, and this takes up a lot of time so that reversing rolls are often used and reversed at each passing of the metal. The reversal is effected either by reversing the engine itself, or by the use of hydraulic friction, or other clutches and gearing on the engine shaft. For lifting the iron on to the top of the single pair of rolls after a passage through them, so as to return it to the man for another passage, a travelling carriage with forked levers is used for light work. For heavy work an iron table is provided which is raised by a single-acting engine, or by a hydraulic cylinder and ram. Three-high rolls consist of roughing and finishing rolls each of which is a combination of three rolls in its own pair of housings. In this case the mill is generally driven from the middle roll, and arranged so that the middle roll revolves forwards with the lower one and backwards with the top one. The work thus passes backwards and forwards alternately through the upper and lower pair. The various shapes into which the iron is finally rolled are: plates, strips, sheets, bars, rails and various sections. Bars are round, half-round, square, flat, oval, octagon, etc.

Special Sections. Other shapes are made, such as tee-iron, T; angle-iron, L; channel-iron ⊔; aitch-iron, H; Z-iron, etc.

There are three chief imperfections in finished iron; these are (1) *spills*, which are due to enclosed foreign matter, such as slag or oxide of iron; such parts prevent cohesion and cause the metal to peel off after rolling; (2) *blisters*, due to the presence of enclosed gases, such as carbonic oxide; (3) *ragged edges*, due to imperfections in the rolls, or careless working, or it may be due to the iron being deficient in cinder, which makes the metal red-short.

HEAVY TIMBERING

Flitching and Trussing. Staging, Towers, and Trestles. Timber Bridges. Piles. Cofferdams. Staithes. Crane-work. Methods of Handling Timber. Gates & Fences

CARPENTRY continued from page 4118

By WILLIAM J. HORNER

IN heavy carpentry there is a greater proportion of temporary work now used than formerly, very large timber structures being often erected only to serve as stagings for permanent buildings in iron or stone. At the same time, for large work of a permanent and substantial character, wood is becoming less and less popular, but it is still employed largely in those countries where it is plentiful and cheap. One result of the extensive use of temporary works is that carpentry is often of a simple character, for there is less necessity for elaborate and neat jointing than there is in permanent structures. Bolts, straps, tie rods and castings are used more freely to unite timbers, and less time is spent in making joints more or less intricate in the wood. They are of the simplest possible character, being, as a rule, nothing more than plain butt or lap joints, united by suitable metal connections. In permanent work more regard has to be paid to appearance, and though in many cases the same metal fastenings are employed the finish must be neater and the fitting more carefully done where there is advantage in making it so. Heavy carpentry, however, is comparatively simple work, and largely repetitive when the arrangement and dimensions of the timbers have been decided on. Some selected examples are given in this article.

Flitch Beams. When beams of great strength are required the wood is often *flitched*. This is done by sawing the balk down the middle and bolting it together again with a wrought-iron flitch plate between [**304**]. The plate is about ½ in. thick, and of the same length as the beam, but generally a trifle less in depth, to allow for shrinkage of the wood, and to avoid the consequent projecting ridge of metal. The heart of the wood in such cases is turned outwards, to expose it to the air and ensure thorough seasoning. Even without the metal plate between, rather more reliance can be placed on a balk which has been treated in this way than on a solid one, because there are then no fissures hidden in the interior which would make its actual strength uncertain. Another method less commonly practised is to bolt plates on the outside, enclosing the beam between two plates of metal. Flitch beams, however, and also those in which great depth is obtained by joggling, or serrating balks together, examples of which were shown in **238** and **239** [page 4115], are being less and less employed, owing to the increasing use of rolled iron or steel girders.

Temporary Towers. Timbers of unlimited length and section can also be built up of deals, as shown in **237** [page 4115]. For the support of the Charing Cross Station roof, after the collapse of the tie rod in December, 1905, the uprights were built in this way. Each upright comprised three thicknesses of 9 in. by 3 in. planking, bolted together to break joint. They were about 80 ft. high, and covered an area of 25 ft. There were eight uprights to each tower, and all braced together with horizontals and diagonals. The towers were connected by strong stagings and to the station walls. Timber lends itself better to rapid work of this kind than metal does, for these massive towers were erected in eight or nine days and nights.

Trussed Beams. These are very frequently employed in preference to more massive solid beams of equal strength. Trussing may be done by tie rods within the depth of the beam, arranged to prevent it from sagging in the middle, but usually the truss extends below the timber, as in **305** and **306**. Square balks are thus usually employed sufficiently rigid to resist transverse strain when trussed, the stress being transmitted to the truss rods as tensile forces, and to the struts as compressive ones. A truss with two struts is properly braced by diagonal ties between, as dotted in **306**, if it has to carry a load moving from end to end, but not otherwise. The reason is that the tie rods tend to straighten out, and bend the beam unless counterbraced. The depth of beam may sometimes be made strong enough in itself to resist this tendency, but that would not be practicable in long spans. If there is no moving load, but a dead one imposed, no counterbracing is necessary.

Trussing may be an alternative to the employment of diagonal struts from the posts which support the ends of a beam, but in many cases strutting is not practicable, as, for instance, in the beams of an overhead travelling crane, which must be free to move along its gantry.

In short spans, the beam is trussed with a single support or strut in the middle [**305**, A]; in longer ones support is given at two intermediate points [**306**, A A]. The struts are usually castings, but are sometimes made of timber. Castings, B B, are usually necessary also on the ends of the beam, having lugs to receive the screwed ends of the tie rods, and provide a seating for the nuts in tightening up the rods.

The carpenters who prepare the timbers also fit the castings and complete the truss. The recesses in the castings are properly ⅛ in. or ¼ in. less than the timber sections to allow a little for possible shrinkage and fitting. They are tapered to drive on tightly, the timber ends are smeared with thick, white lead paint, and the shoes driven on with heavy, long handled mallets. In many cases a single tie rod will be fitted in the centre of the beam instead of two, as shown in **305** and **306**, flanking the beam. Then diagonal

holes have to be bored with an auger to pass the bolts through. The threads of the bolts must never measure less in diameter at their *roots* than the diameter of the tie rods.

Built-up Girders. Instead of trussing a beam with tie rods and struts, its depth may be increased by separating it into upper and lower members, and in place of solid material between connection is made by diagonal braces [**307**]. This increase in depth gives enhanced rigidity without corresponding increase in weight. The material, in fact, is removed from the middle or neutral plane of the beam, where it is of little or no value, and concentrated along the planes of greatest stress. Diagonal bracing and vertical posts are usually associated in this connection of top and bottom rails, but the diagonals are the most essential; the verticals alone would be useless. Often the verticals are of iron rod, while the horizontals and diagonals are of wood [**307**], but frequently all the members are of timber.

Trussing and strutting are, of course, necessary chiefly for horizontal timbers which would otherwise not be sufficiently rigid to resist stresses which would sink or fracture them about the centre. The alternative is to support them at frequent intervals throughout their length by perpendiculars. This is not always practicable or advisable. As vertical timbers are seldom subjected to direct transverse stress as horizontal ones are, they require lateral support to bring them into the condition of short columns. The methods of doing this necessarily resemble the strutting and trussing of many horizontals, for diagonals are required in both cases. It is true that in a narrow structure like a ladder diagonals can be dispensed with, but if length, width, and stability were the only considerations, a much smaller number of transverse members would be used, and equal stability would be attained by diagonal pieces either fitting between them or over all. If we take a framework that is wider, or more nearly square in its proportions [**308**], it is obvious that diagonal braces from corner to corner will tie the frame more directly and securely than a far greater amount of material inserted in the form of transverse bars. Diagonal bracing, therefore, is always employed in structural work between horizontal and vertical members. The result is that the main timbers of the structure are tied at so many points that, no matter what their length or the size or form of the structure may be, stresses produce no alteration in form, for the diagonals come at once into play as rigid ties and struts.

Looking at **309**, which is a typical arrangement of timbers in a tall structure, each vertical member would, if unstayed, become bent or broken by a vertical load as certainly as though it were stressed by direct forces acting laterally. But the diagonals and horizontals in effect shorten the lengths, bringing the structure into a condition of superimposed short columns, which would resist bending, the effective length of the columns being A A, even without the horizontals, which resist tendency to bending midway between the union of the diagonals. In **310**, additional rigidity is obtained by the outstanding struts. These are equally suitable either for a vertical or horizontal structure.

Trestles. Trestles are structures placed at intervals to support overhead roads, railways, bridges, or platforms. They are built up of verticals, horizontals, and diagonals, similar in principle to **309**, but to give increased stability on their base they generally taper, as shown in **311** and **312**. Their design may vary considerably. The two examples given are suitable either for temporary or permanent works, and are typical of many American bridge trestles. Some arrangements of timbers for temporary staging are illustrated in the article beginning on page 1170.

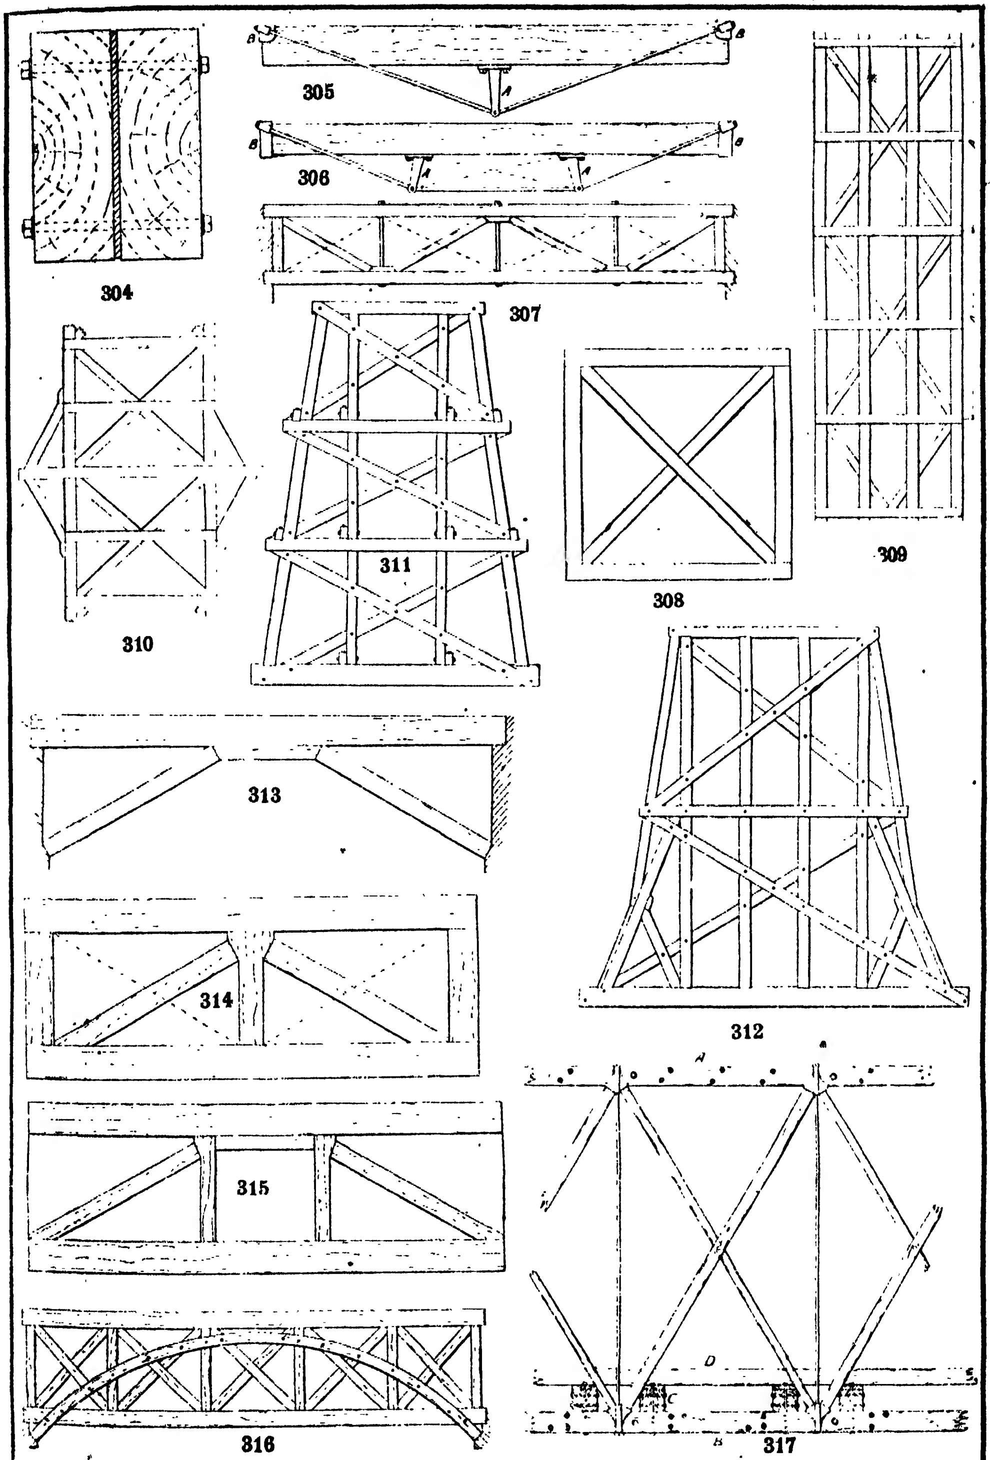
In permanent structures similar arrangements are adopted, but more carefully and neatly designed and executed. Instead, for instance, of bolting braces or transverse members on to surfaces, they would be stub tenoned between in the same plane. Or, instead of securing joints by driving in dogs or spikes, bolts, coach screws, or straps would be used under similar circumstances.

Plain butt joints are very common in temporary work, but not in permanent structures, where stub tenons, joggles, cogs, notches, or dowels are employed to prevent lateral movement of the parts quite independently of the means which hold them together.

Bridges. Bridges entirely or partly of wood are common, especially in America, where timber is the material most readily available. Timber is, of course, more suitable for very small bridges than for large ones. Foundations of stone or brick for a wooden bridge are more permanent than wood piles. If a bridge runs over a river, it is cheaper to drive piles for intermediate supports, but masonry can be employed without difficulty for buttresses. The bridge itself is always trussed in some way to give it sufficient strength to span from one support to another, and to carry the load required. The trussing may be done either above or below the roadway, or both. Fig. **313** shows a horizontal bridge timber supported by struts from the buttresses.

This, of course, is suitable only for a very short span, but strutting of more complicated character is often practised in addition to trussing. Fig. **314** shows a simple truss of the king post type suitable for a short span, or, by inserting a series of posts and struts, the span might be extended. It might also be further increased in rigidity by diagonals or counterbraces in the opposite direction as dotted. Fig. **315** is a truss of the queen post type, suitable only for a short span; **316** is suitable for long spans. The bridge sides are built up of a series of posts and diagonal braces between the upper and lower *chords*, and this may be further stiffened by an arched rib bolted to each side as shown.

Heavy timber work has probably never been so fully developed in any country as in the United States and Canada, where hundreds of railway bridges have been built of that material. Timber was, and is, superabundant and cheap, and the sawmills convert it into squared sections of all sizes at low cost. But for this fact many of the primitive railways in sparsely populated



HEAVY TIMBERING

304. Flitch beam **305** and **306.** Trussed beams **307.** Built-up girder **308.** Braced frame **309-312.** Examples of trestle work **313-316.** Methods of imparting rigidity to bridge timbers **317.** A Howe truss for a large timber bridge

districts could not have been constructed. Though the timber bridges and viaducts are not long lived, neither are those of steel. The first part to decay is the bottom chords, or *booms*, which have to be repaired or renewed in about from seven to ten years if unprotected from the weather. But if covered in they last for about thirty years. Timber has been used for spans of over 200 feet. The ingenuity which has been displayed in building up these spans is an interesting study in how to obtain maximum strength with materials in themselves relatively weak, and with the simplest kinds of joints. These trestle bridges are constructed of trusses with triangular panels, one example of which is shown in **317**, being a Howe truss supported on trestles, or towers, some of which are of great height. One section of a trestle is a repetition of other sections, and one panel of a truss is like another, so that the work is repetitive. Cast and wrought iron enter into the construction only at the joints and fastenings. As the sticks of timber do not exceed from 50 to 60 ft. in length, a number of fish joints, or *clamp* joints, as they are termed, are necessary in making up the total lengths. They are made to break joint at long intervals, and iron or wooden clamps are employed to tie them. Figs. **317** to **324** show these arrangements, and also the method of building up the top and bottom booms or chords, while their position in the bridge truss is seen in **317**, which shows a panel, and **318** a cross section through the bridge, including the rail track.

The top and bottom chords, A B, are each built of four rows of jointed balks, breaking joint as already mentioned, so that the joints in one row or length come several feet away from those in the one adjacent. They are not in lateral contact, but separated about 2 in. [**319** and **320**], which gives spaces for the clamping plates while avoiding having to notch the timbers deeply. To key these open balks together into a practically solid mass packing blocks [**319** A] are inserted at intervals, each set arranged in line across, and bolts are inserted through them and the timbers, as shown in **319**. To ensure a tight fit these packings are tapered edgewise, being about ½ in. narrower at the bottom than at the top, and are thus driven in firmly. The grain runs in the same direction as that in the balks, so that they will not loosen by shrinkage.

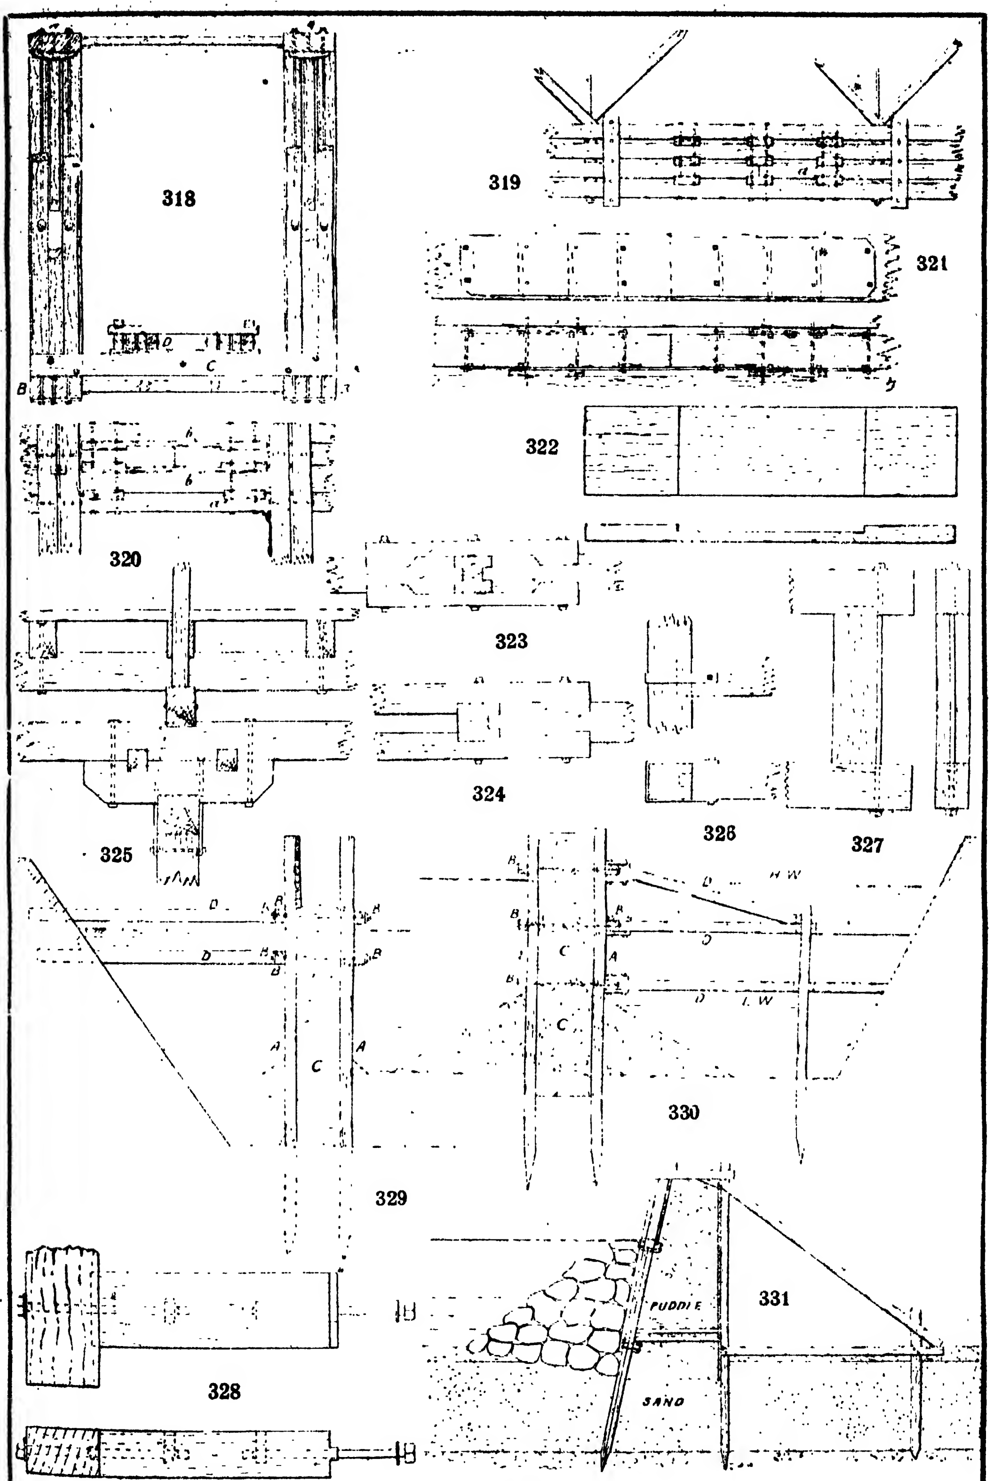
When end joints meet they are variously secured by iron or wooden clamps. If of iron, ½-in. plates are used with iron joggles riveted or bolted across them to enter into grooves in the timber [**321**]. The plates fit on opposite faces, and bolts pass through the whole. If wood clamps are used they are notched to enter into notches in the main timbers on each side of the joint. Two wooden clamps are shown at **320** *bb*, and a clamp separately in **322**. Figs. **323** and **324** show similar clamps uniting horizontal with vertical members. The top and bottom booms are identical in construction, differing only in dimensions, but the bottom booms are connected by cross bracings, and they carry heavy cross timbers [C, **317** and **318**] to receive longitudinals, D, upon which the rail sleepers are laid. The top and bottom booms are connected by the diagonals [**317**], which are stepped against castings through which vertical tie bolts pass. All this notching and fitting seems tedious, but in America the sawmills are erected in the forests and in the course of the railways, and woodworking machinery is greatly developed.

Jointing and Fastening. Fig. **325** illustrates the joggling of heavy balks, involving but a small amount of work, yet being absolutely secure when bolted; **326** shows a stub-tenon and strap connection. The latter makes a very secure union between timbers which cannot be conveniently held by other means. Fig. **327** is a case where a long bolt and stub-tenon joints are suitable. If the timbers were of very large section, and great strength was required, more than one bolt would be employed. Bolt holes slightly weaken the timbers through which they are put, while straps round the outside have the contrary effect. Fig. **328** is a stub-tenon joint similar to the two preceding ones, but instead of holding the parts together by a strap or long bolt comparatively short bolts are fitted into the tenoned ends. This might be done either for neatness or when the tenoned member is too long for a through bolt to be suitable. Recesses are bored for the nuts in one of the faces of the timber, and the bolt holes are bored to suit. The recesses are generally plugged after the nuts are in, and the bolts have to be screwed into their nuts.

Work Involving Piles. Piles are very often used for foundations both in temporary and permanent work, and both on land and under water. The piles commonly used are balks of firwood, but the best are of greenheart or elm, because more durable. Piles are pointed, and usually sheathed in iron to enable them to penetrate. An iron ring is also fitted round their tops to prevent splitting when driving. They are driven by a weight called a monkey, which slides in vertical guides, and is hoisted and allowed to fall by gravity repeatedly on the head of the piles.

Piles for the foundations of structures are spaced according to the weight they have to carry. Those for cofferdams and caissons, which have to be made watertight, are driven closely side by side, and the joints filled with clay or other packing when necessary. This is called *sheet piling*. Piles are braced and tied together after being driven, by *waling* pieces, and the heads are sawn level where necessary. Often piles are driven at angles instead of vertically, according to the character of the structure which they have to support. On land large horizontal balks are sometimes laid to bed the verticals on instead of driving piles into the ground. For permanent structures a concrete bed is often made, the bed itself being laid on the tops of piles, which are driven flush with the ground and tied together by a horizontal framework.

Cofferdams. These are constructed of double rows of piles, which are driven in close contact, usually with sawn edges. To keep them in line they are connected by horizontal waling pieces at intervals of 4 ft. or 5 ft. Short bolts



HEAVY TIMBERING

318-324. Details of large timber bridge **325.** Joggling of heavy balks **326.** Timbers united by stub tenon and strap **327.** Timbers united by long bolt **328.** Inserted bolts **329-331.** Examples of strutted dams

pass through waling pieces and piles. The water is then pumped out from the enclosed space, and well-tempered puddle clay is filled in and rammed down in layers. Thus a watertight wall is built, within which, the water having been pumped out, excavation can be carried on in the dry. In plan view a cofferdam may be of any required outline, circular or rectangular, or simply fulfil the function of a dam of sheet piling to enclose an area from which, without such protection, water might be expected to burst out on works in progress. When a dam is not a self-contained structure it is often strutted. Figs. **329 and 330** show dams of this kind, the struts being combined with the dam. In these illustrations, A A are the timber piles shod with iron, connected by waling pieces, B, and fastened with bolts; C is the clay puddle. In both cases the dam is shown in proximity to an old dock wall. The struts, D, take the external pressure. In one case they are simply driven into the old wall. In the other they are connected to a row of piles tied together with horizontal timbers. The cofferdam often takes the form of a strong sea barrier to keep out the ocean when tidal docks are in course of construction. In some cases they themselves have to be protected by groynes. In such work the construction has to be very strong. The seaward piles are then often driven at a considerable angle to broaden the base, and the sea face is protected with rubble. The inner face is tied to a row of piles. Timbers are often creosoted. Fig. **331** shows a section through a barrier of this class.

Staithes. Some fine examples of heavy timbering are found in the staithes on Tyneside and other Northumbrian ports. They are coaling stages along which the old chaldron waggons or the modern trucks are run out by gravity over the water for the shipment of coals. They carry loading cranes if fixed, or gantry or travelling types. The staithes are built on piles. As they go out from the banks into water deep enough to allow vessels to come under the cranes the length of the piles becomes considerable next the vessel's side. At the shore end the timbering is plain, but as the staith goes out farther the piles are put closer together; sometimes two or more timbers are bolted together or single piles are heavily fished. Struts and diagonal bracings are introduced with horizontal timbers, and bolts and iron straps reinforce the various joints. Some typical constructions are shown in **332** and **333**. The former is a staging built on piles and tied back to other piles driven in higher up the slope of the river bed. The top horizontal members carry the flooring; **333** is a face or end view of one set of timbers in a staging. A A are double longitudinal balks that tie the several sets together. The general arrangement of other horizontals and of diagonals is clearly shown.

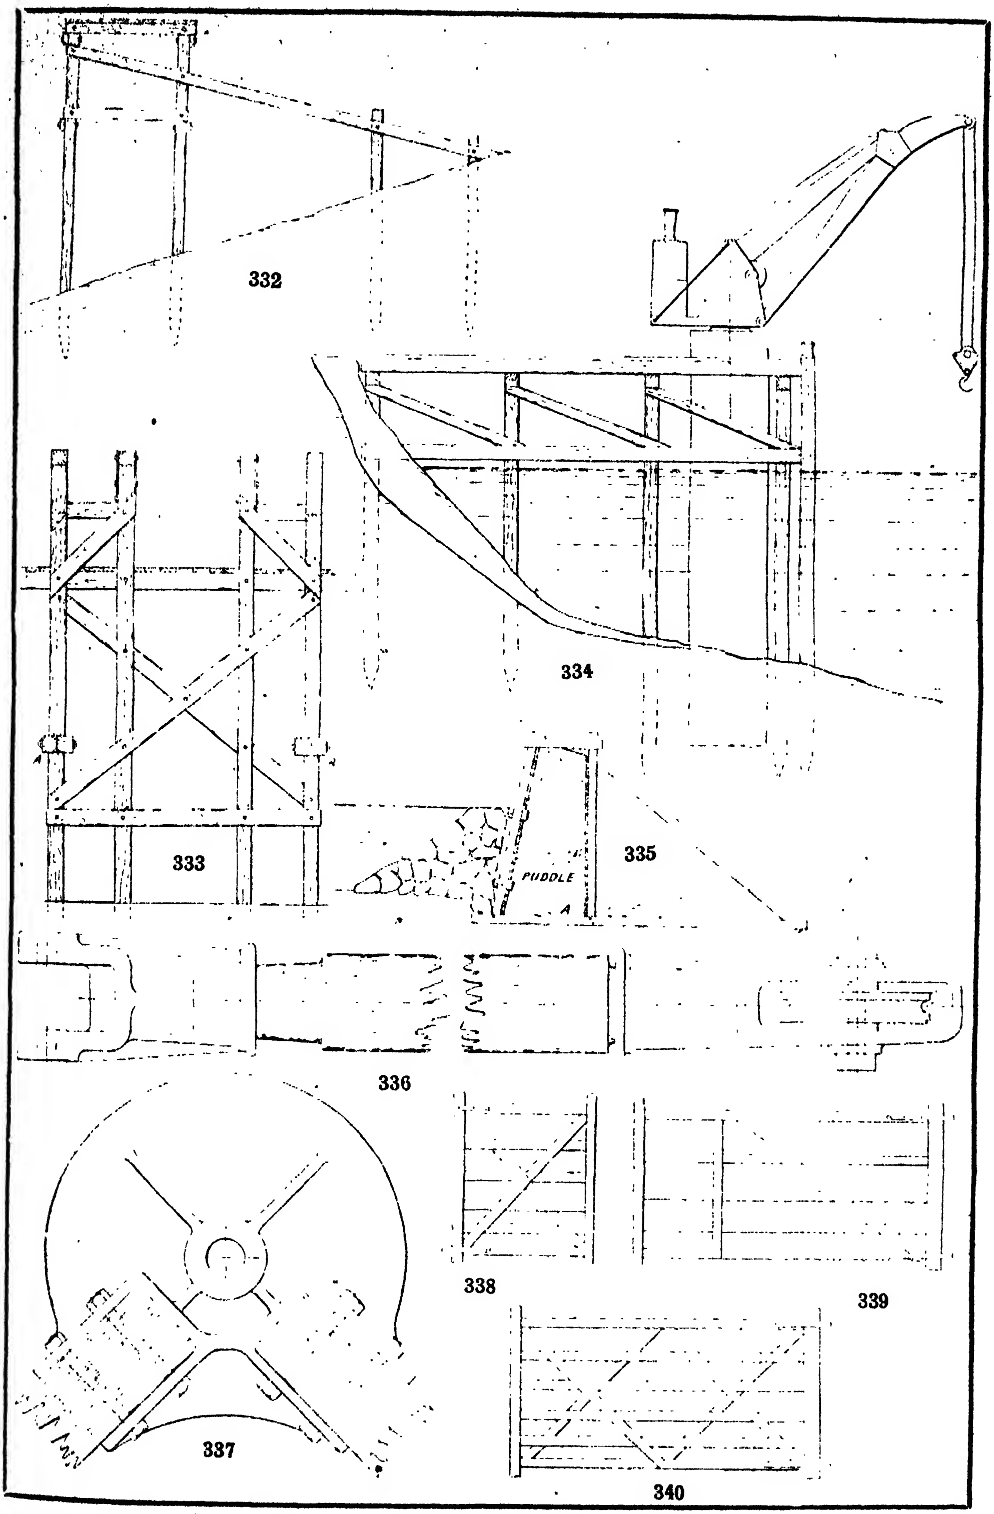
Fig. **334** shows a staith end or staging carrying a steam crane. The timber work is for the staging only, the crane being carried on a deep foundation cylinder of cast-iron rings bolted one on top of another with internal flanges. This is more rigid than timber foundations for cranes doing heavy service. Fig. **335** illustrates an alternative to piling when a rocky bed is encountered into which piles cannot be driven. Balks, A, are laid upon the rock and bolted down with lewis bolts, or retained with rubble thrown on top. These then form ties between the uprights and the diagonal struts, which form stays to the uprights against the pressure of the water. The interior between the uprights is filled with clay puddle, and the sea front is protected with rubble or boulders.

Dock Gates. Dock gates are often built of timber. Greenheart is the best for this purpose, because it resists better than any other the attack of the *teredo navalis*. Another advantage is its great weight. The difficulty is to obtain balks large enough, dimensions of as much as 20 in. square being sometimes required for ribs and heel posts.

Crane Work. In the manufacture of some classes of cranes there is a good deal of heavy timbering employed. Many cranes for foreign and colonial service also are made cheaply by purchasing the necessary ironwork, gears, etc., in England, and building timberwork in the country where required. The principal elements in which timber is frequently used are jibs, the beams for some overhead travellers, the gantries; the masts, guys, and sleepers of derricks, the poles of sheer-legs, and sometimes the trucks of travelling cranes used in quarries and on wharves. All these, without exception, have some metal fittings in the forms of castings and forgings, and as these have to be fitted accurately into their places on the crane to which they belong the carpenter in the engineer's works is somewhat of a specialist.

Some parts are fitted by driving only. Among such are the socketed feet and heads of timber jibs [**336**]. The ends of the stock are sawn nearly to size, and then eased with chisels and planes. The castings are tried from time to time, being driven on with a sledge, the easing being thus done tentatively. When they are within about $1\frac{1}{2}$ in. or 2 in. of bedding, the surfaces are well smeared with thick white-lead paint and the final driving done. The castings are not driven right home, but only to within about 1 in. of the shoulder. This allows for a little further driving subsequently, as at the right hand of **336**, when the timber has shrunk. At the left hand the timber is seen partly out of its casting. Many castings fit around three sides only of timber, leaving one side open. Driving is still practised, but security is ensured by means of bolts [**337**]. In some cases bonds are shrunk on the ends of timber, as in pile tops, ends of gantry beams, but this practice is of limited use.

Tools and Machinery Employed. Among hand tools the two-handled cross-cut, the ordinary handsaw, the auger, the chisel, and axes and adzes are the chief cutting tools employed. The timber in heavy carpentry is not usually planed. Where a considerable amount of work has to be done, preparation of each piece of timber by hand is slow and expensive. The parts, therefore, are either prepared before they leave the sawmill, or suitable machinery is brought to the place where the



HEAVY TIMBERING

332-334. Examples of staithes **335.** Barrier erected on horizontal balks instead of piles fitted into castings **338-340.** Field gates **336** and **337.** Crane timbers

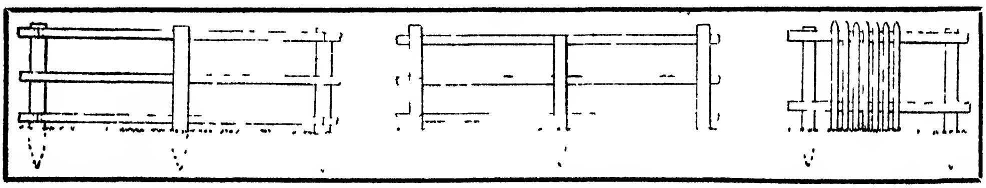
work is being erected. In the latter case the machines are usually of a different character from those which would be installed for permanent use in a shop or sawmill. A small reciprocating saw of the three-feller type, for instance, would be brought in preference to a large band or circular saw. Steam power would be obtained from a portable boiler. Light machines, perhaps worked by hand, would be used for boring bolt-holes, or a combination machine for boring, both horizontally and vertically, and cutting rebates, half laps, and mortises and tenons. If a great majority of either of these classes of work was required, machines specially for it would be employed.

Appliances of various kinds are necessary for handling heavy pieces of timber. Transportation to the locality is effected by railway or on timber carriages drawn by horses. Very large balks are carried by the latter method suspended beneath the axle of a large two-wheeled carriage; smaller ones on a four-wheeled carriage, the distance of the back wheels from the front being adjustable by sliding them along the pole which forms the connecting body. Transportation for short distances at the place where the work of erection is proceeding is effected by travelling cranes, hauling apparatus, derricks, crowbars and rollers, and numerous other means. Lifting is done with ropes or chains round the timber, or wrought-iron timber clips, which grip it tightly as hoisting power is applied. These are also used to assist in turning very heavy balks. Hoisting may be done by cranes or crabs, or by hand tackle worked through a block attached to any suitable support overhead.

Railway Carpentry. A good deal of heavy work is done in railway shops, but it is almost wholly that of machinery—sawing, planing, tenoning, grooving; everything, in short, but the actual putting of parts together. The explanation of this is that it is a class of work in which similar parts jointed similarly are constantly required, and when this is the case machinery for doing the work is always infinitely more expeditious and cheaper than hand methods. In many cases hand work on a large scale would be out of the question, and if the employment of machinery were not possible the work would have either to be done in a much simpler and more primitive style or to be left undone. The woodwork in railway shops consists chiefly in the construction of rolling stock. Oak is the wood chiefly employed.

Field Gates. These are a light class of carpentry. Examples of gates are shown in 338 to 340. Heavier and more ornamental varieties are often used for entrances to parks and villas. Fig. 338 is a wicket gate. The diagonal brace in this and in all other gates slopes from the lower part of the hinged or hanging post to the upper part of the front post. A counter brace as dotted may be added, but the brace in the other direction is the most essential. The hinge post is stouter than the other, and the hinges extend some distance along the rails, packing pieces being put on the latter, if necessary, to form a level bed to attach the hinge to. The rails are mortised into the posts, and are generally spaced farther apart at the top than at the bottom of the gate. Fig. 339 is an ordinary field gate, which, when open, leaves a clear 9 ft. way, the gate itself measuring about 8 in. more than that. The brace in this case is made to support the gate more effectively by carrying it up to a point some distance short of the front post and adding a vertical bar, so that all the rails are supported at this point, and the overhang beyond is a trifle. In 340 two braces are employed in each direction. The two main ones slope as in the previous examples. The first goes from the foot of the hinge post to the middle of the top rail, and the second from the middle of the bottom rail to the top of the front post. These braces might be still further increased in number with beneficial results, except that the gate, being made heavier, would strain the hinges more. Often the top hinge is made longer than the bottom one, because the strain on the top connection is tensile, while at the bottom it is compressive.

Fences. Examples of these are shown in 341 to 343. In all cases posts have to be inserted in the ground to support the rails. The posts are generally about 6 ft. apart, and the rails in 12 ft. lengths, so that the stability of the fence is increased by alternating the joints. Rails may be nailed to the sides of the posts, as in 341, or mortised in with scarfed ends, as in 342. In the latter the ends are supposed to be mortised into thick posts and nailed to the intermediate post, which is of smaller dimensions. Fig. 343 shows how pales may be attached to the rails. When strained wire is used instead of wood rails, the end posts have to be substantially strutted to resist the strain. Where durability is important, creosoted or kyanised wood should be used for gates and fences.



341. Fence rails nailed to posts   342. Rail ends scarfed to fit in mortises   343. Palings nailed to rail

By Francesco de Feo

IRREGULAR VERBS
Second Conjugation
Verbs in **ere** (short)

Of the following verbs, only the irregular forms will be given.

Conòscere, to know (I know somebody)
Past Def.—Conobbi, conobbe, conòbbero.
Past Part.—Conosciuto.

Conjugate like *conòscere*: *riconòscere*, to acknowledge, to recognise; *disconòscere*, to deny.

Crèscere, to grow
Past Def.—Crebbi, crebbe, crèbbero.
Past Part.—Cresciuto.

Conjugate like *crèscere*: *accrèscere*, to increase; *decrèscere*, to decrease; *rincrèscere*, to be sorry.

Assìstere, to assist; *consìstere*, to consist; *desìstere*, to desist; *esìstere*, to exist; *insìstere*, to insist; *persìstere*, to persist; *resìstere*, to resist; *sussìstere*, to subsist, are all irregular only in the past participle, which, instead of ending in *-uto*, ends in *-ito*: *assistito, consistito, esistito*, etc.

Esìgere, to exact; *redìgere*, to redact. These two verbs are regular, except in the past participles: *esatto* and *redatto*.

Nàscere, to be born
Past Def.—Nacqui, nacque, nàcquero.
Past Part.—Nato.

Conjugate like *nàscere*: *rinàscere*, to be born again.

Nuòcere, to hurt
Ind. Pres.—Nòccio, nuoci, nuoce, nociamo, nocete, nòcciono.
Past Def.—Nocqui, nocque, nòcquero.
Subj. Pres.—Nòccia, nòccia, etc.
Past Part.—Nociuto.

Bere (*bèvere*), to drink
Ind. Pres.—Bevo, bevi, beve, beviamo, etc.
Imperf.—Bevevo, bevevi, etc.
Past Def.—Bevvi and *bevetti, bevesti, bevve*, and *bevette, bevemmo, beveste, bevèttero* and *bèvvero.*
Future.—Beverò and *berrò*, etc.
Subj. Pres.—Beva, beva, etc.
Gerund.—Bevendo.
Past Part.—Bevuto.

Piòvere, to rain
Past Def.—Piòvve.

Ròmpere, to break
Past Def.—Ruppi, ruppe, rùppero.
Past Part.—Rotto.

Conjugate like *ròmpere*: *interròmpere*, to interrupt; *irròmpere*, to rush in; *proròmpere*, to burst out.

Essere, to be
[See pages 2194 and 2484-5.]

Note. When the past definite is irregular, only the first and third person singular and the third person plural are irregular. Thus:

Conòscere—Past Def.: conobbi, conoscesti, conobbe, conoscemmo, conosceste, conòbbero.

Piacére—Past Def.: piacqui, piacesti, piacque, piacemmo, piaceste, piàcquero.

When the future is irregular, the conditional is also irregular. Thus; *Bere—Future: berrò, berrai*, etc.; *Condit.: berrei, berresti*, etc. *Vedére—Future: vedrò, vedrai*, etc; *Condit.: vedrei, vedresti*, etc.

Exercise XL.

1. Dove hai conosciuto quel signore? 2. Lo conobbi a Nizza l'anno passato. 3. Riconosco il mio torto e le domando scusa. 4. La mia stima per il gióvine marinàio crebbe di molto, quando lo sentii lodare in tal modo dal suo capitano. 5. Si sa dove si è nati, ma non si sa dove si muore. 6. Egli nacque di genitori poverìssimi, ma con l'assìduo lavoro è riuscito a mèttere insieme una discreta fortuna. 7. Essi hanno insistito tanto che ho finito per cèdere. 8. Alla fine del pranzo tutti bèvvero alla salute degli sposi. 9. I ladri rùppero i vetri di una finestra a pian terreno, e penetràrono nella casa. 10. Oggi ho assistito a una scena terrìbile; un povero muratore è caduto e si è rotta una gamba.

RELATIVE PRONOUNS

The relative pronouns are:

chi (*kee*), he who, she who
che (*keh*), who, whom, that, which
il quale, la quale, who, whom (sing.)
i quali, le quali, who, whom (plur.)
cui (*koò-ee*), whom (compl.)
quanto, all that which
quello che, ciò che, what
chiunque, every one who

1. (*a*). *Chi* never refers to a preceding word. It means *colui che, colei che*; and also *qualcuno che* (someone who). Examples: *Chi ben comìncia è alla metà dell'opera*. Well begun is half done (literally: He who begins well is half way through his work). *Troveremo chi ci mostrerà la via*. We shall find someone who will show us the way.

(*b*). *Chi . . . chi* has a partitive meaning. Example: *Chi dice una cosa e chi un'altra*. Some say one thing and some another.

(*c*). In exclamative, interrogative, and dubitative propositions *chi* means *qual persona*. Example: *Non so a chi rivolgermi*. I don't know to whom to apply.

(*d*). *Chi* in a conditional construction may be used absolutely with the meaning of *se uno* (if one), *per chi* (for him who). Example: *Questo, chi lo vuol sapere* (= *se uno lo vuol sapere*; *per*

chi lo vuol sapere), *appartiene a me.* This (if anyone wishes to know; for him who wishes to know) belongs to me.

2. *Che* is used both as subject and object, and refers to any preceding word, masculine or feminine, singular or plural. Examples: *Lo scolaro che studia,* The pupil who studies; *I libri che avete comprati,* The books that you have bought. It may refer to a whole proposition, and then it is generally preceded by the article. Example: *Gli era saltata la fantasia di farsi frate,* (*il*) *che a quei tempi era il ripiego più comune per uscìr d'impicci,* The fancy had come into his head to turn friar, which in those times was the commonest device for getting out of difficulties. *Che* may also be used instead of *in cui, per cui, da che.* Examples: *Il giorno che* (*in cui*) *ti vidi.* The day when (in which) I saw thee. *Ecco la ragione che* (*per cui*) *non son venuto,* That is the reason why (for which) I did not come. *Sono due anni che* (*da che*) *è partito,* It is two years since he went away.

3. *Il quale, la quale, i quali, le quali* are used like *che,* but are not referred to pronouns expressing things: *fate quello che vi dico* (and not *quello il quale vi dico*). Do as (what) I tell you.

Il quale, la quale, etc., must be used before *nouns* (for example, *le quali case,* and not *che case*), after a preposition (*la scàtola nella quale,* and not *in che*), and where *che* might be ambiguous (*I figli della signora, i quali ho incontrati,* and not *che ho incontrato,* because *che* might be referred to *signora*).

4. *Cui* is generally used instead of *il quale,* etc., after a preposition for both genders, and in the singular as well as in the plural. Examples: *Il motivo per cui io venni,* The reason why I came; *La persona di cui le parlai,* The person of whom I spoke to you; *L'amico da cui mi aspettavo un favore,* The friend from whom I was expecting a favour. Placed between the article and the noun *cui* means "whose." Example: *È un giovane i cui costumi* (*i di cui costumi* would be incorrect) *sono degni di lode,* He is a youth whose manners are deserving of praise.

5. *Chiunque* means "any person who," and is used like *chi.* Example: *Ammettete chiunque venga,* Admit whosoever comes. It may be used also as an indefinite pronoun. Example: *Questo lo sa fare chiunque,* Anyone can do this.

EXERCISE XLI.

1. La casa della quale le ho parlato si trova in via Roma. 2. Chi non sa ubbidire non sa nemmeno comandare. 3. Fate ciò che vi ho detto, e vi troverete bene. 4. Dobbiamo amare chi ci ama, ma non dobbiamo odiare chi ci odia. 5. La ringràzio delle tante prove di amicizia che mi ha sempre mostrate. 6. Fàtemi vedére che cosa avete in tasca. 7. Gli ho restituito il danaro che mi prestò. 8. La signora che avete veduta è la moglie del nostro padrone di casa. 9. L'òrdine che mi avete dato è stato puntualmente eseguito. 10. Ecco quanto so, non posso dirle di più. 11. Il vècchio agricoltore pone il seme dell'àlbero, i cui frutti vedranno i figliuoli e nipoti.

CONVERSAZIONE

Dove volete andare? Non vedete che piove.

Se aspettiamo che finisca di piòvere, ho paura che resteremo qui tutta la notte.

Bisogna avèr pazienza; chi sa che non càpiti una vettura vuota.

Sarebbe una vera fortuna; ma chi volete che venga fin quassù con questo tempàccio?

Intanto si gela. Se si potesse fare un bel fuoco!

Lasciate fare a me che son nato e cresciuto nelle montagne.

Senti come tuona! Meno male che abbiamo portato abbastanza viveri.

Beva un po' di questo vino, vedrà che non sentirà più il freddo.

C'è da fumare?

Ce n'è per una settimana.

È quello che ci vuole: fra una sigaretta e l'altra il tempo passerà presto.

INTERROGATIVE PRONOUNS

The interrogative pronouns are: *chi?* who? *di chi?* whose? *che? che cosa?* what? *quanto-i a-e?* how much? how many? *quale-i?* which? what?

1. *Chi?* means "which person?" (sing.) but when used with the verb *èssere* it is also plural. Examples: *Chi vi manda?* Who sends you? *Chi sono quelle signore?* Who are those ladies?

2. *Che?* means "which thing?" Example: *Che fate?* What are you doing? As an adjective it is masculine and feminine, singular and plural. Examples: *Che libro vuole?* Which book do you want? *Che libri leggete?* Which books are you reading?

3. In familiar language *cosa?* is used as an interrogative pronoun instead of *che cosa?* Examples: *Cosa dite?* What do you say? *Non so cosa voglia dire,* I do not know what he means. The past participle referring to *cosa* is always in the masculine: *Cos' è accaduto?* What has happened? *Cosa ha fatto?* What have you done?

4. *Quanto?* expresses the English "how long?" Example: *Quanto dobbiamo aspettare?* How long must we wait?

The interrogative pronouns are often strengthened by *mai, e.* Examples: *Che dici mai?* What are you saying? *E cosa importa?* And what does it matter? Questions are answered in Italian by *sì, già, certo,* etc., in the affirmative, and by *no, ma che,* etc., in the negative.

The English: Are you? Are you not? Do you? Do you not? Did you? etc., which accompany a question, are rendered in Italian by *non è vero?* (is it not true?). Example: *Lei viene con noi, non è vero?* You are coming with us, are you not?

EXERCISE XLII.

1. Quanto ha pagato questo cappello? 2. Di chi è questo portafogli? 3. Chi ha portato questo bagàglio? 4. Quel signore è un inglese, non è vero? Qual' è il treno per Roma? 6. Cosa hanno comandato per il Natale? 7. Cosa hanno questi ragazzi? 8. Chi è costui? 9 A quale stazione ci fermeremo? 10. A chi avete dato il biglietto? 11. Che cosa ha detto suo padre? 12. Di quale signora parlate?

13. In che anno siete nato? 14. A che pensa sua cugina? 15. Chi ha domandato di èssere ammesso?

KEY TO EXERCISE XXXV.

1. When I entered they had already gone. 2. I am pleased that you have succeeded in this affair. 3. The performance has lasted more than two hours. 4. I have fallen, and have hurt myself. 5. I am not sleepy; I have slept all day. 6. I am waiting for my brother; he was to have come by the seven o'clock train, and I wonder that he has not yet arrived. 7. If you had come ten minutes earlier, you would have met Mr. N. 8. A man-of-war has sunk in the Baltic. 9. A Japanese torpedo-boat has sunk two Russian ships. 10. I have wandered about all day without settling anything.

KEY TO EXERCISE XXXVI.

1. Put them aside; we shall make use of them when we have need of them. 2. That is not correct. 3. This man is so full of himself that it seems that all the world belongs to him 4. This is an author of great merit; that is a most genial poet. 5. I dare not speak openly, because I fear to be misunderstood by these, and combated by those. 6. You do not know what you are talking about. 7. I don't know how things will end; for my part, I do not see clearly in this business. 8. Here are two bottles large enough; in this one we will put the wine, and in that one the water. 9. Do not speak to me of those people; they do not deserve to be helped any longer. 10. Lewis aimed rather at avoiding the blows of his enemy, and at disarming him, than at killing him; but the latter desired his death at any price. 11. That woman speaks only out of envy; it is better not to listen to her. 12. Those who make most noise (literally, shout more) are always right in this world. 13. The prize will be given to him who has deserved it.

KEY TO EXERCISE XXXVII.

1. I am glad to see that you are well. 2. I do not remember you, but it seems to me that I have seen you somewhere. 3. I had the pleasure of knowing you in Rome two years ago. 4. When in the country we are used to taking a long walk before breakfast. 5. Fear nothing; I will think of your future. 6. I am sorry to be obliged to speak to you in this way. 7. My head aches; it will be better for me to remain in the house. 8. It had seemed to me that they had rung the bell. 9 Till now we have always done as you liked; now, it seems to me that you should do as we like.

KEY TO EXERCISE XXXVIII.

1. That poor man must have put together a fair sum, because everyone has given him something. 2. I am speaking generally, and I should not like anyone to consider my words as referring to him. 3. Iniquity is often based upon the credulity and goodness of others. 4. Always act rightly, and do not care what other people may think of you. 5. Knock again; someone must be in, because there is a light in the rooms upstairs. 6. It seems that some people rejoice at other people's misfortunes. 7. If you do not tell me everything exactly, we shall do nothing. 8. Always tell the truth if you wish others to esteem you. 9. Those who possess nothing are always the most generous. 10. Nothing is useless; everything has its reason for existing.

KEY TO EXERCISE XXXIX.

1. In that country it snows very seldom, but it always rains. 2. It rains hard; we must take a carriage. 3. It will be necessary to leave early if we wish to arrive in time. 4. It has hailed and rained all night. 5. It does not thunder any more, but it lightens still. 6. It is better not to go out to-day; it is very foggy. 7. Let us go; it is not worth while to stay here to speak of useless things. 8. Your friend seems very happy; he must have done good business on the exchange. 9. It seems that he is happy, but really it is not so. 10. Russia has imported a great quantity of corn this year. 11. It is of consequence to decide at once, because there is no time to lose. 12. You have already spoken enough; it is my turn now. 13. One is sorry to see young people so idle. 14. One must enjoy oneself a little in this life; one lives only once.

FRENCH

Continued from page 4508

By Louis A. Barbé, B.A.

IRREGULAR VERBS

Second Conjugation

1. **Acquérir,** to acquire, *acquérant, acquis.*

Ind. Pres.—j'acquiers, tu acquiers, il acquiert, nous acquérons, vous acquérez, ils acquièrent.

Imperf.—j'acquérais.

Past Definite—j'acquis.

Future.—j'acquerrai.

Cond. Pres.—j'acquerrais.

Subj. Pres.—que j'acquière, que tu acquières, qu'il acquière, que nous acquérions, que vous acquériez, qu'ils acquièrent.

Imperf.—que j'acquisse.

Conquérir, to conquer, *reconquérir*, to reconquer, *s'enquérir de*, to inquire about, and *requérir*, to request, to call upon, are conjugated in the same way.

In the Future and the Conditional, each "*r*" must be pronounced separately, though the break in the trill must be very slight. This pronunciation is necessary to distinguish these tenses from the Present and Imperfect Indicative.

2. **Courir,** to run, *courant, couru.*

Ind. Pres.—je cours, tu cours, il court, nous courons, vous courez, ils courent.

Imperf.—je courais.

Past Def.—je courus.

Future.—je courrai.

Cond. Pres.—*je courrais.*

Subj. Pres.—*que je coure, que tu coures, qu'il coure, que nous courions, que vous couriez, qu'ils courent.*

Imperf.—*que je courusse.*

The other verbs conjugated like this are: *accourir*, to rush up, hasten; *concourir*, to concur, to compete; *discourir*, to discourse; *encourir*, to incur; *parcourir*, to run through; *recourir*, to have recourse; and *secourir*, to succour. In all these verbs also, the two "r's" of the Future and of the Conditional are to be pronounced separately.

3. **Cueillir,** to gather, to pluck, *cueillant, cueilli.*

Ind. Pres.—*je cueille, tu cueilles, il cueille, nous cueillons, vous cueillez, ils cueillent.*

Imperf.—*cueillais.*

Past Def.—*je cueillis.*

Future.—*je cueillerai.*

Cond. Pres.—*je cueillerais.*

Subj. Pres.—*que je cueille, que tu cueilles, qu'il cueille, que nous cueillons, que vous cueillez, qu'ils cueillent.*

Imperf.—*que je cueillisse.*

Accueillir, to receive, to welcome; and *recueillir*, to collect, are conjugated in the same way.

4. **Mourir,** to die, *mourant, mort.*

Ind. Pres.—*je meurs, tu meurs, il meurt, nous mourons, vous mourez, ils meurent.*

Imperf.—*je mourais.*

Past Def.—*je mourus.*

Future.—*je mourrai.*

Cond. Pres.—*je mourrais.*

Subj. Pres.—*que je meure, que tu meures, qu'il meure, que nous mourions, que vous mouriez, qu'ils meurent.*

Imperf.—*que je mourusse.*

This verb has a reflexive form, *se mourir*, to be dying. *Mourir* is conjugated with *être* in its compound tenses. Both "r's" of the Future and of the Conditional are to be pronounced distinctly.

5. **Tenir,** to hold, *tenant, tenu.*

Ind. Pres.—*je tiens, tu tiens, il tient, nous tenons, vous tenez, ils tiennent.*

Imperf.—*je tenais.*

Past Def.—*je tins, tu tins, il tint, nous tînmes, vous tîntes, ils tinrent.*

Future.—*je tiendrai.*

Cond. Pres.—*je tiendrais.*

Subj. Pres.—*que je tienne, que tu tiennes, qu'il tienne, que nous tenions, que vous teniez, qu'ils tiennent.*

Imperf.—*que je tinsse.*

Idiomatic Uses of Tenir. (*a*). *Tenir de* followed by a personal noun means "to take after," "to resemble."

Cet enfant tient de sa mère, That child takes after his mother.

(*b*). *Tenir à* followed by a noun or preceded by "*y*" means "to value," "to set store by."

Ne perdez pas ce livre, j'y tiens, Do not lose that book, I value it.

When followed by an infinitive, it means, "to be anxious to."

Je tiens à lui dire ce que j'en pense, I am anxious to tell him what I think about it.

Tenir à ce que followed by a personal tense has the same meaning. It is followed by the Subjunctive:

Je tiens à ce qu'il nous dise ce qu'il en pense, I am anxious he should tell us what he thinks about it.

Tenir à used impersonally means, "to depend on": *Il ne tient qu'à vous de réussir*, It only depends on you to succeed—*i.e.*, It will be your fault if you do not succeed.

The derivatives of *tenir* are: *s'abstenir*, to abstain; *appartenir*, to belong; *contenir*, to contain; *détenir*, to detain; *entretenir*, to keep up; *maintenir*, to maintain; *obtenir*, to obtain; *retenir*, to retain, to remember; *soutenir*, to sustain; *se tenir*, to stand, to hold oneself.

6. **Venir,** to come, *venant, venu.*

Ind. Pres.—*je viens, tu viens, il vient, nous venons, vous venez, ils viennent.*

Imperf.—*je venais.*

Past Def.—*je vins, tu vins, il vint, nous vînmes, vous vîntes, ils vinrent.*

Future.—*je viendrai.*

Cond. Pres.—*je viendrais.*

Subj. Pres.—*que je vienne, que tu viennes, qu'il vienne, que nous venions, que vous veniez, qu'ils viennent.*

Imperf.—*que je vinsse.*

Venir is conjugated with *être* in its compound tenses.

Idiomatic Uses of Venir. (*a*). *Venir de* followed by an infinitive means, "to have just": *Je viens de le voir*, I have just seen him; *Il venait de sortir*, He had just gone out.

(*b*). *Venir à* followed by an infinitive means "to chance to," "to happen to": *Pendant que le marquis de Carabas se baignait, le roi vint à passer*, Whilst the Marquess of Carabas was bathing, the King happened to pass.

(*c*). There is also a reflexive form, *s'en venir*, "to come along, to come away":

Nous nous en vînmes ensemble, We came away together.

The derivatives conjugated like *venir* are:

circonvenir, to circumvent
contrevenir, to infringe
convenir, to agree, to suit
devenir, to become
disconvenir, to disagree
intervenir, to intervene
parvenir, to reach, to succeed
prévenir, to warn
provenir, to proceed
redevenir, to become again
revenir, to come back
subvenir, to provide
survenir, to come by chance
se souvenir de, to remember
se ressouvenir de, to recollect again

EXERCISE XXXIII.

1. Little Red Riding Hood (*Le Petit Chaperon Rouge*) set out to go to her grandmother's, who lived in another village.

2. The wolf that she met asked her where she was going.

3. The little girl said to him: "I am going to see my grandmother and to take (*porter*) her a cake (*une galette*) with a little pot (*le pot*) of butter (*beurre*) which my mother is sending her."

4. The wolf began to run with (*de*) all his might (*la force*) by the road which was the shortest, and the little girl went off by the longest road, loitering (*s'amuser*) to gather nuts (*la noisette*) and to run after butterflies (*le papillon*).

5. Puss in Boots (*le Chat Botté*) said to the Ogre (*Ogre*): "I have been assured that you had the power (*le pouvoir*) to change (*changer*) yourself into (*en*) a rat, and a mouse (*la souris*); I confess (*avouer*) to you that I consider (hold) that quite impossible."—"Impossible," replied (*reprendre*) the Ogre, "you are going to see."

6. "It will depend only on you, Marquess" (*Monsieur le marquis*), said the King "to be (that you be, subj. pres. preceded by *ne*) my son-in-law" (*gendre*).

7. The Cat became (a) great lord, and no longer ran after mice, except (*que*) to amuse himself (*se divertir*).

8. The fairy (*la fée*) said to Cinderella (*Cendrillon*): "Go (thou) into the garden; you will find there six lizards (*le lézard*) behind (*derrière*) the watering-can (*arrosoir*, m.); bring them to me."

9. "I recommend you (*recommander*) above all (*surtout*) not to pass midnight; if you remain (*demeurer*) at the ball a moment longer (more) your coach (*le carrosse*) will become (a) pumpkin (*la citrouille*) again, your horses mice, your footmen (*laquais*) lizards, and your old clothes (*les habits*, m.) will resume (*reprendre*) their first form" (*la forme*).

10. The old fairy said that the princess would pierce (*se percer*) her hand with (*de*) a spindle (*le fuseau*) and that she would die of it.

11. The princess will pierce her hand, but she will not die of it; instead of dying of it, she will fall into a deep sleep which will last a hundred years, at the end (*le bout*) of which the son of a king will come and (to) awaken (*réveiller*) her.

12. Little Hop o' my Thumb (*le Petit Poucet*) went to bed again (*se recoucher*) and did not sleep for the (*du*) rest of the night; he got up early (*de bon matin*) and went to the bank (*le bord*) of a stream (*le ruisseau*), where he filled (*emplir*) his pockets (*la poche*) with (*de*) little white pebbles, and then (*ensuite*) came back to the house.

Key to Exercise XXXII.

1. Quand les anciens assiégeaient une ville, ils battaient les murs à coups de bélier.

2. On n'est jamais battu sans être frappé; mais on peut être frappé sans être battu.

3. Le muletier qui nous servait de guide, battait ses mules d'une façon épouvantable.

4. Nous n'avons rien conclu, mais ce n'est pas ma faute.

5. C'est un auteur dont les ouvrages ont été traduits dans toutes les langues.

6. Selon un écrivain distingué, si vous traduisez toujours, on ne vous traduira jamais; et cependant, un autre écrivain tout aussi distingué a dit que si vous voulez qu'on vous traduise un jour, vous devez commencer par traduire vous-même.

7. Je ne l'ai vu qu'une fois, mais je le connaîtrais entre mille.

8. Cette jeune fille coud, chante, lit; c'est tout ce qu'il lui faut pour être heureuse.

9. Qui est-ce qui disait que, partout où la peau du lion ne suffisait pas, il fallait y coudre la peau du renard, c'est à dire joindre la ruse à la force?

10. Il y a des gens qui ne comptent le reste des hommes pour rien, et ne croient être nés que pour eux-mêmes.

11. Un honnête homme qui dit oui et non mérite d'être cru; son caractère jure pour lui.

12. Tout auteur qu'on est obligé de lire deux fois pour l'entendre écrit mal.

13. Ce qui est écrit est écrit veut dire qu'on ne peut rien changer à ce qui est écrit.

14. Le bon pasteur a dit: "Je connais mes brebis et mes brebis me connaissent."

15. Il est admis par tous les peuples civilisés que la personne d'un ambassadeur est inviolable et sacrée.

16. Vous nous peignez si bien les charmes de la vie champêtre que vous nous donnez l'envie d'aller habiter au village.

17. Les Gaulois se transmettaient les nouvelles en allumant des feux sur les hauteurs.

18. Les jours croissent du vingt et un décembre au vingt et un juin; ils décroissent du vingt et un juin au vingt et un décembre.

19. Les hommes sont comme les fleurs qui paraissent et disparaissent avec une incroyable rapidité.

20. Le onze novembre mil cinq cent soixante-douze, une étoile nouvelle apparut tout à coup dans le ciel, où elle brilla du plus vif éclat; elle disparut au mois de mai mil cinq cent soixante-quatorze après avoir duré seize mois.

21. On lit dans la Genèse que les anciens patriarches vivaient fort longtemps, et qu'Abraham vécut cent soixante-quinze ans.

22. Nous écrivons de gauche à droite; les Juifs écrivent de droite à gauche; les Arabes écrivent également de droite à gauche.

23. Les Français vainquirent les Autrichiens à Jemmapes et à Marengo; ils furent vaincus par les Anglais à Waterloo.

24. Les anciens moulaient le blé avec de petites meules mues à bras d'hommes.

25. Les actions injustes nuisent toujours à leurs auteurs.

26. Cléopâtre prit une grosse perle, qu'elle jeta dans une tasse, et, quand elle l'eut vue dissoute, elle l'avala.

27. Vous riez, et avec raison, des sottises des hommes, dont je ferais bien de rire aussi, et dont je rirais comme vous, si je digérais et si je dormais mieux.

28. Quelle passion que l'envie! Elle suit l'homme de mérite jusqu'au bord de sa tombe.

UNCLASSIFIABLE IRREGULAR VERBS—continued

There are still a few irregular verbs which cannot be classified; these are given in the order of their conjugation:

First Conjugation

Andar, to walk, to go about.

This verb is perfectly regular except in the following tenses:

Past Def.—anduve, anduviste, anduvo, anduvimos, anduvisteis, anduvieron.

Subj. Imperf.—anduviera, anduvieras, anduvieramos, anduvierais, anduvieran, or *anduviese,* etc.

Subj. Fut.—anduviere, anduvieres, anduviere, anduvieremos, anduviereis, anduvieren.

Dar, to give; *dando,* giving; *dado,* given.

Ind. Pres.—doy, das, dá, damos, dáis, dan.

Imperf.—daba, dabas, daba, dábamos, dábais, daban.

Past Def.—dí, diste, dió, dimos, disteis, dieron.

Imperat.—da, dé, demos, dad, den.

Subj. Pres.—dé, des, de, demos, deis, den.

Subj. Imperf.—diera, dieras, diera, dieramos, dierais, dieran or *diese, dieses,* etc.

Subj. Fut.—diere, dieres, diere, dieremos, diéreis, diren.

The future and conditional of the indicative are regular.

Second Conjugation

Caber, to be contained in, to hold, to fit into.

Ind. Pres.—quepo, cabes, cabe, cabemos, cabeis, caben.

Imperf.—cabia, cabias, cabia, cabiamos, cabiais, cabian.

Past Def.—cupe, cupiste, cupo, cupimos, cupisteis, cupieron.

Fut.—cabré, cabrás, cabrá, cabrémos, cabréis, cabrán.

Condit.—cabria, cabrias, cabria, cabríamos, cabríais, cabrían.

Imperat.—cabe, quepa, quepamos, cabed, quepan.

Subj. Pres.—quepa, quepas, quepa, quepamos, quepais, quepan.

Subj. Imperf. cupiera, cupieras, cupiera, cupiéramos, cupiérais, cupieran, or *cupiese,* etc.

The verb *Caber* is also used impersonally. Examples: *No cabe en lo posible,* It is impossible; *Si cabe,* If possible; *No cabe duda,* There is no room for doubt.

Caer, to fall.

Ind. Pres.—caigo, caes, cae, caemos, caeis, caen.

Subj Pres.—caiga, caigas, caiga, caigamos, caigais, caigan.

Imperat.—cae, caiga, caigamos, caed, caigan.

All the other tenses of this verb are regular, but subject to the usual change of *i* to *y* when the diphthongs *ie* and *io* of the verbal termination meet the radical vowel.

Past Def.—caí, caiste, cayó, caímos, caísteis, cayeron.

Hacer, to do; *haciendo,* doing; *hecho,* done.

Ind. Pres.—hago, haces, hace, hacemos, haceis, hacen.

Past Def.—hice, hiciste, hizo, hicimos, hicisteis, hicieron.

Fut.—haría, harás, hará, harémos, hareis, harán.

Cond.—haré, harias, haria, hariamos, hariais, harian.

Imperat.—haz, haga, hagamos, haced, hagan.

Subj. Pres.—haga, hagas, haga, hagamos, hagais, hagan.

Subj. Imperf.—hiciera, hicieras, hiciera, hicieramos, hicierais, hicieran, or *hiciese,* etc.

Subj. Fut.—hiciere, hicieres, hiciere, hiciéremos, hiciéreis, hiciéren.

The imperfect of the indicative is regular.

Poder, to be able; *pudiendo,* being able; *podido,* been able.

Ind. Pres.—puedo, puedes, puede, podemos, podeis, pueden.

Past Def.—pude, pudiste, pudo, pudimos, pudisteis, pudieron.

Subj. Pres.—pueda, puedas, pueda, podámos, podais, puedan.

Subj. Imperf.—pudiera, pudieras, pudiéra, pudieramos, pudiérais, pudieran, or *pudiése,* etc.

Subj. Fut.—pudiére, pudiéres, pudiére, pudiéremos, pudiereis, pudiéren.

There is no imperative; the imperfect of the indicative is regular, also the future and conditional, excepting for the elision of the *e* in the termination: *Fut., podré,* etc. *Condit., podria,* etc. The English equivalent of *poder* is can—I can, thou canst, etc.

Poner, to put, *poniendo, puesto.*

Ind. Pres.—pongo, pones, pone, ponemos, poneis, ponen.

Past Def.—puse, pusiste, puso, pusimos, pusisteis, pusiéron.

Imperat.—pon, ponga, pongámos, poned, pongan.

Subj. Pres.—ponga, pongas, ponga, pongámos, pongáis, pongan.

The imperfect of the indicative is regular, also the future and conditional, save for the elision of *e* as in *poder.* The remaining tenses of the subjunctive have *pus* for stem throughout with regular terminations: *pusiéra,* etc.; *pusiese,* etc.; *pusiere,* etc.

Querer, to will, to wish; *queriendo, querido.*

Ind. Pres.—quiero, quiéres, quiere, querémos, quereis, quieren.

Past Def.—quise, quisiste, quiso, quisimos, quisisteis, quisieron.

Imperat.—quiere, quiera, querámos, quered, quiéran.

Subj. Pres.—quiéra, quieras, quiera, querámos, querais, quiéran.

The imperfect of the indicative is regular; the future and conditional have the regular terminations with the stem *querr, querré,* etc. The remaining tenses of the subjunctive have

regular terminations with the stem *quisi*, *quisierais*, etc.

Querer also signifies to love, to like.

Saber, to know ; *sabiendo, sabido.*

Ind. Pres.—sé, sabes, etc. (regular).

Past Def.—sepa, sepas, sepa, sepámos, sepáis, sepan.

Imperat.—sabe, sepa, sepámos, sábed, sepan.

Subj. Pres.—sepa, sepas, sepa, sepámos, sepáis, sepan.

The imperfect of the indicative is regular ; the future and conditional are regular, save for elision of *e*, *sabré*, etc.

The subjunctive, imperfect and future have the regular terminations with the stem *sup*, *supiera*, etc., *supiése*, etc., *supiére*.

Traer, to bring ; *trayendo, traido.*

Ind. Pres.—traigo, traes, trae, traemos, traeis, traen.

Past Def.—traje, trajiste, trajo, trajímos, trajisteis, trajeron.

Imperat.—trae, traiga, traigamos, traed, traigan.

Subj. Pres.—traiga, traigas, traiga, traigamos, traigais, traigan.

The imperfect and future of the indicative and the conditional are regular.

In the subjunctive, imperfect and future, the stem is *traj*, and the *i* of the verbal termination is dropped: *trajera*, etc.; *trajese*, etc.; *trajere*, etc.

Valer, to be worth ; *valiendo, valido.*

Ind. Pres.—valgo, vales, vale, valémos, valeis, valen.

Imperat.—vale, valga, valgámos, valed, valgan.

Subj. Pres.—valga, valgas, valga, valgámos, valgais, valgan.

The rest of this verb is regular save for the elision of *e* in the future of the indicative and in the conditional: *valdré*, etc. ; *valdria*, etc.

Ver, to see ; *viendo, visto.*

Ind. Pres.—veo, ves, ve, vemos, veis, ven.

Imperat.—ve, vea, veamos, ved, vean.

Subj. Pres.—vea, veas, vea, veamos, veais, vean.

• All the other tenses of this verb are regular.

Vocabulary—Vocabulario

EXERCISE XVII. (1)

Translate the following into Spanish :

1. We went from one town to another. I walk a good deal without being tired, but he cannot walk.

2. I gave alms to a poor man ; it pleases me to give to the really needy.

3. I sit in the armchair ; those (persons) sit on the sofa, and the child lies in the cradle.

4. You can take this manuscript, that is, if you can read it. I cannot decipher it.

5. Put the bread on the table, and afterwards I will put it (in) on the sideboard while they lay the table.

6. I wish them to listen to me, and they will not hear me.

7. My friends know the history of England by heart ; I know that of Spain very well, and with time they will know it also.

8. Bring back good luck with you, and when brought, let us hope it will remain.

9. This picture is not worth much, but when cleaned it will be worth more, and I should not be surprised if it were then worth a great deal.

10. I see that your friendship is given to another ; and, seeing it, mine decreases.

11. The fables of Lafontaine are not so well known as those of Æsop.

12. That man's ostentation is ridiculous.

EXERCISE XVII. (2)

Translate the following into English :

1. La fabrica de tabacos de Sevilla es una de las curiosidades de ese pueblo.

2. La gente del pueblo en Andalucia usan fajas de colores brillantes ; el efecto es muy pintoresco.

3. Se usa la palabra *fatiga* ademas del sentido cansancio como una exclamacion que quiere decir, que *fastidio*, que *apuro*.

4. En tiempo de la caballeria andante recibian los caballeros de manos de sus damas un galardon que conservaban y defendian con su vida.

5. La Galería Nacional en Londres contiene muy buenos cuadros.

6. Los toros que vienen á los pueblos para las corridas son siempre llamados *el ganado*.

7. Hay mendigos, que, vestidos de harapos, conservan aún alguna dignidad.

8. Las hazañas del Cid son conocidas por todo el mundo civilizado.

9. Se hacen muy bonitas telas de algodon ; las de Manchester son las mejores.

10. En las huelgas baila la gente del campo alrededor de las hogueras.

11. La humildad es una virtud, pero el humillar al humilde es el acto de una persona despótica y orgullosa.

12. La ignorancia es atrevida. Nadie dá una opinion mas decidida y perentoria que el ignorante.

KEY TO EXERCISE XVI. (1)

1. Sirviendo á la patria se ganan honores.

2. Seguir el mal ejemplo es malo, sigamos siempre el bueno.

3. Al ceñirse la espada gritó " Viva el Rey."

4. No compitamos con esa casa : sus precios son ridiculamente baratos.

5. No compres esa tela : se destiñe y mancha las manos.

6. Gustosamente despedimos á un huesped desagradable y fastidioso.

7. Es dificil elegir á un compañero de viaje, pero una vez elegido hay que avenirse con él hasta el fin de la jornada.

8. Hay que reflexionar antes de investir su patrimonio, pues despues de investido se corre riesgo de no poder retirarlo.

9. Midamos el paño antes de cortar la capa, y cortemoslo segun la medida.

10. Persiguieron al enemigo hasta que no pudieron proseguir más lejos.

11. Reñir con sus amigos es cosa de necios.

12. Contribuyamos con buenas obras al bien del prójimo, pero que la contribucion sea sensata.

KEY TO EXERCISE XVI. (2)

1. She is so old and ugly that she looks like a witch.
2. He hurt that child; he is a brute!
3. That man is a brewer; he made his fortune selling beer.
4. He showed me a very ancient dagger: the workmanship is very fine.
5. The strawberry beds in my garden extend for half a league.
6. There are very fine fruit trees in the orchard.
7. The figs, pears, and apples are very delicious.
8. Heather grows on mountains.
9. The lemons and oranges which grow on our lemon and orange trees are noted for being good. Our strawberry beds also yield very large strawberries.
10. The flower of the pomegranate-tree is as pretty as its fruit.
11. It is the fashion to make rush furniture; it is pretty, but not lasting.
12. The box of the Alcazar of Seville is celebrated for its age and beauty.
13. In Spain they make a preserve of almonds and nuts called *turron*, which is very good.
14. Olive trees are sad and melancholy-looking: their foliage is nearly black.

PROSE EXTRACT XIV.

From "La Barraca" (The Hut), by Vicente Blasco Ibañez.

The wide plain was rousing itself in the blue gleam of dawn, which rose like a broad band of light above the sea.

Desperezábase la inmensa vega bajo el resplandor azulado del amanecer, ancha faja de luz que asomaba por la parte del mar.

The last nightingales, weary of enlivening with their songs the spring-like mildness of the autumn night, sent forth their final trills, as if the light of morning had pierced them with its steely rays.

Los últimos ruiseñores, cansados de animar con sus trinos aquella noche de otoño que por lo tibio de su ambiénte parécia de primavera, lanzaban el gorjeo final como si les hiriera la luz del alba con sus reflejos de acero.

Bands of sparrows arose from the straw-thatched roofs of the huts, like a troop of street arabs in full flight, and the tree-tops trembled with the first gambols of these urchins of the air, which was all filled with the noisy rustling of their feather tunics.

De las techumbres de paja de las barracas salían las bandadas de gorriones como tropel de pilluelos perseguidos, y las copas de los arboles estremecíanse con los primeros jugueteos de aquellos granujas del espacio que todo lo alborotaban con el roce de su blusa de plumas.

The noises of the night died slowly away—the lapping of watercourses, the whispering of rushes, the barking of vigilant mastiffs.

Apagábanse lentamente los rumores que poblaban la noche—el barboteo de las acequias, el murmullo de los cañaverales, los ladridos de los mastines vigilantes.

The plain was waking: its yawning grew louder and louder every moment. The crowing of cocks spread from hut to hut; the belfries of the little villages sent forth their noisy peals for the first Mass, ringing afar from the blue turrets of Valencia, which showed misty in the distance. A discordant animal concert arose from the farmyards—the neighing of horses, the lowing of meek kine, the cackle of hens, the bleating of sheep, and the grunting of swine; the noisy awakening of beasts which, feeling the fresh caress of morning laden with the acrid smell of vegetation, long to roam the fields.

Despertaba la huerta, y sus bostezos eran cada vez más ruidosos. Rodaba el canto del gallo de barraca en barraca; los campanarios de los pueblecitos devolvían con rindosas badajadas el toque de misa primera que sonaba á lo lejos en las torres de Valencia, azules, esfumadas por la distancia, y de los corrales salió un discordante concierto animal, relinchos de caballos, mugidos de mansas vacas, cloquear de gallinas, balidos de corderos, ronquidos de cerdos, el despertar ruidoso de las bestias que al sentir la fresca caricia del amanecer cargada de aire, perfume de vegetación, deseaban correr por los campos.

All space was gradually soaked with light; the shadows vanished as though swallowed by the open furrows and masses of foliage; and from the vague twilight of the dawn emerged the brilliant and humid outlines of rows of mulberry and fruit trees, the swaying lines of rushes, the great squares of growing vegetables like enormous green handkerchiefs, and of carefully ploughed red earth.

El espacio se empapaba de luz, disolvíanse las sombras como tragadas por los abiertos surcos y las masas de follaje, y en la indecisa neblina del amanecer iban fijándo sus contornos húmedos y brillantes las filas de moreras y frutales, las ondulantes líneas de cañas, los grandes cuadros de hortalizas semejantes á enormes pañuelos verdes y la tierra roja cuidadosamente labrada.

Upon the roads appeared files of moving black specks, like a rosary of ants making towards the city. From every corner of the plain arose the creaking of wheels, and a sound of lazy singing, interrupted by a shout of encouragement to the beasts; and every now and then, like the sonorous trumpet-call of morning, the air was rent by the furious braying of the four-footed pariah, as if in protest against the heavy labour which fell upon him almost at break of day.

En los caminos marcábanse filas de puntos negros y movibles como rosarios de hormigas que marchaban hacía la ciudad. Por todos los extremos de la vega sonaban chirridos de ruedas, canciones perezosas interrumpidas por el grito arreando las bestias, y de vez en cuando como sonoro trompetazo del amanecer, rasgaba el espacio un furioso rebuzno del cuadrúpedo pária, como protesta del pesado trabajo que caía sobre él apenas nacido el dia.

In the water-courses the smooth sheet of reddish crystal was troubled by loud plungings, which silenced the frogs, and in a noisy flapping of wings the swans advanced like galleys of ivory, their long serpent-necks moving like fantastic prows.

En las acequias conmoviase la tersa lámina de cristal rojizo con sonoros chapuzones, que hacían callar á las ranas, y ruidoso batir de alas y como galeras de marfil avanzaban los cisnes moviendo cual fantasticas proas sus cuellos de serpiente.

Life, which inundated the plain, together with the light, penetrated into the interior of the huts and farmhouses.

La vida que con la luz inundaba la vega, penetraba en el interior de las barracas y alquerías.

Vicente Blasco Ibañez, who was born in 1867, is considered one of the foremost living novelists in Spain. "The Hut" is a tragic story of village life, told with grim power and great literary beauty of style.

Vicente Blasco Ibañez, nació en 1867, es considerado en España como uno de los primeros novelistas de nuestro tiempo. "La Barraca" es una historia trágica de la vida de aldea, dicha con una fuerza sombria, y un hermoso estilo literario.

By Harald Clegg

PREPOSITIONS

There are thirty-four words in Esperanto which are essentially prepositions, and to each of which a fixed meaning and power are given. They govern the nominative case and not the objective, as in English. Care must be taken in translating English prepositions to see that the exact sense required is given to the phrase. When we say in English, "I saw a man with a telescope," the meaning of "with a telescope" is ambiguous, and "Lessons in Esperanto" may mean that instruction on a subject is given in that language, or that Esperanto is the subject about which instruction is given; so that in all cases the preposition selected must be that which gives a logical meaning to the idea to be expressed. When, however, it happens that none of these will accurately convey the sense desired, there lies in reserve the preposition *je*, with no definite signification; but as proficiency in Esperanto is acquired, the necessity for using that word decreases. It should only be used as a last resort. An alternative course is to omit the preposition and employ the objective case, but this should only be done when the clearness of the meaning is not affected. Nearly all prepositions may be used as prefixes to words. We thus get:

ĉeesti, to be at, to be present at
aliri, to go to
priparoli, to speak about

[See Vocabulary.]

It is important to remember that, as in English, prepositions do not end phrases. "The man John spoke to" must be translated, "*La viro al kiu Johano parolis*" (The man to whom John spoke).

The following are the most commonly used prepositions:

- ***al***, to, towards
- ***ĉe***, at, at the place of, at the time of, with
- ***da***,* of (used after words indicating weight, measure, and quantity)
- ***de***, of, from, by (denoting origin or starting point)
- ***el***,† out of, from among, extraction
- ***en***, in, into
- ***jen***, behold. *Jen estas*, here is, here are
- ***kun***, with, in company of (never indicating the instrument).
- ***per***, by, by means of, through, with (marking the instrument)
- ***por***,‡ for, in order to
- ***pri***, concerning, about, relating to, of
- ***pro***, on account of, for the sake of, owing to
- ***sen***, without
- ***sub***, under
- ***sur***, on, upon (actually touching)
- ***tra***, through

* This word is used instead of, and to distinguish it from, *de* in such cases as the following:

A plate of soup, *Telero da supo*, meaning a plateful of soup, and:

A plate for soup (soup plate), which is *Telero de* (or *por*) *supo*.

† Also, to do a thing thoroughly. Ex.: *Ellerni*, learn thoroughly.

‡ The mood of any verb which immediately follows *por* is always infinitive.

THE VERB (Past Tense)

The past tense is formed by the addition of *is* to the root word, and is the same for all persons, singular and plural. Examples:

The father birched the child, *La patro vergis la infanon*. The men accepted the papers, *La viroj akceptis la paperojn*.

VOCABULARY

afer', affair, matter	*hodiaŭ**, to-day
akv', water	*ir'*, go
aŭd', hear	*ĵaŭd'*, Thursday
amas', crowd	*kant'*, sing
arb', tree	*koncert'*, concert
bezon', need, want	*leon'*, lion
blov', blow (*v.*)	*lund'*, Monday
botel', bottle	*mastro*, master
bol', boil (*v.n.*)	*mard'*, Tuesday
bru', noise	*merkred'*, Wednesday
ĉambr', room, chamber	*muzik'*, music
ĉeriz', cherry	*nokt'*, night
danc', dance	*parol'*, speak
demand', ask, question	*pastr'*, priest
dimanĉ', Sunday	*pet'*, ask for, beg
far', make, do	*popol'*, people
fil', son	*rest'*, remain, stay
frat', brother	*strat'*, street
funt', pound	*sabat'*, Saturday
ĝarden', garden	*semajn'*, week
general', general (army)	*sinjor'*, sir, Mr., gentleman
ĝu', enjoy	*soldat'*, soldier
glas', glass (wine, etc.)	*teatr'*, theatre
*hieraŭ**, yesterday	*tag'*, day
	vend', sell
	vendred', Friday
	vent', wind(s)
	vin', wine

EXERCISE 2.

The soldiers went through the streets. Sunday, Monday, Tuesday, Wednesday, Thursday, Friday and Saturday are days of the week. In the night the son heard a noise. The water and the soup are boiling. The father spoke to the soldier about the matter. The children danced in the room, and the birds sang on the tree. The general had a bottle of wine, and asked for a glass of water. The cherries remained on the tree. On Friday and Saturday (the) father and (the) brother went to the theatre to hear the concert. Yesterday the priest bought a pound of cherries, and to-day the son of the general sold a bottle of wine to the cousin. Here is a pipe and the gazette. Here are some cherries and a water-glass. The lion has teeth. The water remained on the table in the room. Here is a crowd of men in (on) the street. The gentleman and the master heard the noise and spoke to the priest about the affair. The son saw the brother at the theatre. At the concert the gentleman sang and the people enjoyed the music. The bird went out through the window. In his (the) hand the soldier had a stick.

PRONOUNS

The PERSONAL PRONOUNS are:

Singular:

I	*mi*	she	*ŝi*
thou	*ci*	he	*li*
you	*vi*	it	*ĝi*

Plural:

we	*ni*	you	*vi*
They	*ili*		

There are also *si*, REFLEXIVE PRONOUN (used for all numbers and both sexes, in the third person only, and never as subject of a sentence), and *oni*, an indefinite pronoun, which represents it, they, people, one. It is the French *on*. All the above pronouns (with the possible exception of *oni*), like the noun when the direct object of a verb, take the accusative *n*, but naturally they cannot take the plural *j*. *Ci* is very rarely used, only being employed in translation, where fidelity to the original requires it. As will be seen above, *vi* is used in the second person both singular and plural. *Ĝi* is used in speaking of inanimate objects, or to indicate animals, and even children, when the sex is not particularly

to be distinguished. *Si*, the reflexive pronoun, is something new to the English learner, and its functions must be carefully noted. It stands for the English words self and selves, as in himself, herself, itself, themselves, and is employed when the idea expressed by the verb in the sentence refers to the subject. Examples:

He spoke to himself, *Li parolis al si* (not *li*). The father and the brother bought wine for themselves, *La patro kaj la frato aĉetis vinon por si*. She washes herself, *Ŝi lavas sin* (not *ŝin*).

Emphasis may be given to the meaning by adding *mem*, and this word may be used after any of the personal pronouns. Examples:

I myself paid the man, *Mi mem pagis la viron*. They thanked themselves, *Ili dankis sin mem*.

The indefinite pronoun *oni* (third person) is used in a general sense when nobody in particular is spoken of, as:

It is said, They say, *Oni diras*.
I was told, *Oni diris al mi*.

AFFIXES

Besides the prepositions beforementioned, which are used as prefixes to form new words, there is an elaborate system of affixes, consisting of thirty-two words, which are prefixed or added to the regular roots. It is of the first importance for learners to be fully acquainted with the meaning and value of these particles, as they form a stock of separate words which will not be given in the attached vocabularies. By their aid it is possible to form an indefinite number of cognate words which express every possible shade of thought, without obliging the student to learn distinct words for each object or idea. The vocabularies will be searched in vain for such words as small, bad, woman, chicken, forest, as these are constructed by means of affixes from the words large, good, man, cock, tree. From the single word *san'*, meaning health, fifty perfect words can be formed, thus demonstrating the possibility of acquiring words without unnecessary labour.

Prefixes. *Mal* denotes the direct opposite of any idea (not simply its negative). Example: *Admiri*, admire; *maladmiri*, detest. *Bono*, good; *malbono*, evil.

Bo denotes a relation by marriage. Example: *Patro*, father; *bopatro*, father-in-law. *Frato*, brother; *bofrato*, brother-in-law.

Dis denotes separation. Example: *Ĵeti*, to throw; *disĵeti*, to scatter. *Ŝiri*, to tear; *disŝiri*, to tear to pieces.

VOCABULARY

adiaŭ, good-bye, adieu
alumet', lucifer
amik', friend
aparten', belong
barb', beard
bier', beer
blek', cry (of animals)
cigar', cigar
cit', cite, mention
ĉes', cease, stop
ĉeval', horse
decid', decide
dev', be obliged (to)
don', give
dub', doubt
entrepren', undertake
esting', extinguish
faj', fire
famili', family
gas', gas
gorĝ', throat
grup', group
har', hair (*sing.*)
hejm', home
help', help
hom', man, human being
horloĝ', clock
hund', dog
jes, yes
kaf', coffee
*kon'** know
kor', heart
loĝ, live, lodge
pov', able to
propon', propose, offer
sem', sow
sci' † know
skatol', box
ŝip', ship
ŝton', stone
te', tea
ven', come
vintr', winter
viv', live
vol', willing to
vort', word
voj', way, road
vund', wound

* *Kon'* means to be personally acquainted with, to understand the nature of, to know of, to know who such a person is, or what such a thing is.

† *Sci'* means to know, to perceive with the mind, never to know a person.

EXERCISE 3.

I want (beg) a glass of beer and a pipe. You must extinguish the fire and the lamp. I heard the neigh of the horse and the bleat of the sheep. He was doubtful about the affair. Father-in-law. Brother-in-law. The ox belongs to her. I can sing and dance. Yes, sir, I have a cigar and matches. He himself was in the garden. She helped me, and I thanked her for the offer. They gave me the book, and I tore it up. He has a friend, and she has an enemy. They want to hinder you. In the winter I live in the house and work. She decided to buy the clock. You mentioned the matter to me. Man has hair(s), throat, hands, and a heart. The fire is burning. You made me an offer, and I accepted it. The matches in the box belong to us. I know you, and you know me. To-day is Wednesday and yesterday was Tuesday. The son-in-law remains in the street with the cousin. In the night the wind blew. The lion wounded itself; it roared and made a noise. Good-bye, friend, I want to thank you for the help.

ADJECTIVES

The adjective is formed by the addition of *a* to the root word, and always agrees in number and case with the noun which it qualifies. Examples:

Nom. sing.: *Forta viro eniris*, A strong man entered;
,, plur.: *Fortaj viroj eniris*, Strong men entered.
Obj. sing.: *Mi vidis fortan viron*, I saw a strong man;
,, plur.: *Mi vidis fortajn virojn*, I saw (some) strong men.

Adjectives used predicatively always agree in number with the noun, but are always in the nominative case. Examples:

La viro estas forta, The man was strong.
La viroj estas fortaj, The men were strong.
Li trovis la teon bona, He found the tea (to be) good.

In the latter example there is a supplemental predication which is shown by the easy intermission of the auxiliary infinitive, and, as before-mentioned, the accusative can never follow any form of the auxiliary verb *esti*.

KEY TO EXERCISE 1.

Onklo, ŝafo (or ŝafoj), la bastono, la fenestroj, skribi, danki, puni, tondi, vidi. La kuzo laboras. La edzo skribas. La ŝafo staras. Onklo punas. La ŝafoj kuras. La edzoj aĉetas gazetojn. Patro admiras la aglon. La infano tondas la paperon. La aglo estas birdo. Onklo havas seĝon, tablon, kaj bastonon. Ŝafoj kaj bovoj estas bestoj. La patro fermas la fenestrojn. La edzo havas ĉapelon kaj la ŝafoj havas vostojn. La aglo vidas la infanojn. La infano dankas la patron. La viro aĉetis tablon kaj seĝojn. La viro akceptas la ĉapelon.

MODERN COMMERCE

From the Painting by FRANK BRANGWYN, A.R.A., in the Royal Exchange

This picture is a companion picture to "Phœnicians Trading with the Early Britons on the Coast of Cornwall," by Lord Leighton, which is the Frontispiece to Volume I. of the SELF EDUCATOR.

PRODUCTS OF THE FOREST

Temperate and Tropical Timber. Turpentine. Tar. Rubber. Tree Oils. Ground Nuts. Tropical Gums and Resins

Continued from page 4520

By Dr. A. J. HERBERTSON, M.A., and F. D. HERBERTSON, B.A.

IN a limited space it is impossible even to enumerate the commodities of which civilised man makes use. The depths of the sea and the bowels of the earth are ransacked for their treasures. In the plant world, root, stem, sap, bark, leaf, bud, flower, and fruit are all utilised. The very parasites of the tree are sometimes pressed into service. In the animal world there is hardly a creature or an organ for which some use is not found. Meat, blood, intestines, bones, sinews, horns, hoofs, hides, and furs, all have their purpose to serve. If the bounty of Nature is almost inexhaustible, the ingenuity of man is hardly less so.

The Products of the Forest. Two regions of the world are densely forested, the temperate lands, and the tropical regions near the equator. The products of the two are very different.

In the north temperate belt of the Old World forests cover Sweden and Russia and stretch eastwards across Siberia. In the corresponding regions of the New World are the dense forests of Eastern Canada and the Eastern United States. These forests are *coniferous* in the northern and the higher parts, and *deciduous* in the southern and the lower parts.

The chief products of the temperate forests are timber, lumber, turpentine, pitch or tar, and resins and gums.

Timber. Timber is the oldest and most widely distributed building material in the world, as well as the most universal fuel. Its other uses are innumerable, from the great cargo ships of trading nations down to the nicely adjusted handles of an infinite variety of tools. Next to the food-stuffs, timber is, perhaps, the most indispensable of materials.

No natural product has been used more recklessly. Before the introduction of coal, enormous quantities were used, not merely as domestic fuel, but for such purposes as smelting metals. The Weald of Southern England is one of many districts thus deforested. This method of smelting is still practised in forest districts of Russia and Sweden. In regions as far apart as Mexico and Amuria wood is the fuel employed both for railway and steamboat traffic. Still greater is the amount of valuable timber which has been wantonly destroyed in clearing land for cultivation. Forest fires annually destroy vast quantities both in Canada and the United States. The demand for timber is steadily increasing all over the world, while the more accessible forests have been greatly reduced in area. Hence the price is steadily rising. The timber imported into Britain in 1905 was valued at over £27,000,000. [See the section on Forestry in APPLIED BOTANY.]

Timber, being bulky and heavy, can only be cheaply transported by water. Where the forested regions are mountainous, as is often the case, timber can be cheaply floated down stream to the sea. Much timber is sawn by water power, and transported in that form. Much is reduced to wood pulp, of which paper is made.

Lumber. Lumber is sawn timber. The value depends largely on the absence of knots, to avoid which the tree must be prevented from branching as long as possible. [See MATERIALS AND STRUCTURES, page 57.] Pine forests require a century to mature, but a solitary pine only half that time. The Scotch pine, one of the most valuable European timber trees, may live 400 years. Oak forests mature still more slowly.

The timber exported from the Baltic ports is the red wood of the Scotch fir, and the white wood of the spruce fir. Both are used for roofing, flooring, street paving, etc., the latter in the cheaper lines. The Weymouth, or yellow pine—the white pine of the United States—is commercially the most valuable tree of Canada and the Eastern United States. It is very free from resin. The pitch pine, ranging farther south, is heavy resinous, and harder to work. It is extensively used on both sides of the Atlantic. The giant pines of the Pacific seaboard yield timber for masts, etc. The deodar, or Indian cedar, is abundant in the Himalayan forests, and much used in Northern India.

Of deciduous trees, or hardwoods, the strongest and most durable is oak, but it is too expensive unless durability is of prime importance, as in shipbuilding. Unfortunately it rusts iron. Elm, ash, beech, the tough American hickory, and the decorative walnut and maple are the other leading hardwoods.

Turpentine, Pitch and Tar. Many conifers yield a resinous sap. The resin of the New Zealand kauri pine is used for the finest varnishes. Much of it is dug out of the ground on the site of former forests. [See page 1034.]

Turpentine, largely used to dilute paints and varnishes, is distilled from the resinous sap of the pine, particularly from that of the long-leaf or Georgia pine. The forests of Georgia and the Atlantic coastal plain generally yield most of the world's supply of turpentine through the ports of Savannah and Brunswick. The tree is cut near the base, allowing the sap to exude and harden into crude turpentine, from which commercial turpentine is distilled. The residuum forms resin, or rosin, used in making varnish, paper, soap, and sealing wax.

Little turpentine is made in the forest countries of Europe, which supply pitch and tar [see page 1163], obtained from the sap by different processes. In Russia tar is made by allowing wood to smoulder under a covering of turf or earth which excludes the air. Improved methods have been devised by which charcoal can be made at the same time. Creosote, a powerful preservative, is made from tar.

Other Temperate Forest Produce. Oak bark is less used than formerly for tanning; larch bark, hemlock spruce bark (U.S.A., Canada), wattle bark (Australia) and Natal bark being common substitutes. Valonia, the acorn cups of an oak grown in the Levant and exported through Smyrna, are used both for tanning and dyeing. An evergreen oak, found in Spain, Portugal and round the Mediterranean generally, supplies cork.

Tropical Forest Produce. The wealth of the tropical forest, of which only a fraction is yet utilised, far exceeds that of the temperate forest. Many trees yield timber of great strength, while that of others is of exquisite beauty. Teak, with the strength of oak, is largely used for backing the armour plates of ships because it protects iron from rust. It grows in Eastern Asia, Java, and other parts of the East Indies. The British supply is from the carefully regulated forests of Upper Burma. Two gigantic species of Australian eucalyptus supply the hard jarrah and karri wood. The former resists sea water, and is used for piles and the foundations of piers, docks, etc., as well as for railway sleepers, and for street paving.

The forests of the West Indies and Central America supply many ornamental woods, the best known of which is mahogany. Rosewood, another familiar cabinet wood, comes from Brazil. Both are used principally for veneering, a thin layer of the expensive ornamental wood being applied to a cheaper frame. Ebony is the heartwood of a tree found in Ceylon and the East Indies. Boxwood, another Indian tree, which also grows round the Mediterranean, is hard and very fine in grain, and is much used by engravers. The fragrant sandalwood is abundant in the East Indies and New Guinea. Another important group of tropical forest trees are the dyewoods. Logwood, which yields a range of blue and brown dyes, grows in Yucatan and Central America, including British Honduras. Some fine dyewoods are also obtained from the forests of West Africa. Cutch is the juice of an acacia, exported as a dyestuff from Burma and the Straits Settlements. Gambier, a dyestuff obtained from the young leaves of a climbing plant, also comes from the Straits Settlements.

Rubber. Of the tropical trees secreting valuable juices the most important are the rubber-yielding plants, which belong to many different species [see page 808]. The finest rubber comes from South America. Some of its uses were known at the time of the European conquest, but it was of little commercial value till the discovery of *vulcanisation*, which hardens rubber without destroying its elasticity. This is effected by adding sulphur, in quantities varying with the degree of hardness required. The addition of about 50 per cent. of sulphur forms the hard, black substance known as ebonite. Vulcanised rubber is used for innumerable purposes, one of the most important of which is the making of pneumatic tyres.

The finest rubber is the Para rubber, or *Hevea brasiliensis*, from the Amazon Valley, shipped from Para, Manaos, and other ports of the Amazon. Inferior rubbers, from other species, are exported from Ceara and Pernambuco. The rubber exported from Brazil in 1904 exceeded £11,000,000 in value. Many tropical trees of the Old World also yield rubber. In 1904 the Congo Free State exported it to the value of nearly £2,000,000.

The demand for rubber is increasing more rapidly than the supply. Increasing quantities will be obtained from Nigeria, Assam, and Borneo, but less wasteful methods of collection must be adopted, and attention devoted to forming rubber plantations.

Gutta-percha, from the *Dichopsis gutta* and other plants, resembles rubber, and is also capable of vulcanisation. It is obtained from the Malay Peninsula, Sumatra, and Borneo, through Singapore. Its chief use is for coating telegraph wires, especially in submarine cables.

Tree Oils. Many tropical trees yield useful oils. [See page 1032.] The fruit of the oil palm, when crushed, yields palm oil, used in making soap and candles. The coconut palm is a widely-distributed tree which prefers the neighbourhood of the sea. Its seeds are enclosed in a thick husk, and are carried by ocean currents from shore to shore. The oil yielded by the kernel is used in tropical countries for food and many other purposes, and commercially for making stearine candles and soaps, which lather in sea water. The dried kernel forms copra, 100 lb. of which yield about five gallons of oil. Eucalyptus oil is distilled from the leaves of the Australian eucalyptus. Castor oil is obtained from a plant native to India, but cultivated round the Mediterranean and in America. It is used medicinally, but in India also for lighting and lubricating. The finest is "cold-drawn"—that is, obtained by crushing the seeds without heat.

Ground Nuts. Ground nuts are the pods of a leguminous plant, so-called because they bury themselves in the ground to ripen. They are chiefly exported from West Africa, but are also grown in Southern Europe, India, South America, and the Southern United States, where they are called peanuts. The oil can be used as salad oil, and the residuum as a feeding stuff for cattle.

Gums and Resins. The tropical gums and resins include dammar, obtained from a coniferous tree of the East Indies. Copal grows in tropical Africa, especially in Portuguese West Africa, in India, the East and West Indies, and South America. Dragon's blood is a reddish resin from Sumatra. Frankincense, or *olibanum*, is obtained from Southern Arabia and India. Gum arabic is secreted by various acacia trees which flourish chiefly in the Sudan.

PRACTICAL POULTRY BREEDING

Breeding for Utility rather than Ornament. The Chief Varieties Enumerated. Points of Good Table Birds. Feeding for the Table

Continued from page 4576

By Professor JAMES LONG

THE poultry industry has made great strides during the past ten years. During the previous thirty to forty years Englishmen devoted little attention to the economical side of poultry breeding.

The Fascination of Poultry. The number and beauty of the varieties appealed to thousands of persons, who became fascinated with their plumage, their form, and their colours, and who devoted their efforts to the perfecting of those fancy points which form the basis of the awards of judges. Wonderful skill has, in consequence, been developed and exercised, and it is entirely owing to the art of the breeder that the most perfect varieties of to-day owe their brilliant colours, their mathematical marking, and the symmetry of their combs, ear lobes, and general form.

The principle, however, which is necessarily adopted in the selection of the fittest for reproductive purposes on these lines is entirely opposed to the improvement of economical properties of poultry. Instead of developing the breast and the merry-thought from the point of view of an increase in the quantity and quality of the meat, and instead, too, of increasing the laying powers of the hens by breeding from the best layers, the amateur made a point of selecting his breeding stock wholly and solely on the basis of those qualifications which appeal to the eye, and which are alone calculated to secure prizes in competition. We must, however, in discussing this subject, take things as we find them, and our descriptions of the pure breeds will, therefore, be based upon the existing standards of the most perfect exhibition birds of each breed, a few of which may still be regarded as utilitarian, and if not precisely all they should be, still deserving employment in the practice of breeding for economical purposes.

The Two Main Classes. We may divide the pure breeds of poultry into two classes—those which are useful, whether also ornamental or not, and those which are essentially ornamental, their utility being so comparatively small that they are not worth the attention of those connected with the genuine industry. It will be noticed that the hens of the utility breeds are usually sitters, although in many cases they are layers of an inferior order; also that they are comparatively large in size, whereas the hens of the ornamental breeds are as a rule non-sitters, smaller in size, and, in some cases, layers of a larger number of eggs. Where the non-sitting and the sitting varieties are crossed—and we apply the word *sitter* to the hen which hatches eggs—the females produced are usually sitters, although in many instances they are too sensitive and excitable to be generally entrusted with valuable eggs.

The varieties may be classified as in this table.

THE UTILITY BREEDS OF POULTRY.

	Name.	Sitter or Non-sitter.	Average Weight of Table Cockerel.	Average Weight of Eggs (per doz.)	Average No. of Eggs per Annum.
			lb.	oz.	
	Dorking (4 varieties)	Sitters	8–9	27½	120
	Indian Game	"	7	24	100
	Old English Game (several varieties)	"	4½–5½	24	90
	Modern Game (many varieties)	"	6–7	24	85
	Plymouth Rock (3 var.)	"	7½	27	120
	Orpington (several vars.)	"	6½–7	27	120
	Wyandotte (ditto)	"	6–6½	25	120
French varieties.	La Flèche	Non-sitters	6½	30	120
	Creve Cœur	"	7	31	120
	Houdan	"	5½	26	125
	Bresse	"	5	33	155
	Faverolle	Sitters	6½	27	115
Mediterranean.	Spanish (2 varieties)	Non-sitters	5	30	75
	Minorca (2 varieties)	"	5½	28	130
	Andalusian	"	5½	28	130
	Leghorn (sevl. var.)	"	4½	23-27	140-160
	Ancona	"	4½	24	140
	Hamburgh (6 varieties)	"	4	17–19	170–200
	Red Cap	"	5½	20	170–200
Asiatics.	Brahma (2 varieties)	Sitters	8–9	28½	85
	Langshan	"	8	27	100
	Cochin (5 varieties)	"	8–9	25	80
	Scotch Grey	"	6½	29	120
	Campines (2 varieties)	Non sitters	4½	25	150
	Scotch Dumpies	Sitters	5	No data	100

THE ORNAMENTAL BREEDS OF POULTRY.

Name.	Sitter or Non-Sitter.	Average Weight of Cockerel.	Average Weight of Eggs per Dozen.	Average Number of Eggs per Annum.
		lb.	oz.	
Malay	Sitter	7	21	80
Aseel	"	5	No data	No data
Polish (six varieties)	Non-sitters	5 to 6	23	"
Sultan	"	3	16	
Silkies	Sitters	3	15	50
Frizzle	"	4	Small	No data

Among other ornamental varieties, of which no reliable data exist as regards weight and egg production, are Yokohamas, Rumpless, Naked Necks, and the following varieties of Bantam: Game (in several sub-varieties), Black Rose Game, White Rose Game, Gold and Silver Sebrights, Japanese, Pekins, Brahmas, Booted, Scotch Greys, Nankins, Malays, and Spanish.

The Mediterranean breeds, of which a Leghorn is figured in 1, the Hamburghs [2], Red Caps, Campines, and most of the French breeds lay white eggs. The Asiatics, Orpingtons,

Plymouth Rocks, and Scotch Greys, buff eggs; while the Wyandottes and Game fowls, as a group, lay eggs slightly tinted or creamy. The Mediterranean fowls are all inferior table birds; the Asiatic, Langshans excepted, though larger and carrying more flesh, produce meat of secondrate quality; while the best table fowls include the Dorkings [3], the Game varieties, and the French breeds, which are followed by the Langshans, the Orpingtons, the Scotch Greys, Wyandottes, and Plymouth Rocks. The five last-named may be termed the general purpose varieties.

It should be pointed out that the weights of the cockerels represent young birds of sixteen to twenty weeks fit for the table but not fatted or crammed, and that the average number of eggs indicates, not what is possible, or what has been accomplished in public competition, but what is produced in the ordinary poultry-yard.

Eggs. Whoever keeps poultry for utility purposes will not find the Bantams of any value whatever, and the remark applies equally to a number of the larger varieties, and especially to the six named in the Table of Ornamental Breeds. The best layers will usually be found among the modern productions, such as the Wyandotte [4], the Orpington, and the Langshan. The older varieties, however, may be so stimulated by crossing or by the infusion of alien blood from time to time that their laying powers may be revived, and, indeed, brought to the level of the best producers. As a group the nonsitters are the most frequent layers, but with few exceptions their eggs are small. This fault may be remedied in the ordinary process of selection, under which the birds will be increased in size.

1. BROWN LEGHORN

We may take it, too, as an axiom that a bird of a small breed lays a small egg, and the contrary obtains in the case of the large breeds, although this is not an infallible rule. The breeder, however, for productive purposes should make it an invariable practice to select large hens, inasmuch as the usual result is a larger egg and consequently a larger chicken.

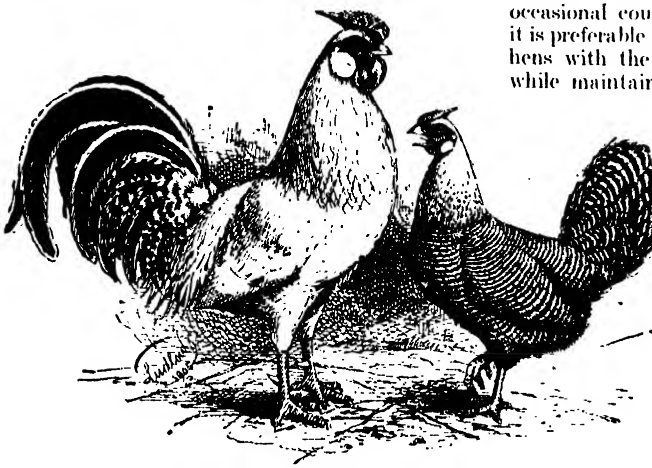
Fowls for the Table. Although many of our remarks apply to poultry of all descriptions—that is to say, to all varieties of birds bred for the purpose of exhibition, as well as to those bred for domestic use or for the market—this course is intended to be chiefly of service to those whose business is the production of poultry for the market. The poultry dealer, curious though the fact may be, is not at all disinclined to set the fashion in respect of the points of the birds which he sells in the course of his business. He is willing to accept birds of first-class quality, and, what is more, to pay good prices for them, so long as they satisfy his customers.

The Points of the Table Breeds. The chief points of a table fowl are size without correspondingly coarse bone, light-coloured skin, abundance of meat upon the breast, the merrythought, and the wing, well-fleshed and tender thighs, and a small proportion of offal; in a word, the natural requirements of the buyer are a maximum quantity of white tender meat and a minimum quantity of waste. If two specimens, one of a good table variety, such as the Indian Game [5], and another of an inferior table breed such as the Minorca, are selected as nearly as possible of the same weight, and the whole of the meat removed as in the process of boning; and if this meat, on the one hand, and the waste, which includes the bone and all that is inedible, on the other, are weighed, a remarkable difference will be shown on comparison, and the amateur will acquire some very definite idea of the relative merits of the table and the non-table breeds.

Again, if we select an imported Russian chicken, which in the spring may frequently be purchased in the retail shops of London suburbs for 1s. 6d., and make it one of a couple by adding an English-bred chicken of first-class quality, we shall find that when both are cooked and placed upon the table the contrast in the quality as well as in the quantity of the meat is very marked. What it is possible to obtain by skilful breeding and feeding may be ascertained by visiting a first-class Bond Street poulterer's shop, and examining the chickens and capons in the early season, when, as we have seen, they realise as much as half a guinea each. Still better shall we realise the remarkable character of the modern industry by a visit to the exhibitions at the Smithfield and National Dairy Shows, at the Agricultural Hall at Islington, in December and October respectively. At these meetings excessive fatness obtained by the process of cramming is allied to quality and quantity of meat.

The Best Meat Producer. The most fashionable birds for the table as we write are those which are the produce of a cross between the Dark Dorking [3], the largest of the Dorking varieties, and the Indian Game, the male bird of the latter being mated with the hens of the former breed. The chickens which are the produce of this cross are precocious in growth, heavily fleshed, producing meat of the finest quality, and laying on fat when they are crammed for the purpose. If the Indian Game cock be mated with Cochin hens, which closely resemble

Dorking hens in size, although the result is a great improvement upon the pure Cochin, the inferiority of the produce as compared with the Indian Game-Dorking is marked. The excessive quantity of offal and the compara-



2. SILVER PENCILLED

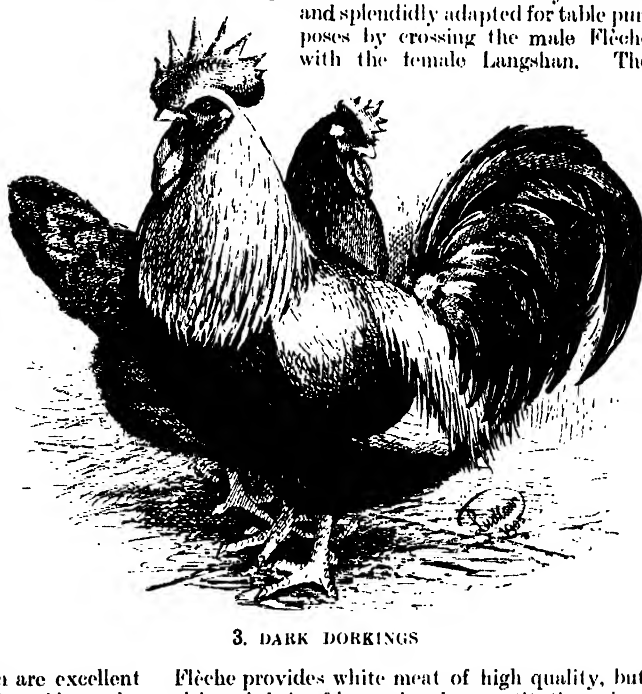
tively small quantity of meat carried by so large a fowl entirely rules the Cochin breed out of the category of table poultry.

How Breeds are Improved. In crossing two varieties, the one naturally supplies in its progeny the deficiency of the other, and we obtain a combination of properties which, if the mating has been wise, is an advance upon those inherent in the inferior breed. In practically all cases crossing improves the constitution and stamina; the chickens are more precocious, more active, and more thrifty, while they display a greater aptitude to lay on flesh and to be ready for market at an earlier period.

It is on almost all occasions advisable in crossing two varieties to select the hens of the larger breed, especially if the eggs are also larger, for the size of the chicken is usually controlled by the size of the egg. Judicious crossing, too, should result in the production of meat of better quality as well as of larger quantity. We have referred to the crossing of the Cochin; the Brahma, also an Asiatic breed, may be taken as an example in another direction. This variety is an inferior table fowl, but mated with the Dorking it produces large robust chickens which are excellent layers and sitters, and which on the table are by no means to be despised.

Plumage and Exhibition Fowls. But, it may be asked, if the Dorking be so superior to the Brahma, why make a cross at all? The answer is obvious, and it applies to many other varieties. Poultry keepers have their fancies, and there are many who keep Brahmas as a hobby, and for purposes of exhibition, but who, nevertheless, require an occasional couple for the table. In such a case it is preferable to mate a separate pen of Brahma hens with the Dorking cock, and in this way, while maintaining the yard of Brahmas practically intact, to secure chickens which will prove much more satisfactory from the economical side. If there be an objection to this plan, two or three Dorking hens may be placed with a breeding pen of Brahmas, their eggs, which are easily recognised owing to the difference in colour, hatched, and the chickens reared with the rest, and killed for the table when mature enough.

Uniformity. There are other cases in which poultry keepers, while not necessarily fanciers of any particular variety of pure-bred poultry, prefer to have something like uniformity of colour and plumage in their flocks. There are some who fancy white plumage; others, in towns and the suburbs of towns, who prefer black. A yard of excellent black-plumaged birds may be maintained consistently uniform and splendidly adapted for table purposes by crossing the male Flèche with the female Langshan. The



3. DARK DORKINGS

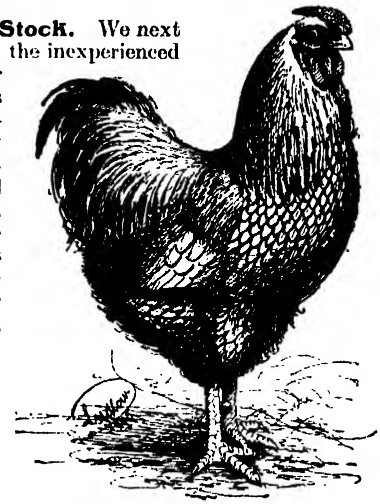
Flèche provides white meat of high quality, but although it is of large size, its constitution when highly bred is somewhat fragile. Crossing, however, with the Langshan results in the production of strong chickens which are large, precocious, rapid growers, producers of large eggs and of

plenty of fine meat on the best parts of the carcase. The birds are handsome, square, hardy, and generally useful. After all, however, has been said, there is no single breed which eclipses the Dorking, either as a table fowl or as a sitter and mother, but the variety is not among the best of layers.

Production of Young Stock. We next come to some questions which the inexperienced breeder must carefully consider in making and conducting his arrangements for the production of young stock. It will usually be found advantageous to mate two-year-old hens with a cockerel bred in the previous year, but where early chickens are essential this may be impossible owing to the fact that adult hens seldom lay in January or even February; thus the breeder is driven to employ pullets of the previous year's hatching in order to obtain what he requires.

It is wise to keep the sexes entirely apart until they are mated. The male birds will be fresher and lustier, while any possible influence which may follow the union of the hens with any other male birds, which might occur should they be at liberty, will be prevented. The number of hens which should be mated to a cock is also a matter deserving some consideration. Where all the birds are free and roam at large, as in a farmyard, one, two, or three males may be found sufficient for a large number, but where they are practically confined to a breeding pen some restriction must be placed upon the number of hens allotted. In the early months of the year the number should be smaller than in later months, as in spring, which is the natural breeding season. A larger number of hens may be placed with a cockerel than with a cock, while as the heavier and coarser breeds are not so prolific as the lighter varieties, fewer hens are usually mated with a single male. Again, it is unwise to mate an active male with too few hens, since their plumage may be spoiled. In the early season six hens may be regarded as sufficient, while a little later two or three may be added, and later still, with vigorous birds of the previous year, the number may be increased to ten or twelve.

Feeding Poultry. It is important, too, that attention should be paid to the feeding.



4. LACED WYANDOTTE

5. INDIAN GAME

If food be supplied in abundance, the hens are certain to obtain all they require, possibly more, and thus over-feeding must be guarded against, as that may interfere with prolific laying. It frequently happens, however, that the male birds will not feed sufficiently well, and when this is the case care should be taken to supply them not only with the grain they require but with occasional morsels of meat, which they cannot pass on to their wives, in order that they may be kept in sufficiently robust condition. High feeding is conducive to early laying and to the production of a larger number of eggs. This, therefore, should be arranged for both sexes, especially for mature hens, but instead of supplying red meat it will be found much more advantageous to provide white meat, which is less stimulating and equally nourishing, and this can be obtained by cleaning, cooking, and mincing the intestines of the sheep or the bullock.

In breeding for the table it is obvious that, on account of their larger size, as many cockerels should be produced as possible. There is no golden rule for the production of an excess of male chickens, but in practice it frequently happens that by mating a lusty cockerel—by which we mean a bird produced in the preceding year—to equally lusty hens which are a year older, and which practically have commenced their third season, success is achieved. It is not precisely known how long the influence of the male bird exists. We may, however, take it for granted that after a week has elapsed between the removal of one male and the introduction of another, the eggs laid by the hens will have been fertilised by the new introduction.

If a pen of birds be too small—namely, if the hens be too few in number—some common hens may be added to bring it up to a normal proportion; but in this case, in order that the eggs may not be mixed and common chickens unnecessarily reared, it will be well that the new-comers should be such as lay eggs of a different colour, or, if this be impossible, that the chickens which are hatched from them should be easily distinguished when they are hatched.

THE FAMILY AND THE RACE

Marriage Provides the Conditions for the Ideal Family. The Family is the Strength of the Race. Parental and Filial Responsibility

Continued from page 4539

By Dr. C. W. SALEEBY

IT is impossible to consider the subject of marriage and to ignore altogether the extremely important question of divorce. Again we make the observation that, from a purely sociological point of view, divorce in the case of a childless marriage is no more important than such a marriage itself. From the impartial standpoint of our science we are concerned merely with divorce in cases of fertile marriage. It is impossible here to summarise, even briefly, the various laws and customs of divorce which historians of the subject recognise. So far as English-speaking people are concerned, the subject is exhaustively discussed in Professor Howard's great book, which is the standard work on the subject.

The Extremes of Marriage. Let us briefly observe, however, the sociological significance of the extremes of practice in this matter. The one extreme is that which the Roman Catholic Church illustrates, the non-recognition of all divorce. At the other extreme, disgracefully illustrated in some parts of America to-day, we have a facility of divorce so great that marriage really ceases to be marriage at all. It is, indeed, no better than "leasehold marriage," into which the parties may enter with a mutual understanding that it is to be terminated at their convenience. Such marriages, it is true, are very frequently childless, and this fact renders them less objectionable to the sociologist than they would otherwise be. Where they are not childless it is evident that such practices strike a mortal blow at the family, and if they were the general rule of any community, as they are not, that community would certainly soon disappear.

As regards the absolute denial of all divorce, it must be remembered that the sociologist, as a sociologist, entertains an entirely different conception of marriage from that held by the Church. If the Church regards marriage as a sacrament of its own institution, the Church is clearly entitled to judge of its conditions. It has more than this life to think of. The sociologist, however, is entitled to his own opinion upon what he conceives to be a purely secular and social institution, and no scientific sociologist will be found who does not admit the propriety both of divorce and of remarriage, under certain conditions.

The Obligation of Parentage. Comparative students of marriage law are sometimes of opinion that English divorce law is as nearly satisfactory as can be, though we must remember that it is still disfigured by injustice in its comparative treatment of the two sexes. It is unquestionably true that laws of divorce are open to abuse, and have at all times been more or less abused. It is also true that the distinction which the sociologist draws between divorce in cases of childless marriage and in cases of fertile marriage would, perhaps, if legally recognised, tend still further to lower the birth-rate. What is commonly forgotten, however, by those observers who are not acquainted with the fundamental facts of biology is that the process of natural selection or survival of the fittest retains its automatic and ceaseless control over human affairs. Not merely is abuse of the divorce law confined to the few, the great mass of the people being of a moral habit in these respects, but also these few who are cast up by each generation tend constantly towards their own extinction. One of the conditions for the survival of any breed or stock in society is evidently the willingness to undertake the obligations of parentage under the normal conditions of family life. Those individuals who do not comply with this condition are of no further account to the sociologist after their individual lives are ended, and he is the less likely to waste his time in useless reprobation of them if he remembers that their faults provide their own doom, and that, though persons of such a kind have always been produced in all generations and in all civilisations, they are not capable of arresting the progress of the race. This is yet another instance of the beneficent working of that law of the survival of the fittest which, in many of its applications, seems at first sight to be cruel and maleficent.

Marriage is a Means, not an End. We have again and again insisted that our interest in marriage is in marriage as a means and not as an end. Thus we have found the ultimate sanction for the form of marriage practised among ourselves in the fact that it provides the conditions for the ideal family. Now, it is the profound conviction of the sociologist that the poets and the moralists are right in teaching that family life is the first condition for the welfare of any society, and we must discuss this question all the more closely and completely because of the tendency, extremely conspicuous among ourselves, towards *the disintegration of the family.*

Sir Henry Maine, a famous pioneer of historical sociology, laid down the generalisation that "the unit of an ancient society was the family, and of a modern society is the individual." It is a definite tendency of civilisation, as it becomes more complex, to supersede family relations in large measure by external relations, which often take the form, for instance, of direct relations to the State. Not only the complexity of social relations in our own time, but many other causes tend towards the weakening of the family

organism. Conspicuous among these is our modern facility of locomotion. Yet another is the radically vicious custom of married women's labour. Another, in such a country as Germany, is conscription; and yet another in all civilised countries is the interference of the State in education. To these questions we must return, but first of all let us consider the historical reason why the individual rather than the family has come to be the unit of modern society.

War is the Enemy of the Family. A fundamental truth, the consequences of which are amazingly forgotten by some, is that there are more human beings on this planet to-day than there ever were at any period in the past, and there will be still more to-morrow. This great fact of *the constant multiplication of man* has to be reckoned with as perhaps the most potent force in history. If, then, we turn our eyes back to a time when societies were small in proportion to the land which they occupied, and when each society was complete in itself—a period this which is all but prehistoric, though, of course, there are more recent exceptional instances of such a state—we shall realise what the struggle between societies involved for family life. Time was when the son's duty to his father and mother *was* his duty to his society. In obeying them, in learning his father's trade, and in at last supporting his aged parents, he was doing his duty to his society as a whole. There was no conflict of duty. But there began as a general phenomenon of human life the history of that appalling thing which we call war, which we must afterwards study. It is not, at present, our business to ask whether war was or was not inevitable at a certain stage in human history; whether it has not even played a part in progress. Here we are concerned merely to observe that when the state of struggle between societies came to be a normal condition of human life, constantly and everywhere, a great blow was struck at the ancient conception of the family.

Militarism is on its Last Legs. In the first place, there came to be a still more disproportionate appraisement of the relative worth of the two sexes. The little girl-baby could only grow up to be a weak woman, but the little boy-baby would grow up to be a soldier. In the second place, there came to be a conflict of duty. Family life might demand of a son that he should work for his father or help to support his aged mother, but the State demanded that he should go forth to fight. In countries where there is conscription the same opposition still manifests itself—conscription, of course, being nothing more than a modern survival from past times, when every able-bodied man was of chief interest to the State because he was capable of being made into a soldier. Thus we may lay down the general proposition that *militarism and family life are eternally opposed*, and that the modern disintegration of the family has chiefly depended upon the development of military struggle between societies; this, in turn, being mainly dependent upon the fundamental fact of the ceaseless multiplication of man. Militarism, however, despite War-lords and Jingoes, is on its last legs—a fact which the biologist explains in his own language, as we shall see. The struggle between societies persists, as does struggle between individuals, but just as this latter is no longer a struggle of muscle against muscle but of mind against mind, so also the physical struggle called *war* is becoming exceptional, while the main field of battle has been transferred to the psychical plane. Thus the chief historical foe of the family life is nearing its end.

But the reader will ask whether the subordination of the family interest to the State, as classically illustrated by the Spartan mother, who sent her son to battle telling him to return with his shield or upon it, has not justified itself by its results; whether, indeed, the subordination of the family is not, as some tell us, the sign of a progressive society?

Where is Sparta Now? But to this, in the opinion of the writer at any rate, a complete answer is possible. The reader must judge of its value for himself. We have already conceived of history as a series of great sociological experiments, and now we must ask ourselves whether these experiments with the family lead to any positive conclusions. The answer is that they do—for where is Sparta now? Where are the purely military nations? They cannot answer to their names, for they are no more. They sacrificed the fundamental social institution in the supposed interests of society, and the sacrifice involved the ultimate destruction of the society. The purely military nations have a brief record of success, and then their history is a permanent blank. So long as the capital of strength and virtue, which spring from family life, was not exhausted, these nations were successful, but permanent failure thereafter was the price they paid. On the other hand, there is one salient instance which proves up to the hilt, in our judgment, that the great social institution for which we have the warrant of biology must necessarily be upheld by any race that would achieve permanence.

The Secret of the Jews. There is perhaps only one such race in the whole of human history. The modern Greeks, as physical anthropology has shown, are the descendants of the ancient Greeks only in name. The same is true of the modern Egyptians and the modern Romans. One race, however, has persisted—and this despite a measure of continuous and extreme discouragement and persecution and repression to which history offers no parallel. Exiled from their native land; subject to continual massacre; scattered broadcast over the whole face of Europe; the object of repressive legislation for 2,000 years; compelled to live in insanitary cities, so that they have not had the advantage of recruits of peasant blood and peasant vigour; never distinguished in the arts of war—the Jews have nevertheless presented the unique phenomenon of a continuous history such as no other race has been able to achieve, even without the appalling disadvantages under which they have laboured.

Where are we to find the explanation of this fact? It is amongst the Jews that we find the ideal of family life, and this it is which has

nurtured their unconquerable strength. In the first place, they have a very high birth-rate, children being regarded as blessings from God. This high birth-rate they have always maintained; it makes for the production of that kind of family which the sociologist, always remembering that human nature is his key, regards with the greatest satisfaction—the younger children learning certain lessons from the older ones and the older children learning certain lessons by their contact with and duties to the younger ones.

The High Ideal of Parentage. Now, it is the rule that a high birth-rate is accompanied by a high infant mortality, but to this rule the Jews, like the present day Irish, have always offered an exception. This in both cases is directly due to the high ideal of parentage. The Jewish or Irish mother who will not nurse her own children, though she can, is practically unknown. After this early period the care of the children is maintained. Thus, comparative study of the Jewish and Gentile children, in the schools of Leeds, by Dr. William Hall, has lately proved that at all ages the Jewish children of both sexes have a very great advantage in height, in weight, and in physique, the difference being very similar to the difference between board-school boys and public-school boys of similar ages. But the explanation is not exactly the same, for the board-school boy profits not by any high ideal of the family in the class to which he belongs, but in virtue of his parents' means; whereas the Jewish children, despite their parents' poverty, profit by the assiduous care and self-sacrifice displayed by them. Just as a drunken Jew is practically unknown, so there is nothing among the poor Jewish families in any part of Europe which corresponds at all with the fact that one-sixth of the income of the working-class family in this country is spent upon alcohol. We submit, then, as a lesson of history, that the sociological value of the family as the necessary unit of any stable society or race is demonstrated in the amazing case of the Jews.

Science and the Fifth Commandment. It must be remembered that, for the sociologist, the family has two aspects of value. The first, and the most important, is that which is concerned with the upbringing of the children; but the other is expressed in the commandment, of such profound sociological importance, which the Jews have obeyed since it was given to them, "Honour thy Father and thy Mother." This, as has been said, is the "first commandment with promise," and the essence of the promise has been fulfilled. Part of the ideal of the family is that the parents, in their declining years, shall be supported by the children for whom, in time past, they have made so many sacrifices. This certainly is an arrangement to which we see no parallel in the case of sub-human nature, but it is as certainly part of the ideal of the human family, and makes very greatly for the stability and security of any society. We can hardly say that any one was ever encouraged to parentage by the thought that his children would afterwards become the staff of his old age, though it is an interesting fact that this argument has quite lately been employed by those who are alarmed at the declining birth-rate in this country. The neglect to obey this ancient commandment, gravely threatening as it does the ideal of the family, is of the greatest concern to the philosophic sociologist. Probably there is no other commandment so generally neglected by the mass of people at the present day.

The State and Filial Responsibility. Herbert Spencer regarded the care of the aged by the young, who owe them so much, as the most conspicuous instance in which our practical morality needs mending. The recent scientific study to which, as we have seen, social reformers are nowadays lending themselves, has thrown an extremely sinister light upon this very question. We are coming to see that under our modern social arrangements we are doing our utmost to diminish and destroy that sense of filial responsibility which is as valuable a social force to-day, even in our complex state of society, as it was at the foot of Sinai more than three thousand years ago. One or two contemporary facts bearing upon this point may be cited.

Many observers have lately shown that among the gravest defects of our system of outdoor relief, for which the responsible and valuable members of the community have to pay, is its encouragement of filial irresponsibility. A scandalous proportion of the whole sum spent upon outdoor relief is devoted to the maintenance of elderly persons who have children living and able to support them, but unwilling to do so. The legislator must reckon with human nature, and human nature being what it is, we cannot be surprised that a very large proportion of men, forgetful of the benefits they have received, will refrain from supporting their parents when they know that the State will do this for them.

A Lesson for England from Japan. A similar theoretical objection applies to any hasty and ill-considered scheme of old-age pensions. In considering such a scheme it is at least right that we should steadfastly hold before our minds *the ideal*—which unquestionably is that in the case of aged persons who have living children able to support them, the support should come from that source. And the further question must be asked, whether we are not weakening the sense of filial responsibility, and therefore complicating the problem of the aged, by all such measures as weaken *parental* responsibility, causing children to be cared for by others than their parents, and therefore diminishing those feelings of filial gratitude to which, in an ideal world, the aged parent would not have to look in vain?

In Japan, as in some other parts of the world, the ancient fear and worship of the spirits of the departed has gradually developed, as students of religion tell us, into a form of ancestor-worship that has many beautiful and moral features. Now, wherever we find such ancestor-worship we have to recognise its value for family life. It leads

to an extremely healthy reverence for the aged, and especially for parents. Practical proof of this is easily forthcoming. The population of Japan is much larger than that of Great Britain, but in that country there are yearly relieved only 30,000 paupers, as against very nearly a million amongst ourselves. But in Japan the young man puts aside, from his first wage-earning days, a small sum towards the future support of his aged parents. In a land of ancestor-worshippers this is recognised as the very first duty of every decent son, and the statistics of pauperism show the consequence. It was not of Japan but Great Britain that Herbert Spencer spoke when he said:

"The last to show itself, among the bonds which hold the family together—the care of parents by offspring—is the one which has most room for increase. With the strengthening of intellectual and moral sympathy, the latter days of life will be smoothed by a greater filial care, reciprocating the greater parental care bestowed in earlier life."

The Cradle of all the Virtues. That the phrase *parental responsibility* corresponds to a great reality no biologist or sociologist can question; but, unfortunately, it has been so greatly abused in recent times that it would almost be well if some new term could be invented. The value of parental responsibility has been quoted again and again by a certain school of thinkers as a sufficient reason for permitting children to starve. The argument apparently is that we are to punish and reform the careless parent in the hapless body of his child, though it would appear a reasonable argument that, just because he is a careless parent, this method is not likely to reform him. There is no sociological warrant for the argument that it is worth the while of any society to injure the rising generation in order to uphold the doctrine of parental responsibility. Unfortunately, it is arguments such as these that have cast the whole conception into discredit, and therewith the true conception of the family. Thus it is possible for the Countess of Warwick to refer to this conception as "some malignant eighteenth century theory," and to speak of "the fetish of parental responsibility," so that the truth which the phrase expresses has become discredited.

It is well, then, for us to realise that *the family* and *the home* necessarily depend for their integrity upon the realisation of the idea for which this phrase stands. No one would dare speak of "the fetish of the home"; the good sense of the people would not tolerate such a phrase. In serious argument with serious and intelligent people it is always possible to obtain a full and free admission of a plea for the family and home life as the cradle of all the social virtues and of worthy character.

Why the Well-to-do Classes are Disappearing. Once this is admitted, it does not require much reflection for anyone to see that the idea of parental responsibility is inextricably involved in any true conception of the family. Postponing for the moment that part of our argument in which finance is involved, and which therefore arouses our unscientific passions, let us first of all consider this question of parental responsibility as it practically affects the well-to-do classes. We shall find that there exist, and have long been patronised, various means by which the family and the home may be weakened and parental responsibility ignored, even in these classes of society. We may, or we may not, according to our judgment, correlate these facts with another fact of the most serious kind to every sociologist—namely, that society is an organism which recruits itself from below. The well-to-do classes constantly tend towards extinction, and are kept in existence only by constant reinforcement from the classes beneath them. This may or may not be a general law of all societies; it probably is. If, however, we believe in heredity, we cannot but deplore the working of any law which seems to select the fittest and most capable, the most original, industrious, and intelligent from the mass of the community and, after making them into a special class, leads to the extinction of the valuable stocks which they represent.

Neither the psychologist, the sociologist, nor the educationist can regard with satisfaction the institution which is known as the boarding school. It is, of course, an obvious necessity, though in the nature of a last resort, for orphans, children whose parents are compelled to live abroad, and those whose parents are themselves ignorant and undisciplined, and therefore incapable of teaching or training their children.

A Grave Indictment of the Boarding School. But in controversion of the general assumption that a boarding school is the proper place for all boys and girls whose parents have sufficient means we may quote two authoritative and recent opinions. The first is that of one of the greatest living students of the mind, in health and disease—Dr. T. S. Clouston, of Edinburgh:

"Unquestionably the ideal mode of education for both sexes, were all parents wise and firm and intelligent, and had they plenty of time and opportunity to devote to their children's upbringing, would be home life with day-school teaching. No one will convince me that the accumulated wisdom which the parents have acquired, and the family ties and amenities of home life are not the best educative influences. I have no doubt whatever that the general intelligence of the educated classes in England has suffered greatly through so many of its boys and girls having lived a monastic life away from home for most of their time. It is always to me pathetic to consider the way in which the boys at Rugby were influenced so much for good by Dr. Arnold, when I think that hundreds of those boys must have had parents at home almost as wise as Dr. Arnold, quite as good in the example of their lives, and far more interested in them. Education plus affection exhibited in daily life must surely be a better thing than education minus affection and minus intense personal interest. The widely held assumption of English parents that their duty has ceased, and that of the schoolmaster begins, when their children reach eight or nine years of age seems

to me an essentially selfish notion. It implies an incomplete conception of fatherhood and motherhood." ("The Hygiene of Mind," Methuen. 1906.)

Artificial Societies. More serious still, perhaps, because of the peculiar position of the author, is the following quotation in which Dr. Gray, the headmaster of Bradfield College, briefly and unanswerably condemns—though he remains himself quite unaware of the condemnation—the essential facts of boarding schools. "It must be remembered," he says:

"(1) That we have to deal with a society of immature minds and plastic morality;

"(2) That this society is *artificially* constituted—that is, it does not proceed on the lines of family relations, which Nature intended should be followed throughout life, but is isolated and 'monastic.'

"Here, then, at the most critical stage of a boy's life, at a time when, along with violent physical changes, the character is being formed with at least equally startling rapidity, when reason is often comparatively weak, and sentiment and emotion are always strong, a boy is taken away from the formative influences of the other sex, from the mother and sister, and thrust into a community composed of one sex only, where all do the same things, think the same thoughts, and talk round the same confined circle of subjects." ("Hibbert Journal." July, 1906.)

Unfortunately, a much graver indictment even than anything contained in the above quotation may be made against boarding schools, but that is not strictly relevant to sociology. It is worth briefly noting, however, that one of the cardinal objections to the boarding school, the unnatural isolation of the sexes, is removed by the practice of co-education, which, though it still seems startling and dangerous to us, has been found highly successful wherever it is practised, as, for instance, in the United States.

A Fatal Blow at Family Life. The decadence of parenthood, both of maternity and paternity, which is so conspicuous in the upper classes and of which their vanishing birth-rate is the most fatal indication, remained of relatively small importance so long as family life throve unvitiated in the most vital part of society—in those classes whose birth-rate is high, and from which the "higher" classes are ever reinforced. Fundamentally bad though the boarding school system may be, at least its influence was confined to a relatively small section of society. But there now arises the question whether something like the same system is not threatening to introduce itself even amongst the masses of the people—from whom the next generation mainly springs. Now, the pivot of family life is the mother, and though we must leave to a subsequent chapter the systematic consideration of the place and function of woman in society, we must here consider the woman as mother in her relation to the family. It is certain that the employment of a wife and mother in a factory strikes a fatal blow at family life, and from the point of view of any sound sociology is a fundamentally vicious practice. We are not here concerned with its financial aspects, though it is worth while to note, in passing, that the combined wages of husband and wife in such cases are very frequently found to be no greater than those of the husband alone in cases where the wife confines her activities to the supremely important work which she alone can perform.

The Destruction of Childhood. Quite apart from this question, we have to consider the effect upon society of this blow at the family. The results are best expressed in terms of the infantile mortality.

When we make inquiry into the condition of those towns, such as Burnley, Preston, and Blackburn, which show the highest infant mortality, we find that these are the very towns in which the percentage of women who work outside their homes is highest. Dr. Newman has gone most exhaustively into this matter, and has proved this up to the hilt. He says, "Broadly it is true that to whatever town or district we turn the same general conclusion is inevitable—*viz.*, that where there is very much occupation of women away from home there will be found, as a rule, a high infant death-rate." His chapter on the Occupation of Women in his recent book on Infant Mortality constitutes as serious and as painful reading as is to be found anywhere.

The Supremacy of Motherhood. We have chosen the infant mortality as the most expressive index of the injury to the family, and therefore o society at large, caused by married women's work. We cannot here discuss the larger question of the effects upon the female organism in general, upon its supreme functions, and therefore upon society, of physical labour such as men can undertake. But it is possible to say, without the smallest qualification, and in the earnest desire to emphasise the gravity of the proposition, that *the factory employment of married women is an outrage against Nature*, an outrage against children, an outrage against the family; and that no industry or apparent prosperity which depends upon it is worth while. In time to come it will be regarded as a mark of the shameful social state of our age, and of the wicked carelessness with which it defied the laws of Nature, that wives and mothers should be employed as beasts of burden, doing the work which a man or a horse or a dynamo can do, while their children were allowed to die at home. It is the lesson of history that blasphemy against motherhood is, for societies, the unpardonable sin, and never were there any truer and worthier words spoken by any statesman in the whole of the past than those which Mr. John Burns addressed to the Infant Mortality Conference last May: "We must glorify, dignify, and purify motherhood by every means in our power."

MULTIPLE NEWS MESSAGES

Quadruplex Instruments and their Working. News Wires and Press Messages. Classified News

By D. H. KENNEDY

The Quadruplex. We have dealt with the duplex system, in which two messages can be sent in opposite directions at the same time. There is another system called the diplex, in which two messages can be sent simultaneously on one wire in the same direction. It is rarely used, but is sometimes installed when all the traffic between two stations is in one direction. Duplex and diplex have been combined in the quadruplex [13], by means of which two messages in each direction can be simultaneously telegraphed.

Balancing a Quadruplex. So far as the operating is concerned, the *quad*, as it is called, corresponds to two duplex circuits, one of which is called the A side, and the other the B side.

The principle will be dealt with in another section, but, as in the case of the duplex, it is possible to give instructions for balancing and adjusting. The procedure is as follows. The controlling office requests the down station to "earth." For this purpose a two-way switch is provided at each station, which, on being turned to the right, cuts out the batteries, substituting a resistance coil. The balancing of the circuit is now proceeded with on the same lines as in the case of the duplex, using the A side key with B key held down, and adjusting both rheostat and condenser until the needle of the galvanometer remains steady at zero, and no false marks are received.

If necessary, the home station apparatus and batteries may now be proved by withdrawing the 4,000-ohm plug. This will cause the galvanometer to deflect to the left. Now press the A side key. This should reverse the deflection on the galvanometer, and register a signal on the A sounder. Depress the B side key. The galvanometer deflection will increase, and a signal will be registered on the B sounder. Now send on the A key. Corresponding reversals should be observed on the galvanometer and signals on the A sounder. There should be no clicking on the B sounder, which is being held down by the continuous depression of the B key. If clicking occurs, it can be remedied by the judicious adjustment of the B relay and sounder, usually by increasing the spacing bias on the relay and reducing the spring tension on the sounder.

Now send on the B key only. The left deflection of the galvanometer will be increased by each depression of the lever, and corresponding signals will be heard from the B sounder. Finally, work both A and B keys, and observe signals on the related receiving instruments. The 4,000-ohm plug should now be replaced, and the distant station told to "cut in." He will return the two-way switch to the left, and his action will be indicated by the immediate appearance on the up-station galvanometer of a "left" deflection, due to his "*spacing*" current.

The up station will now "earth," to allow the down station to balance. After balancing it is good practice for the stations to take readings from the galvanometers of each other's currents, to ensure that the respective A currents and B currents correspond in value, and that the right proportion between A and B exists.

Standard Practice. The standard procedure is as follows: Observe the "spacing" deflection at normal. Ask the distant station to close A key (the abbreviation C A is used). Take a note of the galvanometer deflection, which should correspond with the spacing deflection. Now say "C B" (close B key). Take the reading of his increased, or B, current, and say "R A" (release A). Observe reversal of big current, and then say "R B" (release B), which completes the process for one station. It must then be repeated in the opposite direction, and the results compared.

These instructions have been written as applying to an increment quadruplex, in which the depression of the B key increases the current. By reading "decrease" for "increase" throughout they apply equally well to a decrement quadruplex, in which the B key decreases instead of increasing the current.

Faults due to "earth" on line and "disconnections" affect the quadruplex in the same way as the duplex. The former is, however, much more sensitive. A steady partial earth, through which a duplex would work, will often make "quad" working impracticable. The leakage has the effect of reducing the difference between the A and B currents, so that the B relay fails to respond. Duplex working on the A side is resorted to. On "increment" sets, if the fault is very pronounced, the whole battery is brought into play by permanently depressing the B key at each end.

News Distribution. It is fortunate, in a sense, for the telegraphic administration that the messages on short suburban and local lines are usually of a very simple character. They are an admirable training ground for the novice, who probably has no special difficulty, unless it is in deciphering the betting messages which unhappily bulk so largely in our telegraph traffic. He must, however, be well advanced in his novitiate before he is allowed to take part in the news work, to which we now turn our attention.

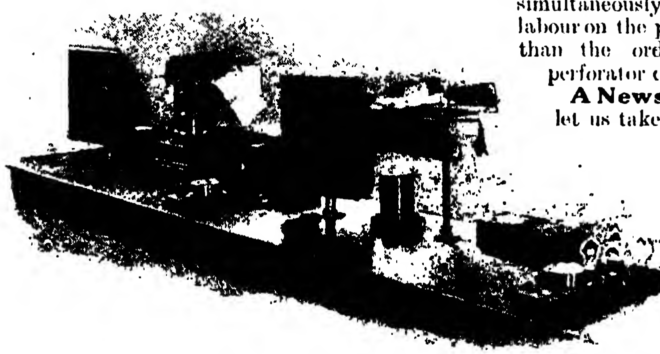
The methods adopted for dealing with news are entirely different to those employed in

ordinary public message work, and this is due to causes which are somewhat interesting.

Press Rates. The predominating cause is the system of charges, or rates, applied to news telegrams. The ordinary day rate is one shilling for 75 words; this applies between 6 a.m. and 6 p.m. In order to provide inducement for news telegrams to be sent at night, when the wires are free from commercial work, the 6 p.m. to 6 a.m. rate is 100 words for one shilling. Second and subsequent copies of the same telegram are delivered to additional addresses *in any town* at a charge of *twopence* per additional address. The italicised words have had a wonderful effect in reducing the cost of Press telegrams and in concentrating the distribution of news into the hands of a few powerful organisations. This will be better understood if we take a case and consider it.

Let us suppose a Press message containing a text of 100 words is handed in for transmission to 100 newspapers. We will suppose each address consists of three words. The cost will be calculated thus

	£	s.	d.
Text 100 words, and addresses, say, 300 words; total, 400 words at 1s.	0	4	0
99 additional copies at 2d.	0	16	6
Total cost	£1	0	6



13. QUADRUPLEX CIRCUIT

Now, if we divide this total cost of 20s. 6d. by the number of newspapers, we find that the average cost of transmitting and delivering the message of 100 words to each newspaper is 2·46d. or under 2½d.

News Agencies. The four principal Press agencies are the Press Association, Central News, Exchange Telegraph Company, and Ivan (Ashley & Smith).

The first three deal with all classes of news, the last-mentioned deals only with sporting reports.

News Wires. London is, of course, the natural centre of news distribution, and on the accompanying map [14] is shown the fourteen principal news distribution circuits radiating from the metropolis. Altogether 33 cities and towns have permanent news wires, while 13 of these—namely, Aberdeen, Birmingham, Bradford, Dundee, Edinburgh, Exeter, Glasgow, Leeds, Liverpool, Manchester, Newcastle, Nottingham and Sheffield have two wires each.

These are the normal circuits, but it is, of course, frequently necessary to supplement these at night by making up additional circuits from wires which during the day have been used for commercial work, and during parliamentary sessions the number reaches 45. One effect of the multiple address rate is visible in the fact that the circuits are of the omnibus kind, several towns being grouped on one wire. The apparatus used is the wonderful Wheatstone automatic system. It is specially well adapted to the peculiar conditions.

As the traffic is all in one direction the transmitters are at the London end, while the outstations are provided with receivers. Keys and sounders are included at all stations to provide for communication between the operators. The perforators at London are specially arranged so that by using pneumatic power several slips can be prepared simultaneously and with less labour on the part of the operator than the ordinary mechanical perforator demands.

A News Message. Now let us take the simplest case. Suppose that a Pressman hands in a despatch containing, say, 60 words, addressed to a provincial newspaper. The charge will be one shilling. It will be sent by pneumatic tube to the news division, recorded by a news distributor and passed to a puncher. He will proceed to prepare a slip beginning with the prefix (which will be "S P"), code, name of sender, "Address to," and then follows the texts.

In the text abbreviations are used freely. Indeed, this applies throughout to news messages and to the Pressmen as well as the telegraphists. On completion the perforated slip and the message sheet are handed to the key clerk. He calls up the distant office by signalling its code three times and adding T S, the code of the London office. Without waiting for a response he switches on the transmitter, inserts the slip under the wheel and allows it to run through. This done, the transmitter is switched off, the signal . . . —— . sent by hand, and the reception acknowledged by the outstation clerk, who signals the code of his office, followed by . —— . —— . .

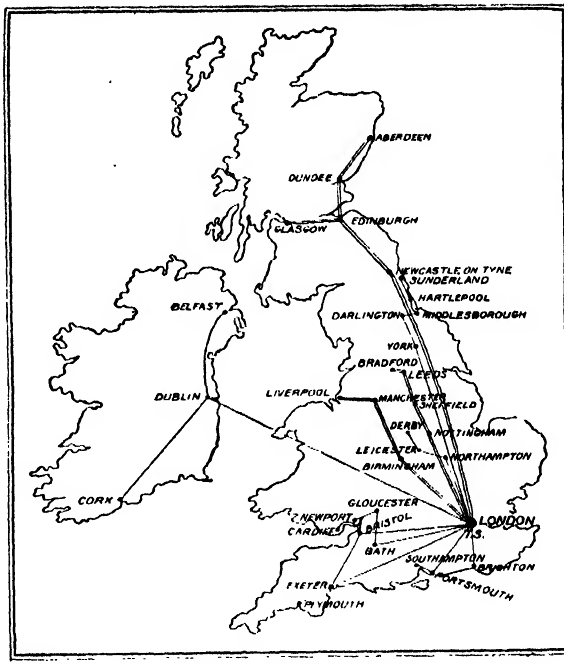
Classified News. Between the four Press agencies already referred to and the department closer relations have been established than ordinarily obtains, and as a result a system of classifying news has been instituted, which considerably simplifies matters for all concerned. One instance will typify the general lines.

The Press Association arranges with its newspaper subscribers to supply to them each day items of general news under the classified heading:

P.A. Midday Special.

Each month a list of the newspapers entitled to this service is furnished to the Post Office, and the various provincial cities and towns concerned are duly advised that all "P.A. Midday Specials" are to be delivered to certain newspapers.

Now let us follow the course of one of these despatches. It reaches the news division by tube in a special envelope with space for initials, so that its progress from point to point may be recorded. It is written on flimsies, and there are about six copies—duplicates prepared by the ordinary carbon process. The envelope is opened by a clerk in the news distribution branch, who marks on the copies the codes of the towns to which they should be transmitted. The despatch now goes to the puncher who prepares the slips. It would be possible to use only one slip and pass on in succession through all the transmitters, but this would cause delay, and, moreover, the slips deteriorate if used too much. It is usual to run one slip through two or three instruments, and the marking of the towns on the duplicates is arranged with this end in view. Arrived at the transmitter, the method is a repetition of what has been described for a single address, the only modification being the calling and the use of the "C Q" signal when all stations are required.



14. NEWS CIRCUIT ROUTES

At the Receiving Stations. The slip is taken off by the key clerk and handed to one of his "writers" along with the sheets on which it is to be written. In front of the key clerk is a notice board on which the titles or numbers of all classified news are displayed, and after each a figure which indicates the number of copies required.

For instance, if P.A. Midday Special is to be delivered to three newspapers the figure will be four, and he will hand out what is called a "top four." It is made up of four flimsies and two carbons. The top sheet is ruled and the under sheets plain.

The writer transcribes the slip and places the sheets on the wire basket near him, from whence it is collected by the messenger boy and conveyed to the news distributor. This officer also has a notice board showing the classified news, but in this case it gives the names of the addressees and so enables him to select the proper printed envelopes and send the news to the delivery department for the messenger or to the newspaper by pneumatic tube, as the case may be.

Long Messages. In every case where a news message is longer than one sheet it is paged and signalled as page one, page two, etc, and in the course of transmission it is split up and no order is observed at any intermediate point between the news distributors in London and the news distributors at the provincial offices. On the former devolves the duty of marking the pages so that the latter will be enabled to piece together the fragments. When this has been done the complete despatch, or some complete portion of it, is issued to the addressee. In the case of long speeches the despatch is divided into lettered sections, each section containing anything up to ten or a dozen pages, but in every case the parts are assembled by the provincial news distributor and put in regular order for delivery.

THE FREE-LANCE IN JOURNALISM

A Career Calling for Courage. The Temptation of London. How to Read the Papers. Editors and Contributors. Why Articles Come Back

By ARTHUR MEE

THE man who succeeds in journalism as a free-lance holds one of the most enviable positions in the world. He is tied to neither time nor place. He can work where he will, when he will, as he will. If he lays his plans well, and organises his life well, he may live an almost ideal life. He has the happiest position in journalism. Others may prefer to be editors, with all the anxiety and potentiality for sleepless nights that editing brings, but the free-lance has the success of journalism without its worries, its influence without its penalties. For the ideal journalist the freedom of the free-lance is the ideal life.

Always at His Best. We have made up our minds what the ideal journalist should be, and the free-lance must have his qualities in ample abundance. There are some qualities that are specially his. He lives a life of great intensity, which will admit of no dissipation of energy, which insists upon method, regularity, punctuality, and application There is no severer test of a good journalist than six months as a free-lance, and no man who is a bad journalist survives the test.

The successful free-lance is invariably a good journalist, because his success is the result of the work of his brain, and is not due to any of the varied circumstances that may keep a merely mechanical journalist in regular employment inside a newspaper office. The free-lance has a barometer for testing the quality of his work which never fails him. His income depends entirely upon his keeping up to the mark, and the freedom which he has given himself in his career is a discipline which must be constantly making him a better man and a better workman. He can never say to himself with impunity, as, perhaps, the regular journalist can, that he will not take much trouble with this, or will quickly dispose of that, or will neglect the other altogether. Such things spell ruin for him. The free-lance journalist must be always at his best.

A Rare Courage. And, because of this, he must have a courage that is one of the rarest things in the world—the courage to cut off his income at any moment. He will find that the strain is at times greater than he can bear, and there is only one penalty, as tragic as it is sure, for the man who neglects the warning that Nature always gives in time. No man should rely upon a free life as a journalist who is not prepared to face the risk of having to stop his income for a week or a month or a longer period at the bidding of a master who cannot be disobeyed. Let us go further, and say that no man should rely upon a free life as a journalist who cannot establish himself upon a foundation so strong that he can lay aside his work for a time without running the risk of losing it. The man who holds his work by the quality of it need not trouble greatly about resting from it. Yet this is one of the chief perils of free-lance journalism. To take a holiday means to be for the time without an income, and, even when the normal income is great enough to allow it, this course is not easy to contemplate. But it is one of the first things that a man must be prepared to do when he sets out upon a career in which freedom can only be enjoyed at freedom's price.

Chief, perhaps, of all the practical essentials to success as a free-lance is method. The free-lance journalist must be prepared to write about anything at any time, and only method can make this possible. This subject, however, is considered fully in the final article in this course, on the Journalist's System. We need only discuss now some of the more obvious ways and means by which the free-lance may establish himself.

An Intimate Knowledge of Papers. The first thing that he should do is to make himself familiar with the papers for which he wants to write. It is amazing how often this essential condition, surely the simplest and most obvious thing in the world, is disregarded. A man who thought a great deal more of himself than his capacity justified called upon an editor the other day for an introduction to another editor. "I used to see his paper fourteen years ago," said the remarkable young man, "but I have not seen it of late years, and I should like to write for it." "Then the best introduction I can give you is to the nearest bookstall," said the editor: and he was perfectly right. It is impertinent to expect to contribute articles to a paper with which one is not familiar, and the free-lance would do well to make up his mind for which papers he would like to work. He will find the field wide and varied, and open on every hand; and he will find that there is no safe guide through any part of it except his own ability and the experience of those who have been that way.

It is assumed in this course that what is wanted is to know how to begin at the bottom rather than what to do at the top, and no attempt is made here to help the journalist who knows his business. And, assuming that our journalist is a beginner in free-lance journalism, all that is attempted here is to help him to set his feet firmly on this broad highway. Two things should be said. Unless he has had newspaper experience, a young man would be unwise to depend upon free-lance journalism for his bread-and-butter; and even with a newspaper training the journalist may make the most serious mistake of his life by leaving a sure and steady post in a provincial town for a less steady but more brilliant post in London.

Those who have read this course so far have not found in it any great sympathy with the timidity which holds men back on the verge of great opportunities, but it is well to utter a warning to those journalists who, succeeding well on a quiet provincial paper, imagine that all they have to do to distinguish themselves and win fortune is to take a single ticket to King's Cross and pick up gold in Fleet Street.

The Provincial Journalist's Temptation. It is the saddest of delusions, and a great book could be filled with tragedies that had no other beginning than this. It cannot be repeated too emphatically that the conditions of journalism in London are utterly different from the conditions outside London, and if it is possible to frame any piece of counsel likely to be applicable to all journalists, at all times, in all circumstances, that counsel is never to give up a post in the provinces to come to London unless a definite post is offered; never, in response to any persuasion, to let go a bird in hand in the provinces for two birds, or even for three or four birds, in a London bush. The writer could tell of many journalists who left provincial newspapers to come to London. Three occur to mind at the moment who came to London within a few years of each other from the same provincial town, each of whom has an income to-day greater than any he could have obtained in any possible post in the provinces. But each of the three came to a definite post, with no kind of risk except the risk common to any change. There comes to mind, on the other hand, the case of the only man the writer knows who came to London without a secure post. He made friendships which brought him influence, but no journalist in this world has ever succeeded entirely through influence, and his career is a failure.

This course is not for the man who can fling defiance at probabilities, or for the born journalist who needs neither help nor warning; but the journalist inclined to risk coming to London with no other support than an empty optimism and the example of somebody else will be wise to heed this counsel and let it give him pause.

What to Write and Where to Send it. Arrived in London, the journalist will order from his newsagent an abundant stock of newspapers and magazines, and will consider no time lost that is spent in reading them. His own instincts will guide him to the right papers. If he will spend a shilling at a bookstall every week, keep a close eye on the magazine departments of the halfpenny newspapers, and study all the London evening papers intimately, he will soon come to understand the kind of copy editors are waiting for. It would fill far too much space to make an adequate list of papers and the kind of articles they like, but there is a much better reason than this for not doing so. The journalist who needs such a list had better at once give up the attempt to earn his living as a free-lance. He has missed the great essential. It is the very first condition of his success that, having written his article, he shall know where to send it with the utmost probability of success.

He may find, however, that his difficulties begin long before he comes to send in his article. He may be puzzled, though it is greatly to be hoped that he will not, by the thought, "What shall I write about?" It is to be hoped that this problem will not trouble him, because there is no excuse for the journalist with nothing to write about. It is the unpardonable sin. The true journalist has always more subjects than he can deal with, and by a process of elimination makes up his mind which to use. Many considerations will influence him in making this decision, varying according to time and circumstance and the character of the paper for which he writes. But if he knows how to read the papers, and where to put his hand at once on material, he will find there is no famine in the Land of Good Copy.

Notes from a Morning Diary. Let us take up the first morning paper that comes to our hand and see what a rich harvest it is to the man who has a fountain-pen, a pad of paper, a good library, and an alert mind. It has in it the potentialities of a hundred articles, and only a few ideas are set down here, exactly as they come to mind in a ten minutes' glance at the paper. They are set down without any attempt to "dress them up" or "round them off," and they pretend to be nothing but what they actually are—the rough mental notes of a journalist on going over a morning paper.

When a New Idea Comes into the World. How a new invention or the discovery of a new system kills an old one; the remarkable commercial effect of the change—suggested by a paragraph announcing the cancel of Government orders based on a superseded system.

The Unseen Wealth of the Church. An article on the mineral royalties on ecclesiastical property—suggested by a paragraph on the estates of the Bishopric of Durham.

The World's Unrealised Debt to England. "When England intervenes"; behind the scenes in diplomacy—suggested by a speech.

How a Groom made £100,000. A public calamity which a clever man knew how to turn to his own good—suggested by a will.

Immortal Nobodies. A shoemaker who fooled a nation, and a host of other cases—suggested by the trial of "Captain" Koepenick.

How Many People Earn £1,000 a Year? Where they earn it, and how—suggested by the report of the Commission on Income Tax.

The Hidden Perils of all Our Lives. The dangers we run in everyday life but rarely think of—suggested by the breaking of a wire on an electric tramway.

A Vision of a New World. A forecast and a reality in the new science; a glimpse of "a totally new and unexpected world"—suggested by a speech of Sir William Huggins.

The Aladdin's Lamps of the British Empire. The great commercial potentialities of the Empire, and the way to realise them—suggested by a picturesque phrase in a speech.

Have We Two Personalities? The power in us that sleeps when we wake, and wakes when we sleep—suggested by a law case and a story of drawings made under "influence."

Do the Rothschilds Earn Their Income? Or is it unearned increment?—suggested by the Income Tax Report.

"Thinking Out" a Battleship. The incredible marvels of battleships—suggested by the death of a man who designed battleships for half the navies in the world.

Rich People with no Use for Money. The extraordinary things they do with it—suggested by a curious story of hidden money.

Nothing is Old Under the Sun. So, if we had space, we might go on, fascinated by the ideas that leap to us wherever we turn. We have glanced rapidly through one paper, and there are a dozen papers, *all different*. It is important to the journalist not to make the fatal mistake of thinking, as the public is apt to think, that all papers are the same. In their appeal to the mind no two papers are the same. There may be a world of difference in the way in which two papers put the same thing, and the same thing put in different ways may bring quite different ideas to the mind.

Many years ago, a House of Commons gallery man called one night at his old office in a Midland town, and the junior member of the staff manifested a keen interest in what he had to say about life in the House of Commons. It was all new to him, and the conversation opened up a new avenue of interest. "I will write an article about it," he said. The older men laughed. "These young men don't know that all this has been done before," said a sage sub-editor, who had sub-edited telegrams at the same desk for forty years. "I understand that quite well," said the junior reporter. "It is all very commonplace to you, but it is new to me, and everything depends on the way it is put." The sub-editor sat at his desk until, in the fulness of time, he died; the junior reporter rapidly rose to be an editor in London. The junior was quite right. Nothing is old under the sun. One man's knowledge is another man's news, and, even to the man who knows, the subject may be presented with all the freshness of a new outlook and a virgin enthusiasm.

"Everything has been Done." The population of London is six millions: how many articles, one wonders, are there in that fact? How many books have been written out of it? It is a fact that everybody knows, yet it is a fact that can be written about by a thousand men in different ways, or by one man in a thousand ways, without ever wearying us or driving us to say "I knew that before." There is nobody so hopeless as the man who discards a subject merely because "it has been done before." If the subject had any inherent interest yesterday, it has the same inherent interest to-day. There may, of course, be a hundred reasons why it need not be written about to-day, but the fact that it was written about yesterday is no reason at all.

It is the superficial journalist who, seizing upon the obvious and ignoring the deeper interest, gives way to the feeling that "everything has been done." Everything has two interests; every substance has its shadow; and there is a journalism of shadows and a journalism of substances. One of the cleverest journalists the writer knows was once in one of the most beautiful rooms in Europe. There is probably no room anywhere with a greater number of interests from a greater number of points of view. One of its interests is a diamond—a dazzling thing of transcendent beauty which has figured in the history of Europe, and is stained with the blood of many wars. It is an experience to have looked upon a thing so historic; it is an asset in every journalist's career to come in touch with people and places and things that have made or have been used in the making of history.

The Journalist's Interest in Realities. But it is easy to make a mistake here, and our clever journalist made it. He sacrificed the substance for the shadow. He spent all his time in looking at the diamond, and the thousand other things made no impression on his mind. Yet they were of equal interest, and it can hardly be doubted that a general impression of the room and its contents as a whole would have been a much more valuable contribution to the mind of the journalist than a much stronger impression of one thing in the room. And the journalist was doubly wrong, from our point of view, for he was interested in the diamond because there is a story *about* it, because of an *accidental circumstance*, and not because of anything *inherent in the diamond itself*. It would not have mattered, so far as the impression on him was concerned, if the diamond had been another diamond, or even a piece of clay, since what impressed him was not the thing he saw, but a story that it brought to mind; and the lesson of this is that our gain is all the greater if we are interested in things intrinsically rather than in things for their associations' sake. The journalist's interest in the diamond will pass away, because his lasting interest is not in the gem, but in a story about it; and the gain to him of his visit to the Louvre will pass away to that extent. Had his interest been excited in the diamond as a thing of wondrous beauty, it would have remained with him. As it was he left without any adequate impression of the vast intrinsic beauty of the room, its abundance of treasure, its wonder of craftsmanship, its amazing collection of things all as compelling as that little bit of it which he allowed to steal away all his time.

A Sound Foundation of Knowledge. The example will not have been quoted in vain if it helps us to appreciate the vast difference between a thing itself and its associations. That does not mean, of course, that the associations have no legitimate interest for the journalist. On the contrary, he is the best journalist who knows most of these things, who knows all the stories and incidents and accidents and circumstances which make up the environment of all concrete things. The point of all that has been said is, not that the story is uninteresting or even unimportant, but that the wise journalist fixes his interest in the things themselves rather than in their associations, in things that are permanent rather than in incidents that pass; that his knowledge is at the root rather than hanging on the branch.

If his foundation is thus sound, he can erect any superstructure upon it, and the more varied the superstructure is the more certain his success as a journalist will be. With his interest thus fixed in the substance, he will miss nothing that is interesting in the shadow, and he will find that the day never comes when there is nothing in the papers for him to write about.

The Ideal Contributor. His subject found, his article written, and his paper in mind, the next interest of the free-lance is to reach his editor. Here the simplest advice is far the best. He should send his article to the editor in the ordinary way. He need not bother about introductions. If he can get them easily so much the better, and as a means of reaching an editor an introduction is often useful; it sometimes sets up a connection which might otherwise take a long time to establish. But that is all that introductions can do. Nine introductions out of ten only annoy an editor, and introductions have ceased to have much weight because they are too often used by those who have no merit of their own to introduce them. It may be taken as universally true that an editor has much more esteem for the contributor who sends him a good article than for the would-be contributor whose first excuse for calling or writing is that he knows somebody who knows the editor.

An interesting article might be written on how to manage an editor, but we can do no more here than give one or two hints. We have been considering all through this course ideal journalists and ideal papers; let us consider for a moment the ideal contributor. He has behind him a system such as we shall come to consider in due course, enabling him to write on any subject at any time. He is always available, always reliable, always prompt. He does not worry the editor with unnecessary letters or ask him to wire if he accepts an article. He regards an editor as a gentleman, and does not intrude into an editor's room, as a journalist bearing a well-known name did the other day, violently demanding an explanation why an article sent the day before had not been returned. He does not ask an editor to verify quotations, or to post an article on to another paper if his own paper cannot use it. He does not call himself "Author and Journalist" on his notepaper, or put "M.J.I." on his card, or address himself "Esq." on his return envelopes. He does not write "Will you look at an article if I knock one up?"

MS. He knows how to prepare an article. He uses thin paper of a regular size, easy to handle. He types neatly without many corrections, and sub-edits his manuscript with care. He belongs to the very, very small number of journalists whose copy an editor can send straight to the printers. He does not send out stained or crumpled manuscripts, or spend much time in explaining his talents in general or his reasons for writing one article in particular. He does not trouble much about money, and rarely asks an editor how much he will get for an article. He is in search of reputation and connection, and, however poor he is, these things are more to him than cheques. He never refuses to do an article if he can help it. He never writes such disgraceful letters as these:

"Hearing that you are the editor of a new publication, I wish to ask if you require a writer to do a few columns weekly. I did a page of birthday news weekly in the ——— (a dead paper). Many of my dates have only been secured by personal application. I find amusement sometimes by printing the wrong dates and noticing which other birthday writers crib them and give themselves away. You will find it advantageous to retain me. I can do anecdotes about anybody."

"January 21st: On the 12th inst. you received a story from me entitled 'When We Two Went Maying.' As I have not received it back, I presume you are going to make use of same. Let me tell you that you cannot do so without first sending on a remuneration for same. Shall expect either one or the other within the course of a day or two. If I do not, shall put the matter before a solicitor. Yours sincerely, Sarah G——"

The ideal contributor can be relied on for brightness and originality, for giving the editor as little trouble as possible, for knowing the paper as well as the editor himself, for sending an article of the right length at the right moment. He is not discouraged if an article comes back, because he has learned by experience that often the last reason in the world why an article is returned is that the article is bad. He knows that a good article may be returned for a dozen reasons. The editor may have arranged for one on the same lines, or may have published one recently which the contributor did not notice; the article may clash with some other article that has been or is to be published; the treatment of the particular subject may be uncongenial to the editor; the editor's desk may be so congested with manuscripts that he has no right to keep the article until he can consider it. Even ideal contributors may be disappointed for reasons such as these, and the unideal contributor, of course, runs a hundred other risks of disappointment which he never seems to realise.

Contributors who Never Contribute. The writer who never gets into the papers has generally an explanation of his own; probably there is a plot against him among the editors. But it is really not the case that all the editors in England are taking great pains, at the risk of ruining their papers, to deprive the reading public of the intellectual output of Mr. Richard Tomkins or of Miss Susannah Jones. It is conceivable that there are other reasons. Their articles are probably far too long, or they may be unintelligible, or written on both sides of the paper, or underlined and crossed out in such a way that nobody can read them, or about things which interest nobody, or on subjects of which everybody is tired, or summer articles in winter, or winter articles in summer, or abstruse discussions of theology, or long exordiums on philosophy, or abusive articles on public men, or hysterical articles on private matters, or articles full of glaring errors, or essays as dry as dust, or politics opposed to the paper's own, or articles with libels in every line, or attacks on the paper's contemporaries, or insidious cultivating of private

interests, or articles likely to be mischievous in the money market.

It would be possible to go on at any length giving reasons why papers do not publish articles. A glance at an editor's "rejected" box would be an effective lesson to amateur journalists who write whenever they can instead of only when they must, and allow their lives to be soured by the disappointments they bring upon themselves.

An Editor's Rejected Box. Let us take a peep into the rejected box of the editor of what are probably the most coveted columns in English journalism. They afford a journalist the most powerful pulpit that he can find in England, and if the reader will remember this it will help him to understand the editor's point of view in sending back the dozen articles we have picked out for notice. We set out the authors' headings of the articles, along with an explanation why they were not accepted.

Our Dreadful Musical Likes and Dislikes. Not published for several reasons. 1. The style did not suit the paper. 2. The manuscript resembled a map of Europe with its mass of blots and corrections. 3. The article was twice as long as it should have been had it been twice as good as it was. 4. It was accompanied by this impertinent letter: "Dear Sir, If you are not brave enough to use the enclosed, will you kindly fold it twice, returning it in the enclosed cover? If it is to be used, will you please settle terms with me before it is put in type?"

Behind the Walls of a Lunatic Asylum. The writer declared it to be the most thrilling narrative ever seen on the subject, and wrote: "Please see that Mr. —— sees it. It is good enough for the Christmas number. I expect a cheque for it. If not accepted, return. Tell Mr. —— I expect £20 for it."

The Present-day Snob. In sending the first of a series of six articles the writer, an example of the intolerable "smart" contributor, said: "I am desirous of seeking fame and, incidentally, cash, by asking you to read the enclosed article, the first of a series of six. If, however, the article is too feeble, and makes you feel at all peevish, be good enough to return it in the accompanying stamped envelope, and I will use it for pipe-lights."

Opportunities in the East. Extract from author's letter: "I admit the writing is feeble, but perhaps, with many additions known best to an editor, you may find an odd corner in the least important of your publications. It is very much in season, and will do you good if it appears."

The Gate of Empire. Not published in spite of the fact that a friend of the author wrote to the editor: "Will you be good enough to say when an article entitled 'The Gate of Empire' is to appear, as I intend securing several copies of the paper?"

Vegetarians and Fruitarians v. Meat Eaters. Extract from author's letter: "Would you be willing to take an essay on this subject? It would probably occupy eight or ten columns."

Santa Claus. Extract from author's letter: "Perhaps the enclosed manuscript may be of use when you have nothing suitable at hand."

No Title. Extract from author's letter: "I enclose an article for your Thursday issue. If you would like it re-written plainer I will do it."

A Short Story. Extract from author's letter: "Mr. —— of the —— ——, after reading the enclosed story, advised me to send it to you. I have for some time been trying to get a personal introduction to you, which I still hope to do, although I have so far been unsuccessful."

The Wild and Woolly West. Extract from author's letter: "You may blue pencil it as you see fit. I am after dollars, not glory. Of course, the stuff is original and exclusive. If you think it is 'fishy' any of the gang round the Cecil will O.K. it.

Problems on Juggernaut and the Great World's Misery. Seven columns from a rector's wife.

Tariff Reform. Extract from author's letter: "I beg to enclose an article. You will perceive I have not even troubled to correct or alter same. I have always written under the *nom de plume* 'Vincit veritas,' as I believe truth always conquers, and can write more articles on the same subject."

Women in Journalism. The sensible contributor does not call, as a woman called at the office of the Daily Mail, to see "if there is any personal reason why articles are not accepted." He goes on writing until his articles are accepted, and until he has made his connection so secure that all anxiety concerning his manuscript comes to an end.

Nothing has been said in these articles as to journalism for women. It is true that there are certain departments of work in which women are useful, and, indeed, necessary, as contributors to magazines, and, more rarely, to newspapers. But the woman journalist is not usually a success. The conditions of journalism are not for her, and women are wise in confining themselves, if they write at all, to work involving none of the rush and anxiety of ordinary journalism. There are regular departments such as dress, health, cookery, and domestic interests generally which afford scope for the woman who has a stock of useful knowledge and a gifted pen. But this is not journalism proper, and from a professional point of view the prospect for women journalists is not particularly bright. Obviously, however, all that has been said of journalism applies to journalists apart from sex.

The Journalist's Income. The free-lance who succeeds in journalism should be perfectly happy in his work. He may make any sort of income within reason. It is not surprising to hear of men who make £1,000 a year, though it is common enough to meet men who make the barest living. It is a highly creditable thing if a man can sit at home and make £500 a year by his pen, and, with some capacity for organisation and the instinct of journalism within him, this should not be very difficult. It is a good plan to have a regular piece of work, such as two days a week in an office or a daily or weekly column of notes, and this security of an income sufficient to meet the bare needs of existence saves the free-lance from much anxiety. He should write only for papers that pay regularly, and should cultivate connections upon which he can rely.

With half a dozen papers to write for, a well-equipped library to work in, and good health, the journalist with a brain is the happiest man in the world. He is monarch of all he surveys, and would not change places with a king.

GROWING TREES FOR TIMBER

Shade-bearers and Light-demanders. Pure and Mixed Woods. Sowing and Planting. Species of Trees. Sylvicultural Systems. Forest Management

By HAROLD C. LONG

THE systems of *sylviculture*, like those of ordinary farming, depend, to a larger extent than is often allowed, on the position and locality of the area concerned, and also on the species of trees which are selected. It must be clearly understood that the habits of various trees differ very materially, and in selecting a system it is necessary to consider especially the soil, climate, aspect, and species of trees. Let us now deal with and define some of the commoner terms employed in sylviculture.

When the leaves of a tree fall at a certain time of the year, leaving it bare, as in common oak, elm, and plane, that tree is said to be *deciduous*. If a tree retains leaves throughout the year, such as the pine, it is an *evergreen*. Not that the leaves or needles of pines do not fall; they do, but they are so continuously renewed that such trees always bear leaves.

Certain species of trees—*e.g.*, the yew, beech, spruce, and silver fir—flourish under more or less heavy shade in early youth, not requiring full conditions of light in order to live and produce good timber—that is, they will "bear shade," and hence they are termed *shade-bearers*. Other trees—*e.g.*, the oak, larch, and Scots pine—require a great deal of light, not only to enable them to produce good timber, but in order to sustain life. Such species are termed *light-demanders*. In America shade-bearing and light-demanding species are respectively termed *tolerant* and *intolerant* of shade.

Pure and Mixed Woods. When a wood or forest consists practically of one species of timber tree it is said to be a *pure* wood, while if several species compose a crop a *mixed* wood is the result. It may, perhaps, be said that pure woods are more frequently composed of shade-bearing than of light-demanding species. The latter generally occur in mixed woods, as when alone they neither preserve the soil sufficiently nor produce the best quality of timber. Oak and larch, for instance, are grown to greater profit when associated with beech and silver fir, though they are also capable of forming pure woods. Trees which bear cones, and which in general do not shed their leaves or needles, such as Scots pine and spruce, are *coniferous* trees; those like the oak, lime, and ash are *broad-leaved* species. Those species of trees, whether coniferous or otherwise, which are most suitable for forming pure woods are termed *ruling* species—for example, silver fir, beech, Scots pine, oak, spruce, and larch; those trees, on the other hand, generally found in mixed woods, where they do not predominate numerically, are *subordinate* or *dependent* species, as ash, lime, Norway maple, and sycamore.

Rate of Growth. The various species of trees differ considerably in their rate of height growth, and this fact is of great importance, especially during the youth of the trees. On soil specially suited to larch this species would grow faster than spruce, practically until mature, whereas on soil less suited to larch the spruce would overtake it in height growth in about 25 years or less, with disastrous results to the larch. Again, in a mixture of oak and beech, in a locality suited to the former it would grow ahead of the beech for 50 years or more; where the locality proved less favourable to the oak, it might be caught up in 20 years, and suppressed. In such a mixture, therefore, the oak is given a start, the beech being introduced when the oak has attained 40 years of age or more. We see, then, that in mixing species an important factor, *height growth*, must be considered. *Diameter growth* is, generally speaking, fairly proportionate to height growth, but depends very largely on space allowed per tree. If space be too limited, or, in other words, if the wood be overcrowded, the diameter growth is decreased, while the height growth is increased; too free a position increases diameter growth at the cost of height growth. A judicious space allowance permits a correct combination of height and diameter growth, the result being the best yield in *volume growth*. Regular and slow growth produces the best timber. A close canopy must always be maintained if first-class timber be required, and this means that trees must stand close together, but not so close that injury results.

Sowing. In the forest nursery the principles involved in sowing the seed are somewhat the same as in farm practice—the larger the seeds the deeper they should be planted; the majority of seeds are most suitably sown in drills, although the smaller light seeds (elm, birch) are sown broadcast. The soil should be deep and friable, and as free as possible from stones. A cleaning crop, such as turnips, may profitably be taken in the first year, after which the land may be used for raising seedlings, and for transplanting these for three or four years. Drills for sowing may be prepared with a common hoe, or by a board with attached mouldings, which are impressed on the seed-bed. After the seed is sown the soil is raked over with an ordinary rake. Light rolling makes the bed moderately firm. The hand is used for broadcast sowing, and for placing large seeds, like acorns; but a special seed horn is useful for smaller seeds. Broadcast sowing absorbs far

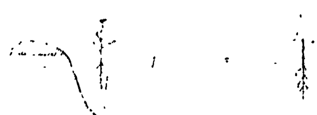
1. NURSERY SHOWING LARCH SEEDLINGS AND TRANSPLANTED LARCH

more seed than drill sowing, while it also needs a more carefully prepared seed bed. The usual time of sowing conifer seeds is almost invariably in spring, but broad-leaved species are sown from November to March, when temperature and the condition of the soil admit.

In the forest, partial sowing is often resorted to—that is, small patches or strips are prepared and sown, or large seeds are dibbled.

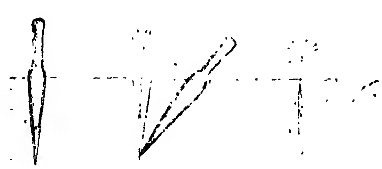
All seeds used should be fresh, ripe, of good size and weight, and have a good germinating capacity. The quantity of seed sown depends largely on the local conditions, on the quality of the seed, and on the rate of growth of the species.

Planting. Seedlings are pricked out in the nursery and transplanted, only once or it may be several times over [1]. The utmost care should be exercised in taking up and transplanting either seedlings or larger and older plants. Fairly small plants are more easily manipulated, and are less expensive than larger ones for planting in the forest. Nursery stock, when planted out in the plantation, should be healthy, shapely, well developed, and have good root systems, the roots being more "bushy" than "tap-like." It is of the utmost importance that no stock in any way affected by disease be used. The best age is perhaps four years, but seedlings, or plants from the seed-bed, are also occasionally suitable for planting out, transplants being used to replace any failures as necessary. Small plants are best removed with soil attached. In correct sylvicultural practice planting is usually done in *pits*, that is, holes dug expressly and of such a size that the roots may be arranged as naturally as possible [2]. In no case should the roots be in an unnatural, cramped position [3]. The *pits* are frequently dug during the winter before planting, the final insertion of the plants taking place in spring, after the soil has become mellowed. Loose soil is sprinkled over the roots when these have been *spread*, the soil gradually burying the roots. The whole is finally trampled firm. *Pit planting* is the most expensive method of establishing plantations. *Ball planting*, using small plants with the soil firmly attached as removed from the nursery bed by a circular or semicircular spade, is especially adapted to loose soils and for unfavourable localities generally. With small balls the expense of planting is not great. In some cases *peg planting* is resorted to [4], this method resembling ordinary dibbling. It



2. GOOD PLANTING

3. BAD PLANTING



4. PEG PLANTING

is only suitable for small plants, and is then cheap. Plants may be thus inserted fairly naturally, and if roots are long, they may be somewhat curtailed. *Notch-planting* is largely recommended on account of its cheapness at the outset. It may be done in several ways: (1) By making a cut in the sod to form an L or a T. The corners of the sod are raised and the plant inserted and trodden in. This system is seldom to be recommended, the roots being almost always twisted or buried too deeply, with serious results. (2) By using the "wedge" spade, in which case a wedge-shaped opening is made in the soil, and by movement to and fro of the spade a vertical face is obtained on one side of the "notch." The plant is placed at this side, the spade again inserted two or three inches back on the other side, and a fresh cut of soil pressed against the plant, closing the notch.

Time, Density, and Cost of Planting. Wounding the plants in the course of planting should be carefully avoided, as wounds may afford entry for fungoid diseases and insect pests, and are responsible for much trouble.

Autumn and spring are the best times for planting—just when growth is over before winter, or just before growth begins in spring. It is desirable to get a good cover in six or seven years, and planting must be dense enough to effect this. *Density* of planting will depend on the species, size of plants, and on the class of timber or other wood it is desired to raise. Three to four feet for Scots pine, 4 ft. to 4½ ft. for larch, and about 4 ft. for oak may be taken as average distances for average plants. At 3 ft. apart each way, 4,840 plants are required per acre. The cost of planting varies according to the number of plants per acre and the method of planting. It may be from £3 to £6 per acre.

5. WINDFALLS IN A SPRUCE WOOD

Species of Trees. Of timber trees of chief importance may be mentioned, among *broad-leaved* species, the oak, beech, ash, birch, hornbeam, alder, elm, lime, poplar, and among *conifers*, the Scots pine, larch, silver fir, Douglas fir, Weymouth pine, and Corsican pine. Of these, the most important are oak, larch, beech, silver fir, Scots pine, and spruce, followed by the ash, birch, and alder. At this juncture we shall discuss briefly the chief points of some of these trees.

Oak. For our present purpose two species of oak, *Quercus pedunculata* and *Q. sessiliflora*, may be considered together. The oak is a strong light-demander, and withstands storms better than almost any other tree. It may live to a great age, grows fairly rapidly in youth, requires a fertile, deep soil (being decidedly exacting in this respect), and occurs both in pure and mixed woods. It is perhaps seen at its best when grown in mixed woods with beech, which may most advantageously be introduced as the oak begins to thin out. As it reproduces with ease by coppice shoots it is admirably suited for the *simple coppice* system and for *coppice with standards*, while with *high forest* systems it does exceedingly well. When grown for bark for tanning purposes, the coppice with standards system is usual. [For qualities and uses of the various timbers see MATERIALS AND STRUCTURES, page 51.]

Scots Pine. Scots pine (*Pinus sylvestris*) is one of the most important of coniferous trees, large quantities of the timber being imported into this country as red Baltic pine or Baltic red-wood. It is hardy, storm-firm, withstands frost and drought well, and prefers a deep, porous soil, but is very adaptable in this respect, a moderate sandy soil suiting it excellently. Like the oak, it is strongly light-demanding, and it grows quickly all through life until mature, attaining upwards of 100 ft. in height. Although extensively forming pure woods, it is suited to form mixed woods with beech and silver fir, and is adapted for growth under most sylvicultural conditions.

Beech. Beech (*Fagus sylvatica*) is one of the first of shade-bearing or tolerant trees, and is eminently suitable for growing in pure high forest, though excellent for mixed woods, while for underplanting pure high forest of oak, ash, etc., it stands unrivalled. In mixed woods it is the chief species, and Scots pine, oak, ash, larch are at their best when mixed with beech. It needs open, good soil, grows slowly at first, but faster after about 30 years of age, is somewhat damaged by late frosts when young, and its volume growth exceeds that of any native broad-leaved species.

Ash. Ash (*Fraxinus excelsior*) is a useful timber tree, being next to the oak in its light requirements, but it is especially liable to fork or divide its stem. Ash coppices well, and takes a firm hold of the soil, which requires to be moist and porous, but it is apt to suffer from late frosts and drought. It is most suitable for admixture with beech, and occurs in high forest; it reaches maturity about the seventieth year, and ought to be felled shortly thereafter.

Larch. Well-grown larch (*Larix Europaea*) yields a very durable timber, which is perhaps more valuable than any coniferous timber in Great Britain. It demands light more than any other British timber tree, is very stormfirm, a quick grower, requires a moderately deep porous soil, and is very hardy as regards cold. It may often be underplanted with beech or silver fir when about 30 years old, but is quite unsuited to pure forest. It is grown in high forest, and can be employed as a shelter wood for tender species—such as beech. Especially within recent years larch has suffered severely from the attacks of a fungus, to be described later.

Spruce. The striking conifer spruce (*Picea excelsa*), with its long leading shoot and conical shape, is a tree of the mountains. Like the beech and silver fir, it is able to endure shade. Spruce is hardy, but requires a moist locality; it is not found in dry soils, but a deep soil is unnecessary. The spruce is easily uprooted by gales [5]. When grown in well-stocked woods, it forms a first-class timber, which is soft and light, being known in the trade as *Baltic white pine*, Scots pine being the *Baltic redwood*. Being one of the chief shade-bearing species, it is well suited for pure woods in high forest, but is not so useful for underplanting as beech.

Silver Fir. Silver fir (*Abies pectinata*) may be termed the chief shade-bearer among our coniferous trees. It is liable to suffer from frost in youth; grows but slowly in early life, later on, however, forging ahead very rapidly, its volume increment being second to none of our common forest trees; and it is at its best on a deep, somewhat firm and moist soil. Like the spruce and beech, the silver fir is peculiarly a pure forest type of tree, maintaining a close cover until late in life, although frequently occurring in mixed woods. With beech silver fir forms an excellent stock. It may be usefully employed for underplanting Scots pine or oak, when it is best introduced as these are about to thin out.

6. MATURE BEECH WOOD NORMANDY ORIGINAL NATURAL REGENERATION

Douglas Fir. Douglas fir (*Pseudotsuga Douglasii*) is a recently introduced species from the North American continent, where it is known as the *red fir*. Owing to the fact that it grows rapidly, attains a great size and forms a first-rate timber, it is likely to prove a very valuable introduction to this country. It is fairly hardy, but when exposed to the prevailing wind is apt to lose its leading shoot. It can be grown in pure woods.

Sylvicultural Systems. Under the systems of sylviculture we shall consider both natural and artificial regeneration, the first being undertaken by Nature, and the second by man's interference and direction. The choice of the system to be followed depends on locality, species, economic grounds, and a variety of conditions. The systems which generally prevail are (1) Clear-cutting in High Forest, (2) Regeneration under a Shelter-wood, (3) Regeneration by Coppice, and (4) High Forest with Standards.

Under the system of *Clear-Cutting in High Forest* an area is directly sown, or planted, or sown naturally with seed from an adjacent wood, the crop completely cut when mature, and the area resown or replanted. The produce is usually of a good class, the most unfavourable point being that an interval occurs when the ground is bare. *Regeneration under a shelter-wood* may be carried out in one of several ways.

(*a*) In one case, the existing wood is thinned, and a new crop allowed to come up naturally from seed under shelter of the parent trees; or regeneration is effected artificially by direct sowing or planting under the old trees, which are cut over when the new crop is established [6 and 7]. (*b*) In a modification of (*a*) the wood is treated in *groups*, instead of in its entirety. (*c*) Another modification is one in which trees, or groups of trees, or definitely arranged blocks, are *selected* for cutting and regenerating in turn, so that there is always some part under treatment. The shelter-wood is suitable for shade-bearing species.

Regeneration by Coppice. In the case of broad-leaved species, *Regeneration by Coppice* is very frequently effected by shoots which spring from the stem, roots, or stool, ordinary coppice being that resulting from stools of trees which have been cut over close to the ground. Growth is rapid under this natural system of regeneration, and cutting takes place at from one to two years with osiers, at 20 years or more for oak (grown largely for bark), or over 30 years in the case of the alder. A combination of this system with high forests results in *Coppice with Standards*, in which some of the best trees are left and allowed to reach maturity as in high forest, the simple coppice forming an underwood.

In the *High Forest with Standards* system a few of the best trees are left at the time of cutting over high forest that they may mature more fully, and in the following crop they exist as standards. Under certain conditions, especially with light - demanding species, woods begin to thin out at a certain age, when a second crop may be introduced to protect the soil. In such a case there will be two high forest woods of different age classes growing together. This is termed *Two-storeyed High Forest.* This again may vary in such a way that the introduced crop takes the form of a scrub or coppice, when the system is *High Forest with Soil Protection Wood.*

7. NATURAL REGENERATION OF BEECH UNDER A SHELTER WOOD

Natural regeneration is cheaper than the artificial method. When a wood or forest is to be established on new ground, this is best done by planting the area with young plants raised in a nursery.

Forest Management. Coarse, knotty timber is largely due to unrestricted development of side branches, due in its turn to absence of competition between individual trees. That is, instead of close planting (the correct procedure, which yields fine, clean timber, the boles being long, straight, and of good shape), the trees have been planted, or allowed to grow too widely apart. From the time an area is planted, a close canopy should be kept, but all dead, suppressed, diseased, and dying individuals should be *thinned* or weeded out. Sufficient space must be allowed for right development, consistent with maintaining good cover for the soil. Under such close canopy, *self-pruning* takes place owing to pressure of individual trees on one another, the lower branches dying off as the crowns press upwards to the light.

How Trees Suppress Each Other. Thinning also takes place naturally in this way, the more vigorous members suppressing their weaker neighbours. In thinning it is usual to remove the very worst trees, such as dead, dying, and diseased ones, together with the smaller and weaker individuals. All the best are left to attain maturity, or at least as many as may safely be left. Close growth means slow growth—that is, good quality timber.

Dead wood in a forest may be taken as a healthy indication, provided the trees are not found dying in patches throughout the wood.

A newer method of thinning departs from the ordinary principles in two ways: (1) it does not countenance the removal of weak and partially suppressed trees; (2) it is not afraid to attack the dominant class, or even to interrupt the canopy temporarily for the removal of objectionable trees, the idea being to benefit the remainder. By this method sound and vigorous trees are in some cases removed; the remaining trees are encouraged to increased production, while more timber is obtained from the increasingly severe cuttings than is general from the usual process of thinning. No more wood should be removed from a forest in a given time than it is able to produce in that time.

Felling. The final felling of the mature crop should preferably take place when snow is on the ground, and timber is best removed in frosty weather, when the ground is hard.

In the case of natural regeneration by seed, the later thinnings may take the form of fellings, the object of the first felling being to prepare the seed-bed where there is too much humus, to strengthen the trees and give light for the production of seed; a later felling—termed the *seed felling*—by which trees not required for seed or shelter are removed; and, lastly, the felling of the remaining trees when they have done their duty in seeding the area. Final felling of timber usually does not take place until the trees have a fresh crop established under them.

Figs. 2—7 are taken from Dr. Schlich's "Manual of Forestry" (Bradbury Agnew & Co., Ltd.).

HOW TO FEED & CLOTHE CHILDREN

Infant Feeding. The Importance of Pure Milk. Hygienic Underwear. A Child's Bath. Exercise. The Nursery

By Dr. A. T. SCHOFIELD

IN all ranks of life the young mother approaches her double task in a state of pitiable ignorance, and, unless she is gifted with more than the average common-sense, the result is more or less lamentable. The young life is either sacrificed outright, or the child is stunted, ill-developed, and bears all through its life the painful result of the maternal ignorance.

The Making of a Healthy Child. Birth is really the second stage of the child's existence, and for many reasons it is important to recognise this fact. The first stage of life is, however, to a large extent a passive one. The child's wants are at this period so perfectly met in every way by the mother that the whole complicated machinery of the body is idle. It neither breathes, digests, nor thinks. The most important condition which at this period determines the child's health and growth is the health of its mother. No woman should risk becoming a mother unless in good health during the time.

The conditions mentioned being favourable, and the parents of average size, the baby will measure from 20 to 21 in. long, and will weigh nearly 7 lb. (a weight now frequently exceeded), part of which weight will soon be lost, but made up again by the end of the first week.

A baby requires little food at first, *no butter or sugar*, and no laxative. It should in every case be put to the mother's breast as soon as possible, and nursed, at any rate for the first three months, even if it be impossible to nurse it longer.

The Composition of Milk. The question of infants' food is so all-important to the race that it will be well to go into the matter in some detail. Milk is a fluid consisting of two sorts of cells (fat cells and living white corpuscles suspended in serum); or it may be regarded as water in which is dissolved milk-sugar, serum, albumen, and casein. Some of the cells are believed to retain their vitality in the milk if it is not boiled. Milk kept for a time tends to separate into serum and solids, just as blood clots when drawn out of the body. The boiling of milk coagulates the serum albumen (as a skin), but not the casein or curd. Milk is not merely a secretion from the cells of the mother, but consists partly of the cells themselves, which are an actual part of her, and has thus been supposed by some to have a vital influence on the child. Mother's milk contains also any drugs, or alcohol, or other special fluids that may be circulating in the mother's blood; and Professor Kanthanck has pointed out that if the mother be immune from any infectious disease owing to an antitoxin, her milk will render the baby immune from the same disease, a virtue that disappears if the milk be boiled.

The importance of breast-feeding is unquestioned; 500 infants in 1,000 are known to die in some localities where the child is never nursed, and impure cows' milk is given. The lowest infant death-rate is in Sweden and Norway (10 per cent.), where they are always breast fed; but in England it is 42 per cent. In the Siege of Paris the infant mortality, instead of being increased, was reduced 4 per cent. by compulsory breast-feeding.

How to Treat Milk. Where the child is not nursed, diluted cows' milk is given, or the mother's milk and cows' milk can both be used.

Humanised milk is cows' milk made to resemble mothers' milk. This is done in various ways. The following are two good recipes:

Sterilised cows' milk, eight tablespoonfuls; cream, two teaspoonfuls; sugar of milk, half a teaspoonful; boiled water, two tablespoonfuls.

Sterilised cows' milk, eight tablespoonfuls; cream, six tablespoonfuls; water, twenty tablespoonfuls; sugar of milk, six teaspoonfuls; lime-water, two tablespoonfuls.

Humanised milk can now be bought sterilised and ready for use in sealed feeding bottles that only require fitting with a teat to be taken directly by the infant.

When humanised milk is not given, pasteurised (sterilised) milk should be used. The old idea was to boil the milk. This was necessitated by the facility with which the milk receives and multiplies bacteria. Sterilised milk is superior to boiled milk in several ways:

(1) Because the process can be conducted in the very bottle from which the baby drinks.

(2) Because the bottles of milk are heated in a water bath, and only raised to 180° because the boiling point of milk is so much higher than water; whereas if boiled it is raised, of course, to 212° or more.

(3) The curd is not hardened, but disintegrated and flocculent when it reaches the stomach.

(4) No skin (albumen) forms on the surface, and therefore this valuable ingredient is retained in the milk.

(5) All germs are destroyed as at 212°.

Mistakes About Milk. The sterilisation of milk has now reached such a pitch, and is so universal, that, curious to say, it has almost become a danger.

As knowledge spreads among mothers, milk is increasingly boiled at home before use. If it be sterilised unknown to the consumer before it arrives, and then boiled by the purchaser the result is an impoverished food, and anæmia and scurvy not infrequently follow.

Condensed milk may be another and much more serious evil. First the quality varies so much. In the Milkmaid and other good brands, the fat will average 11·5 per cent.; in common

brands 2 per cent. On the cover of the tin of the cheaper brands, in small letters, the word "separated" is found, signifying that what is condensed is "separated" milk worth ½d. or 1d. per quart, from which every particle of fat or cream has been removed, and on which the child can only starve. This word is often overlooked, and the parent wonders why the child pines.

Another evil is that the right strength is not given. Good condensed milk should be added to the water in this proportion: Before one month, $\frac{1}{10}$; from one month to five months, $\frac{1}{30}$ to $\frac{1}{10}$.

A third mistake is that due distinction is not made between condensed milk with and without added sugar. It is best *without*, but then it will only keep good for a day or two when the tin is opened, whereas with 30 per cent. of added sugar, which does not agree with the child, and tends to produce all sorts of skin eruptions, it does not go bad.

It is said that 100,000 infants die needlessly every year. Picture this enormous waste of human life, and then let us remember that it is principally (four-fifths) due to improper food.

Not until a child is six months old can it live on vegetable food; till then it is an animal feeder, and consumes, *in proportion to its weight*, twice as much animal food as a man, averaging daily 30 grains per pound weight as compared with 15 grains per pound in an adult.

Infant Nursing. In nursing a child the mother should lead a healthy, regular life, with plenty of nourishing food. Stimulants are not required, and it is important to remember this, as the habit of giving young mothers stout and strong beer, to say nothing of spirits, lays not only a disastrous foundation for the subsequent married life, but for the baby's constitution as well. The best milk maker is milk; the next best, perhaps, is cocoa. Nothing that tastes very strongly, such as onions, should be eaten, and all rich food should be avoided.

With regard to the times of feeding the child, it should, in the first place, be fed regularly, and not always when it cries. This is of the utmost importance to both parent and child. For the first three months every two hours in the daytime, and every four at night, is quite enough; and after then, if the child be strong and well, every three hours in the day and every six hours at night.

The amount of milk that is yielded by a good nurse is about four tablespoonfuls in each breast every two hours. At first a child exhausts one breast only, later on, both. A child should, as a rule, be allowed to suck until it shows it has had enough. A child would then, if under three months, drink about a pint a day, and about a pint and a half over this age.

When a child has sucked, its mouth should always be washed to prevent the formation of thrush, a small white fungus that grows about the tongue and sides of the mouth. The nipples should also be well washed, and can be hardened, if needed, by sponging with brandy. Of course, nursing is a great tie to a mother, who must be in at the regular hours if she would do justice to her child; for if the food be given at too long intervals, the child takes it too quickly, and all sorts of dangerous stomach disturbances are caused.

Occasionally, through worry or overwork, mother's milk is too poor; it may become scanty and insufficient, or some sudden shock or other cause may stop it altogether. In these cases it is better partly to suckle a child than not at all. There is absolutely no foundation for the popular idea that it is wrong to give cows' milk and the mother's milk together. If the milk be scanty, a better plan than giving the breast in the day and the bottle at night is to give them alternately.

Feeding Bottles. Setting aside wet-nurses as being too difficult to obtain readily when wanted, the question is, if the natural supply fails, how should the infant be fed? In the first place, the bottle itself should always be kept perfectly clean. A boat-shaped bottle, with a calf's teat, is easily kept clean, but until lately it has been completely driven out of the field by other shapes. The bottle with the long indiarubber tube can be placed in almost any position without being upset, and hence is so popular because the mother can leave the child to suck by itself. This is not a good plan, for not only are the bottle and tube always dirty, but too often it leads to the child gulping down quantities of air through sucking at the bottle when empty. The best course is to use the bottle (fitted with a teat) in which the milk has been sterilised. The milk, not necessarily obtained from the same cow, should be perfectly fresh and sweet. It should not be kept in the bed-room, and the jug or bottle should be scalded and made perfectly clean. The least dirt or drop of sour milk will soon turn a whole quart. The milk should be sterilised by the bottle being placed in a saucepan of water until the water boils. The proportion of *boiled* water added should be one-half, and if the milk be rich, a little more at first; a small quantity of white (preferably milk) sugar may be added. The bottle should be given at blood-heat.

How Milk Should be Warmed. It is very dangerous to keep the milk warm all night by a small light, as, in this case, it constantly turns sour. It should be kept quite cold, and warmed only when needed. Nothing whatever in the way of food but milk-and-water should be given to a healthy child. After the first three months only one-third of water is needed to two-thirds of milk. Should the milk disagree with the child, and heavy curds be brought up, then a little lime-water may be added, which may be increased, if necessary, until nothing but lime-water (which is quite harmless) instead of water is added. Sometimes, when the milk is "on the turn," a pinch of bicarbonate of soda will put it right, but it is better not to use it. If it be still found to be too heavy, as is shown by curds being brought up or passed, some change must be made. Condensed milk is lighter than cows' milk, but generally contains such a quantity of sugar that it often produces

skin eruptions, and makes the child fat rather than strong, although with some it agrees fairly well. Barley-water (two teaspoonfuls of pearl barley to a pint of water, simmered slowly to three-quarters of a pint, and strained) and cream is very light. The humanised milk prepared by the great London dairies is highly to be recommended, and will nearly always agree with the baby.

Prepared Foods. If the child still appears starved and hungry, and needs something more, there are some digested foods, prepared by Allen & Hanbury, Mellin, and others, which can be safely tried. Ridge's Food, biscuits of any sort, and other milk foods, must *not* be given till after the child is nearly six months old, since before that age it is absolutely incapable of digesting any sort of flour.

It is a great mistake to feed the baby too frequently. After the first six months the child will go at night, from eleven to five, without food.

If possible, a child should not be weaned in summer, but about the sixth month the amount of nursing should be decreased. After the first teeth are well through, about the seventh or eighth month, the child may be weaned. It is a great mistake for mothers, for any reason, to continue suckling as long as fifteen months.

After the sixth month the child can take Ridge's Food and plain flour foods, rusk, and biscuit. Rusks and tops-and-bottoms are very good at first, but bread should not be given until the child is well accustomed to the finer food. At eight or nine months the child can begin to take a little broth or beef-tea. Milk should always be the child's mainstay for the first few years of its life. Sugar is good for children *with* their meals, and after one year a little meat may be given once a day. Oatmeal is very fattening, although rather heating. The diet should be light and nourishing. Light-boiled eggs are very suitable, and there is no objection to a little *ripe* fruit.

A Child's Menu. The great danger a careful mother is apt to fall into when her child is between six months and two years old is giving it too much farinaceous and too little animal food. We are apt to think flour foods can take the place of milk; but, though they present somewhat the same appearance, they are in reality very different from it. Milk is truly animal food, and contains plenty of material for building up the child's body. Now, a child requires, seeing it is growing rapidly, far more animal food in proportion to its size than a man, and this is most conveniently given in the form of milk. Any vegetarians who read this must clearly understand that if they had excluded animal food from birth they would not be alive to-day, for we are all born animal feeders. At eight or nine months a baby may have a little beef-tea and, at fifteen months, a little under-done meat scraped into fine pulp and moistened with beef-tea or plain gravy.

A suitable dietary for a child of two years old is a breakfast of bread-and-milk, porridge-and-milk, or an egg; a dinner of meat, fish, or chicken, with a little mashed potato and a light milk or egg pudding; a tea of bread-and-butter and milk, with a little treacle; and for supper, bread-and-milk. The child should continue to take at least $1\frac{1}{2}$ pints of milk in the day.

Children's Clothing. There is no doubt that there is room for a greater reform in infant clothing. As much as is possible of a baby's clothing should be of flannel of a fine and non-irritating quality. An elastic woollen binder round the body is very useful during the first few months. This binder used to be sewn round the baby's body very tightly, and was made of rigid and unyielding cotton cloth. One result was that babies continually suffered from jaundice, and there can be no doubt that when the body is so soft a very tight binder must seriously interfere with the action of the liver. The ideal binder should be made of some webbing which will give a little. Beyond this, the child needs nothing indoors but the cambric, or fine linen shirt, the flannel gown, and, if needed, a warm shawl.

Napkins should only be worn when the child is being carried about, at other times its legs should be quite free; no waterproof should be worn over them. For out-of-doors an extra soft woollen gown, and on the head a soft light woollen hood. The child's face should always be uncovered, and no thick veil or handkerchief ever allowed. All clothes should be made to open in the front.

At night the child should be all in flannel. A baby should wear soft woollen socks; no stiff boots or shoes should be allowed, excepting when absolutely needed out-of-doors.

At the age of four months the child's clothes should be shorter; but even before they should never be of the absurd fashionable length. The change, however, should not be made in wintry weather. The short clothes should also be of flannel, the sleeves loose and long, the neck high - not tight. The legs should now be protected with woollen gaiters, and no infant should be allowed to go about with bare legs and arms.

The Nursery. Infants require an immense amount of light and air. Fresh air and sunshine not only invigorate and promote the growth of their young bodies, but they also kill and destroy all germs of disease. Light is a great factor in forming good blood. Infants cannot thrive, even with every care, in a dull and sunless room; while, on the other hand, they do grow wonderfully when they have plenty of light and air, though they may be often grossly neglected in other ways. The nursery should always be the brightest room in the house. It should be on the first floor, or higher, and should be sunny; it should have a fireplace and plenty of access for fresh air at night. The room should be as bare as possible, and scrupulously clean.

Young infants should not be taken out-of-doors during the first month; and when it is for the first time, a fine warm day should be chosen. If the temperature out-of-doors is 60° F., the baby may begin to go out on the fifteenth day. Of course, if it is winter-time, it should not go out until it is

older. Long exercise in a perambulator soon chills a very young child: the nurse's arms are far better, and the continual exercise for the child as she walks about is very good for it. A child should be carried on the right and left arm alternately.

Older children should be kept out-of-doors as much as possible, and, well wrapped up, they can endure most weathers, excepting east winds and rain. In summer, a child should be kept indoors in the middle of the day, and taken out morning and evening. The temperature of the nursery bed-room should never fall below 55° F. in winter, or be above 65° F. in summer. The nursery may range from 65° F. to 70° F.

With regard to cleanliness, the first step is at birth, when the child's eyes should be carefully bathed. If this be not systematically done, and any poison has entered during birth, the eyes soon swell and inflame, and a child often goes blind during the first week of its life. For children to be "born blind" is the rarest of events, but for them to be blind from birth is very common, and nearly always is due to nothing but want of cleanliness

Baths. All infants should be bathed at first in warm water, about 95° F., gradually reduced to 70° F. by the end of the first month. The water should be soft—rain water is best—and curd soap should be used: a soft flannel for the soap, and, when it can be procured, a Turkey sponge for the water. Very little soap should be used to a baby's skin, as it destroys the secretion of the oil glands and renders the body liable to cold. The baby should be bathed before his breakfast, and it is most important that the nursery door be locked during the first few baths.

After the first fortnight he can be put in the bath instead of being washed on the knee. He should not remain in it long, and be quickly dried with a warm, soft towel, and then rubbed all over with the warm hand, and dressed.

Cold baths should not, as a rule, be given to infants till they are eighteen months old, at any rate. The best way, at first, is to put the children into warm baths, and finish up by a sponging with cold water. As they get used to this, they can stand in warm water, and be sponged more freely with cold, and in hot weather the bath can be taken quite cold.

The child should never be allowed to get cool before the morning bath, but should be taken straight to its bath out of bed. Great care should be taken thoroughly to dry children after their bath, or sores and chaps soon appear in the folds of the skin. When quite dry, the part liable to friction can be powdered. It is important, therefore, that all the little folds of the body—between the toes, etc.—be dried carefully.

Children begin to walk between 12 and 18 months. Heavy, weak children should be kept off their legs as long as possible. They begin to walk about the second year.

Teething. The beginning of dribbling is always an interesting event in the nursery, being a pretty sure forerunner of the cutting of the first tooth. The milk teeth are 20 in number, and the first that should arrive are the two middle ones on the lower jaw: these are generally cut about the seventh month, the two front teeth of the upper jaw about the ninth, and the other two front teeth of the same jaw just afterwards. The remaining two front teeth generally come at the close of the first year; at the same time the first four double teeth appear, so this is a troublesome period in child history. The last four double teeth appear about the twenty-fourth month.

If teeth are cut out of their proper order, it is of no importance, provided they are not too long delayed. If they are backward, a little phosphate of lime, given with white sugar, will soon bring them on.

Ailments of Young Children. During teething, children are specially liable to convulsions, bronchitis, diarrhœa, and general nervousness. It is the later teeth that give the most trouble. It is a good practice to give them a hard substance to gnaw, but lancing the gum is not generally required, nor is it beneficial. Easy cutting of teeth is a good indication of general good health.

The ailments of children spring, in nine cases out of ten, from the stomach and from errors of diet. Diarrhœa is a common trouble, but is sometimes also an epidemic and a dangerous disease in itself. It should never be allowed to continue, and if there be any evidence that the food is not being digested, an appropriate change will at once cure it. Medical advice in any case should be sought early. Constipation is not uncommon, but should never be relieved with strong drugs. A little cold water is an excellent purgative; combined with a little glycerine it is stronger. A little oatmeal water when young, or a little porridge when older, will soon cure constipation.

Vaccination is best carried out before the teething sets in, and should always be done thoroughly, as smallpox is very fatal in infancy. Care should be taken that the lymph is obtained from a healthy baby, or fresh from the calf.

How a Child Should Sleep. A child ought not to sleep alone during the first few months of its life, but afterwards it should always sleep in a cot, and not in a bed. When in bed with its mother its face should invariably be turned away, for fear of being overlaid, and the face should *never* be covered. During the first year the child should average 18 hours' sleep, and after should decrease to about 12 at five years of age

With regard to indiarubber "comforters," a point that is often overlooked, it is important to know that it does far more than spoil the shape of a baby's lips. It has been recently pointed out that the prolonged sucking makes the roof of the mouth painful and swollen, and many serious alterations in the mouth, nose, pharynx, and ears, are the direct consequence of breathing through the mouth, brought on by sucking the solid rubber teat known as the "comforter."

RAILWAY SIGNALS & BRAKES

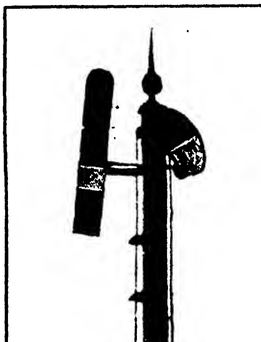
Varieties of Signalling Systems and their Methods of Working. Railway Brakes. Vacuum and Westinghouse Systems

continued from page 4601

By H. G. ARCHER

BRITISH railways are worked on the absolute block system, the object of which is to maintain a certain interval of space between all trains, instead of an uncertain interval of time as formerly. The line is divided into sections, varying in length from a few chains to several miles, according to the volume of traffic. A signal-box is placed at the termination of each section, and provided with a number of fixed signals outside, and within are the levers that actuate the movements of the latter, together with electric bells, block telegraph instruments, telephones, etc. The principle of the block system is that two trains travelling on the same set of rails shall never be in the same section at the same time, though this rule is relaxed in certain circumstances by employing what is known as the *permissive block* system, which is governed by stringent conditions.

Semaphores. The form of fixed signal generally adopted is the semaphore, which consists of a timber or iron pole, varying in dimensions according to circumstances, but usually from 20 ft. to 30 ft. high, with an arm about 5 ft. long, capable of assuming two positions when actuated by mechanical force. When this arm is in its normal position—namely, horizontal and at right angles to the post—it signifies "stop"; when it is nearly vertical it indicates "go on." Of all semaphore signals none has a less equivocal "go on" or safety position than the Great Northern pattern [16]. The arm being centre-pivoted does not fall, but jumps out from the post, and turns a somersault, so to speak, in assuming a position quite parallel with the latter. The face of every semaphore signal is painted red, with a white band, spot or stripe; while the back is painted white, with a black band, spot or stripe.



16. G.N.R. CENTRE PIVOTED SEMAPHORE

Selection of Position of Signals. All semaphore signals are placed in such a way that on approaching them the arm appears on the left hand side of the post, and, except where the line curves sharply, the signal posts are kept as far as possible on the left-hand side of the track, in the direction in which the trains travel. When two or more posts are clustered together, controlling several lines of way, the signal on the extreme left refers to the track on the extreme left, and the second to the second from the left, etc. In the signalling of two or three lines of way branching out from a common line at a junction it is, however, usual to bracket the posts, in which case the posts often number in height from the right, the tallest referring to the fast or main line, the next highest to the second line from the right, etc. In the event of the main line being on the extreme left, this procedure, of course, is reversed. At junctions, the posts, whether placed separately or bracketed, agree with the geography of the route. Some companies further distinguish the signal arms that refer to the slow or loop lines by giving them hoops. Three or four arms referring to different lines should never be placed one below the other on one post; each line should have a separate post or bracket.

Different Kinds of Signals. Fixed signals are distinguished as follows: home, distant, starting, advanced starting, siding, calling on, backing, and shunting. The home signal is placed close to the point at which it is desired that a train shall stop, and at such a spot that a driver may run up to it without any fear of being foul of points and cross-overs which such signal is intended to protect. The distant signal is placed at varying distance behind the home signal—that is, a driver comes to it first—according to the gradient of the line and other circumstances, but 1,000 yards is about the limit. Its function is to repeat the action of the home signal, so that if the latter is at "danger" a driver has timely intimation of the fact, and can at once reduce the speed of his train so as to stop at the home signal.

We do not speak of a distant signal as being at "danger" when the arm is in the horizontal position, but as at "caution." This is the only signal which a driver may run past when it does not signify "all right." "Distant" signals are distinguished by a fish-tailed end, and, together with "starting" and "advanced starting" signals, they are interlocked so that they cannot be taken "off" until the corresponding home signal has been lowered. Starting signals are usually placed at the end of the platform at a station, and they indicate to the driver when he may start his train and enter the section in advance, provided that there is no "advanced starting" signal, but where the latter exists the starting signal gives only permission to go on to the advanced signal. The advanced starting signal is placed some distance in front of the starting signal, and enables a train which has been allowed to pass the latter,

for the purpose of picking up waggons from sidings or to clear the section in the rear, to be brought to a stand without entering the section in advance.

Some Minor Signals. "Calling on" and backing signals have shorter arms than those of the ordinary type and also of somewhat different pattern. The former are usually placed upon the home signal post, below the home arm, and connected to the siding points to which they refer.

However, most shunting and siding operations are controlled by ground disc or dwarf signals, which notify to a driver when he may leave and enter a siding, or when he may cross over from one track to another. These signals furnish the required indications as to the state of the line. We have said that ordinary signal arms ought never to be placed one below the other on the same post. Nevertheless, in cases where the block sections are short, and consequently signal-boxes are situated near together, it is advisable to have the "distant" from the one box placed upon the home, starting, or advanced starting post of the next, when the "distant" must be the lower arm. Both signals must be mechanically "slotted" in such a way that the "distant" can never be taken "off" when the "home" above it is "on," while in order to avoid the discrepancy of the "distant" showing "off" when the home is "on," the home signalman must be able simultaneously to place both to "danger" as soon as a train passes.

Indications at Night. Signal arms, discs, etc., of course, cannot be seen at night, so the indications have to be given by a lamp working with the arm in a frame containing coloured glasses, termed *spectacles*. These latter cause the lamp to show a red light to indicate "danger," and a green to indicate "safety." No other light is allowed. Several attempts have been made to differentiate "distant" signals at night, by equipping them with purple and white glasses to indicate "caution" and "safety" respectively, but now they show the same lights as all other signals. In the United States a fairly satisfactory yellow light for distant signals has been evolved. Knowledge of the road alone enables a driver to distinguish a "distant" signal at night.

Interlocking Signals and Points. But the fixed signals do not do more than direct train movements. To turn a train off one line of way and on to another connecting with it, a pair of tapered movable rails, called *switches* or *points*, are utilised. If these points lie towards a train they are termed *facing points*; if in the reverse direction, *trailing points*. Facing points are usually to be avoided as much as possible. Thus, a train generally enters a siding, or crosses from one line of way to another by means of trailing points—that is to say, it backs. Both signals and points are actuated from a signal cabin, and in order to prevent contradictory movements on the part of each, the signal and point levers are concentrated in one frame, and mechanically interlocked. Consequently, the locking frame of an important signal cabin is a wonderfully complex piece of mechanism. Among the refinements that tend towards the perfection of interlocking, mention must be made of the following. The *locking bar* is a long flat bar lying along the edge of a rail and close to a switch. Each time the switch is moved this bar must be raised above rail level; thus, a train travelling through the points is master of the situation; not even the signalman can either intentionally or inadvertently change their position. The *detector lock*, if, owing to a broken rod, the points have not been moved, prevents the signalman from lowering any signal which would be contrary to the actual position of the points themselves. The *facing point lock* ensures that the points are properly set close home to the stock or fixed rail; otherwise the road cannot be signalled clear. The *clearance bar* consists of a series of locking bars, placed between the starting signal and the signal-box, and so long as a train is standing upon this portion of the line the block instrument and home signal are automatically locked at danger, and a signalman is unable to commit an error should he have forgotten the presence of the train in question.

Manual Operation of Signals and Points. Signals are worked by wires, and the points by rods connecting with their respective levers. Levers are of sufficient length to enable the signalman to manipulate them with moderate exertion, but, where signals are placed at long distances from the levers controlling them, counter-balance weights are provided both on the lever and the signal post to assist the operator. It should be added that the Board of Trade limits the distance at which trailing points may be manually worked from a cabin to 300 yards, and that of facing points to 250 yards.

The Signal-box. Great care is taken in the design of signal-boxes so that they shall be light and airy, and give those in charge a clear view of the track from every point. A gallery often runs along the front of the box, so that the signalman can go out to transmit messages to engine-drivers, guards, shunters, etc., without losing audible touch of his electric bell instruments. Every lever in the frame is numbered, and on the floor beside it or on a board in front of the frame there is fixed a brass plate engraved with its name and use—namely, "Up home," "Down advanced starting," "Main line cross over," etc., etc. Sets of levers are distinguished by being painted in different colours below the handle and spring catch. The following is the standard colour arrangement: red for home signals, green for distant signals, black for points, white for spare levers, and fancy hoops for anything out of the ordinary. In junction boxes it will be further observed that many levers bear an array of numbers, sometimes a dozen or more. These numbers form the key to the interlocking. Before any numbered lever can be moved, each of the levers to which the numbers on it refer has to be pulled over in the order in which the numbers run. Above the lever frame hangs a shelf on which stand the block telegraph and bell instruments, repeaters, route indicators, telephones, etc., and above the

17. INTERIOR OF A SIGNAL-BOX WITH "CREWE" ALL-ELECTRIC SYSTEM

shelf is displayed a large chart of the tracks, sidings, switches, cross-overs, and fixed signals, controlled and operated from the cabin.

System of Signalling. The two block telegraph instruments—one communicating with the signal-box on one side of him and the other with that on the other—instruct a signalman when he is to move his signals. The instrument consists of bells, possessing different tones for the boxes on each side of him, one bell serving for both "up" and "down" lines respectively, and of dial instruments. The former are used for calling attention, and for giving the complete code of signals descriptive of the nature of the trains. The latter, by means of a needle, miniature semaphore, or revolving shutter, give visible indications of "line blocked," "train on line," and "line clear." The normal state of the indicator is "line blocked." On the approach of a train to A, the signalman there will call the attention of B, by means of a given number of strokes on the bell to indicate the nature of the train. The signalman at B, if the previous train has passed his cabin, and he knows that the section A B is clear, repeats the signal correctly, and pegs the indicator to "line clear." The train is then despatched from A, the signalman at A gives the bell signal "train on line," and B acknowledges this by moving his own indicator and the one at A to "train on line." B then calls the attention of C with the "be ready" bell signal. When train has passed B, B puts his block instrument to the normal position, "line blocked." And so on throughout the block system. The "be ready" or "is line clear?" signal must never be sent until "line clear" has been received for the previous train, and the indicator has been put to "line blocked." If the second train should arrive at the signal-box before the preceding one has been signalled as "out of section," it must be halted and detained at the starting signal until the section ahead is clear.

An instrument of the needle type is worked with a handle, and that of the revolving disc with tapper keys. Instruments for both the "up" and "down" lines are now usually contained in one case, thus effecting economy in shelf accommodation.

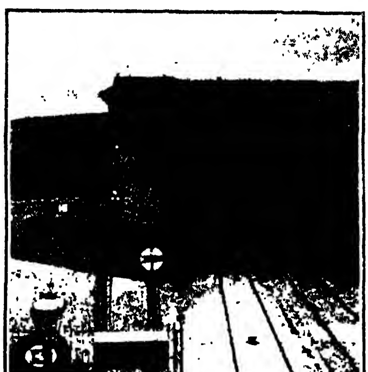
"Lock and Block." Obedience to the audible and visible instructions conveyed by the block telegraph instruments means that signalmen would never lower the fixed signals so as to permit of two trains being in the same section at the same time. Nevertheless, the human equation is liable to err; therefore, as a further safeguard, the block and interlocking systems have been combined, by means of electrical apparatus, whereby either the train itself assists in providing for its own safety by telegraphing its arrival at and departure from signal-boxes, or the signals, say, at B, are placed under the physical control of A and C—that is, the signalman at each side of B. This is known as the "lock and block" system, and it is employed only on sections of line where a large number of trains run with short headway. Undoubtedly, the best known and most widely applied "lock and block" system is the Sykes, with which a signalman is unable to lower the signal that admits a train to the block section ahead until the signal has been electrically released by the signalman at the box in advance, who cannot so release the signal until the

preceding train has passed over a rail contact in advance of his own starting signal, and that signal, again, has been put to "danger."

There is a variety of other "lock and block" systems which, without employing rail contacts or treadles actuated by a train itself, electrically unite the block telegraph and interlocking apparatus, so that they cannot be manipulated in a contradictory manner.

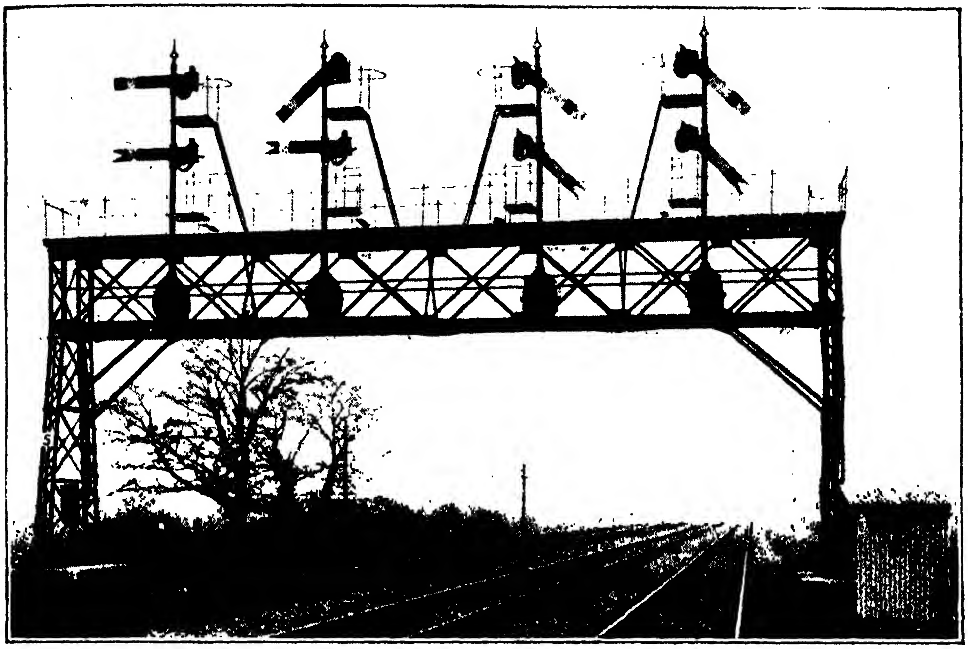
Electricity in Signalling. The function of electrical signal repeaters and light indicators is to inform the signalman whether the arms of such signals as may be hidden from his sight, by reason of curves or other circumstances, have acted in accordance with the movement of his levers, and also, during the night, whether the lamps keep alight. The movements of a signal arm are faithfully repeated by a miniature semaphore in a case, and similarly a little disc inscribed "light in" changes to another inscribed "light out" should the lamp fail. With many patterns of repeating instruments one wire only is required between the signal and the instrument to show all five indications—namely, arm "on," "off," and "wrong," "light in" and "light out." At big junction and terminal station boxes several other kinds of electrical instruments for the guidance of signalmen are in use—namely, train-starting indicators which announce when trains are ready to start from certain platforms; route indicators, by means of which signalmen are advised beforehand of the route an approaching train is required to take where several routes diverge; and shunting indicators.

Power versus Manual Signalling. Various new systems of signalling have been prominently to the fore in recent years in consequence of the large increase of traffic (which has necessitated a greater number of tracks and considerable enlargements of stations and yards), causing a distinct demand for some form of operating signals and points which shall give greater ease and safety in handling heavy traffic, together with more economical working than can be obtained by ordinary manual plants. The feature of a power system is that the signalman is provided with means for easily moving points and signals by electric, electro-pneumatic, hydraulic, or electro-hydraulic power. As with the manual system, it is necessary to have levers in a signal-box interlocked with each other, and connections between the box and the points and signals. With some power installations, like the Westinghouse and the "Crewe," the ordinary mechanical levers [17] are retained in miniature; thus, the signalman has nothing new to learn in the way of movements or catches. As a rule, however, the interlocking machine for a power system is smaller and more compact, and it is possible to interlock points and signals by return connections to the levers in the box. A signalman, therefore, when moving a lever is made aware that the point or signal has answered his lever. Again, with several power systems, should a signalman omit to put a signal to danger it will be thrown up automatically by the passage of a train. The connections with the signal and switch motors are invariably underground, and it is now agreed on all hands that surface rods and wires should be abolished in station yards, on account of the great risk to railway officials from exposed gear. Moreover, with the connections laid underground mechanisms are not liable to accident, neither can they get clogged with snow, ice, or dirt. Train movements can be effected much more rapidly by means of a power installation than by any manual plant. With the former the levers are nearer together, and the physical effort required to move them is too small for notice. Then, it is claimed that the automatic return indication relieves the signalman of considerable mental strain, so that not only can one man do the work of three, but he does it with less mental and physical effort, and consequently with less risk of being overcome with fatigue during long hours. Other advantages possessed by power systems are the fact that the Board of Trade permit facing points to be worked at a greater distance from the signal-box than with a manual, that little difficulty is experienced in "leading out" of a signal-box a maze of connections in many lines of way, and that the cost of maintenance is small. On the other hand, with a manual system, power costs nothing, it being provided by the signalman; and in the initial cost of installation a power plant is considerably greater, while specially trained men are required to supervise it. To sum up, although power signalling effects a considerable saving in working and maintenance expenses, the increased cost of installation largely precludes its adoption, except at busy centres, where, however, power signalling is undoubtedly more economical, and here also the system offers the advantage that, the operation of the levers being quite easy, the signalman is able to devote himself entirely to outside operations.



18. SYDENHAM HILL TUNNEL ELECTRO-MECHANICAL SIGNAL

Growth of Power Signalling. Within the limits of this paper it would be impossible to discuss the technical details of the various power systems partially adopted by different companies. Suffice it to say, therefore, that the London and North-Western Railway employs the "Crewe" all-electric system; the North-Eastern, Great Eastern, Lancashire and Yorkshire, and Metropolitan-District Railways, the Westinghouse electro-pneumatic (normal pressure); the Great Western Railway,



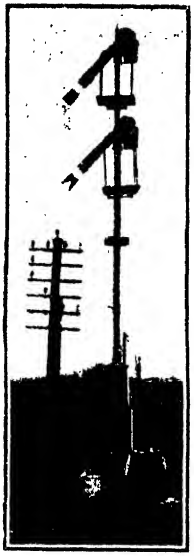
19. AUTOMATIC SIGNALS, LOW-PRESSURE PNEUMATIC SYSTEM, L. & S.W.R.

the Siemens all-electric; and the Glasgow and South-Western, and South-Eastern and Chatham Railways, the Sykes electro-mechanical. It is commonly supposed that power signalling came to us from America. The idea originated however, with an Englishman, Mr. W. R. Sykes, who in the early seventies took out the first patent for operating signals by power, and in 1875 installed the first power signals in the world actuated by electricity at the portals of the Sydenham Hill tunnel. These latter signals [18] consist of a red banner, moved on a spindle, to which is attached an armature with an opal background, through which a lamp shines at night, and so the signal takes by night the same form as by day.

Automatic Signalling. A further development of the power system is automatic signalling, whereby the trains are made to signal themselves. There are several different kinds of automatic signalling systems [19-22] in vogue, but one feature is common to all—namely, an electrical wire and track circuit circulating over each block section. The currents are furnished by gravity batteries, and are of low tension, inasmuch as they do not perform the signal movements, but are required merely to regulate the actual motive power, which is led through valves to the signal motors. The motive power is usually compressed air, as in the case of the London and South-Western and Metropolitan-District Companies' installations; but the North-Eastern Railway employs cylinders [20] charged with liquid carbonic acid gas at a pressure of about 800 lb. to the square inch. The gas motor possesses the advantage of obviating the employment of an air-compressing plant and pipe-lines. The Great Western Company is trying an all-electric system.

When a train enters a section its wheels short circuit the track battery—that is to say, the current flows through the axles, thereby putting the actual motive power into operation to set the signals which it has just passed at "danger." The train having cleared block 1, and entered block 2, the current of the track battery is again flowing through the rails, thereby causing the signals to resume their normal position. With some installations, while the circulation is free, the semaphores stand at "safety," but with others, the normal positions of the signals conform with the Standard Block Regulations—namely, "Danger," and on the approach of the next train, the line being clear, a mechanical contrivance attached to the section enables the signal to drop at "clear."

The advantages of automatic signalling are as follow: augmented track capacity, for it enables a greater number of trains to be passed over a given stretch of track; uniform running of trains; the guarantee that the section is clear for a train, and that the track itself is in good order. It cannot, however, be utilised at junctions, and as our railways are punctuated with these to an elsewhere unparalleled degree, there is not the same extensive field for its employment in this country as in America. Trips or train stops [23] form another new refinement. They automatically prevent trains from over-running home signals. The apparatus consists of an iron arm between the track rails, acting in unison with the adjacent signal. While the signal is at "danger," this arm is elevated to a position in which it engages with a cock on the

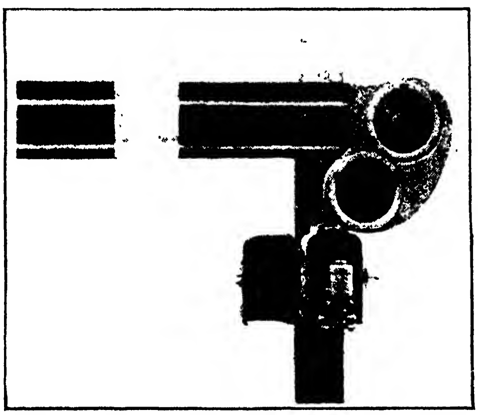


20. ELECTRO-GAS AUTOMATIC SIGNALS, N.E.R.

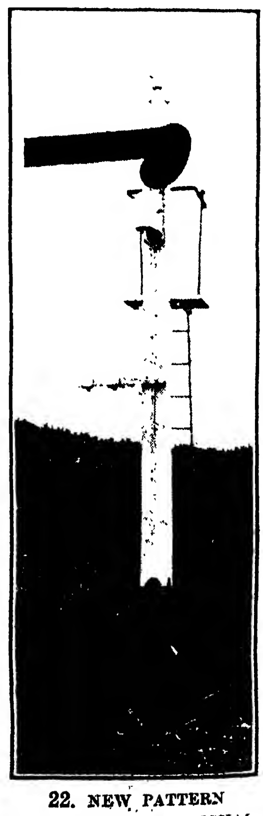
brake pipe of a train. Thus the continuous brake is instantly and automatically applied if by any chance the driver should run past the signal.

Signalmen. As a rule, the selection of candidates for the post of signalman, together with the training and allocation of signalmen, rests entirely with the traffic department. The practice observed in the main by all companies is to appoint youths between fourteen and sixteen years of age as lad-porters, and those among them who wish to become signalmen are at once allowed to learn single-needle telegraphy. Again, a lad between the ages mentioned may join a company's service as telegraphic messenger, earning between 6s. and 14s. per week, and at once devote himself to learning the use of the single-needle instrument. A sharp lad will be able to receive and transmit telegraphic train messages in from four to six months' time, and when he has demonstrated his ability he is placed in a large signal-box to act as telegraphist or train boy. Here his duties are to read and transmit telegraphic messages, and to write up for the signalmen the train books that record the times at which every train is accepted into the block section and clears it. While acting as train boy, a youth soon gets thoroughly acquainted with the working of the block telegraph instruments, the diagram of the line, and interlocking. Some companies keep train boys until they attain twenty years of age, and then allow them at once to pass the examination before the district superintendent for promotion to third-class signalman. Others, however, relieve the lads of their duties at seventeen years of age, and compel them to revert to porters, lamp-men, shunters, or clerks for a period of three or four years. This latter rule holds good with companies which will not appoint a man as a signalman until he attains twenty-three years of age. When a man who has not previously acted as train boy, or learnt single-needle telegraphy, wishes to qualify for a signalman he is not allowed to take any steps to carry out his desire until he has been in the company's service for a period of six months. The procedure is then to despatch him in his original capacity, as porter, shunter, or clerk to some small station, where his ordinary duties are sufficiently light to enable him to learn the practice of signalling and single-needle telegraphy. It is not every company that insists upon the would-be signalman qualifying as a telegraphist, but a man not so qualified could never hope to rise above the rank of third-class signalman on a remote branch line. The same procedure is observed by the companies alluded to above, which do not allow train boys or boy-telegraphists to continue as such till they come to the limit of age for promotion to signalmen. The Great Western Railway has a school of signalling, the equipment of the class-room [24] including a scale model of a double-line junction, with interlocking frame, signals, points, sidings, rolling-stock, etc., in full working order.

The Complete Signalman. Having acquired a fair knowledge of signalling in a wayside station signal cabin, an aspirant is promoted to a more important station, where, besides fulfilling his ordinary duties, he is put on to relieve for a few hours at a stretch a fully-fledged signalman. Lastly, when a vacancy occurs, a man who thinks he has mastered the subject may apply to be examined for third-class signalman, either by the district traffic superintendent, or a signalling inspector, according to the company's practice. The examination is of a searching character. It generally comprises both oral and written examination in the working of the block system, any patent method of signalling, such as

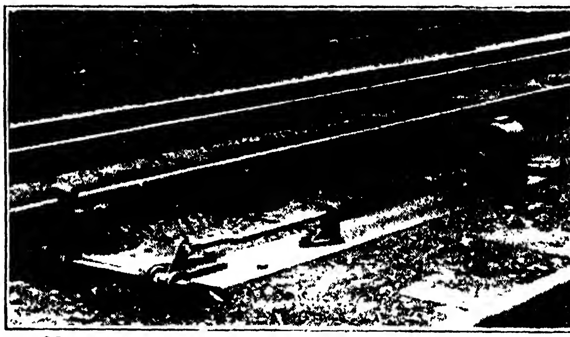


21. SIGNAL SHOWING WESTINGHOUSE ELECTRO-PNEUMATIC MOTOR



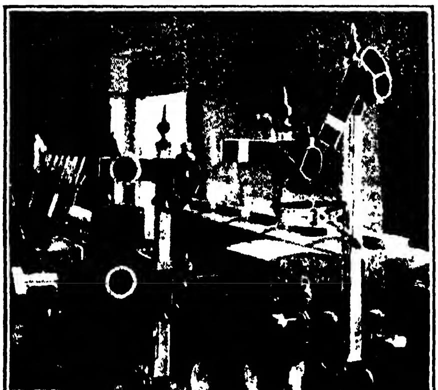
22. NEW PATTERN AUTOMATIC HOME SIGNAL ON DISTRICT RY.

the "lock and block," electric train staff or tablet system, etc., which may be adopted by the company in question, and "emergency" signals, or what to do in a dozen or more different kinds of accidents. Signal-boxes are classified as belonging to principal main lines, secondary main lines, and branch lines. In each of these divisions there are three different grades of signalmen—namely, third, second, and first class, and with some companies there are two higher grades on principal main lines—namely, "special" and "extra-special."



23. TRAIN TRIP: METROPOLITAN-DISTRICT RAILWAY

Pay and Promotion. The rates of pay vary not only according to class, but also according to division. Thus, a third-class signalman on a principal main line earns more than a first-class man on a secondary main line. Signalmen earn from 18s. to 25s. a week, and receive for correct working a bonus of from £2 to £5 per annum. All vacancies are posted among the men, and each man has a chance of applying for promotion, which is decided by seniority and merit. When a man is promoted to a fresh box, he is allowed a fortnight or so in which to learn it to the satisfaction of his superintendent before taking charge. Each signalman is responsible for his own block telegraph instruments, and his first duty after signing on in the train register book is to satisfy himself that all the electrical instruments, signals, points, etc., are in good working order. An adjusting apparatus enables him to adjust his signal wires for expansion and contraction from heat or cold without leaving his cabin, while the "point rod compensator" automatically compensates the rods which actuate the points. The signalman is responsible that his signal lamps are lighted and extinguished at the regulation hours and that they are lighted in foggy weather or during falling snow, but the lamps are trimmed, placed in position, lighted, and extinguished for him by porters or lamp men. A signalman's hours are never longer than twelve, and that only on unimportant branch lines, from eight to ten hours being the rule elsewhere. Where the work is heavy more than one man is put in a box, and when the telegraph work is heavy a telegraphist also is allowed. The stationmaster supervises the duties of the signalmen at his station, and must frequently visit the signal-boxes for the purpose. Every signalman is examined from time to time in all emergency working by his stationmaster and inspector.



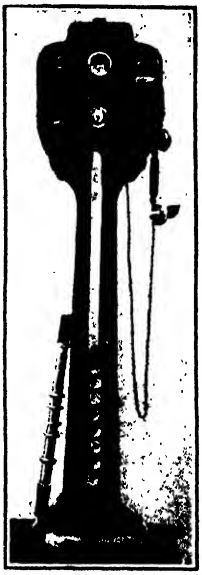
24. G.W.R. SCHOOL OF SIGNALLING
Model of Junction

Department of the Signal Engineer. When men are promoted from being signalmen, they usually go to the traffic department, becoming platform inspectors and rising to district traffic inspectors. The maintenance of the complicated array of signals, interlocking apparatus, and electrical instruments is a work of great magnitude. It is entrusted to a signal engineering department, which has nothing to do with the training of signalmen or manning of the boxes. The work of the department is divided into a mechanical and electrical side. To begin at the bottom, there are signal and telegraph linemen, who are responsible for the maintenance of a certain number of boxes, which they visit periodically according to roster. The signal linemen clean and oil the fittings of each signal and point, and execute any small repairs or renewals that may be required, but they are not allowed to tamper with the interlocking apparatus or to take in hand any important repairs or renewals. Signal fitters come round at less frequent intervals to overhaul, test, and clean the interlocking frames, facing point locks, etc., while heavy repairs and renewals are carried out by an extra gang attached to each district,

25. AUTOMATIC FOG SYREN OPERATED BY THE TRACK CIRCUIT

in charge of a responsible foreman. The telegraph linemen, however, are considered competent to overhaul the block telegraph and all other electrical instruments, in addition to recharging the batteries and mending broken circuits. These men maintain the Post Office wires under an agreement between the Post Office and the railway company. For the purposes of maintenance the whole line is divided into districts, each of which is in charge of both a telegraph and signal inspector. A special department often exists for carrying out new works, under the superintendence of a new works inspector, who acts directly under the head office. The whole organisation of maintenance is vested in a managing staff, which comprise electricians, draughtsmen, assistants, and clerks, all of whom are employed under the control of the chief of the signalling department.

Fog Signals. Some space must now be devoted to discussing the problem of signalling during foggy weather and falling snow, in which circumstances all the foregoing arrangements may be nullified by reason of the impossibility of reading the visual signals. A primitive procedure, still very widely practised, consists of posting men at the foot of the signal posts, where they can see the positions of the arms. So long as the signal indicates "danger," a fogman must place and keep one or two detonators according to rule—if two, ten yards apart—on one rail of the line for which the signal is at "danger" and exhibit a red hand-signal to the driver of an approaching train. When the signal is taken off, he must remove the detonators from the rail, and show a green hand-signal. To facilitate the work of the "foggers," and reduce the risks of an extremely dangerous occupation, it is now usual to have miniature signals on the ground, which either mechanically or electrically repeat the indications of the real arms; and, as a further safeguard, one company at least — the Great Eastern—have constructed fog-pits between the tracks in places where there are many lines of way. The repeating signals and fogmen are stationed in these pits. In the immediate vicinity of London and other large towns a regular staff of fog signalmen is employed at all the places where their services are required; elsewhere the services of platelayers are requisitioned. A list of the names and addresses of the fog-signalmen, showing the post to which each man is appointed, is exhibited in the stationmaster's office and signal-box.



26. WEBB-THOMPSON ELECTRIC TRAIN STAFF MAGAZINE

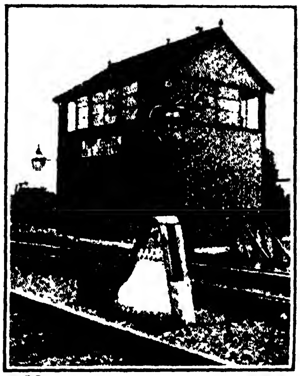
Mechanical Fog Signalling. The great defect in the foregoing system of fog-signalling rests on the fact that fogs often come on suddenly, when, until the "foggers" arrive, there is the risk of drivers running past signals at "danger," which, owing to the absence of a detonator warning, they believe to be all right. Inventors have been busy in seeking a solution of this problem for many years, and patents innumerable have been filed on the subject. Some of them would substitute a mechanical for a human arm in placing detonators on the rail, which mechanical arm could be fed from a magazine and operated from a signal-box. Others would fix a lever alongside the rails, so that while the signal is at "danger" it would engage with another arm projecting from the locomotive, and then produce some audible or visual indication, which could not fail to be heard or seen by the men on the footplate. But the weak point of any such system is sufficiently obvious. The force of the blow would be so great that with constant use the triggers would be liable to get thrown out of gear; while again, the triggers might become clogged with snow, ice, or dirt. Nevertheless, there is in use on the Great Northern Railway, at Doncaster, a rocker and trigger apparatus, which, thanks to an arrangement of double-coiled springs (with coils in reversed order) that distribute the force of the tremendous blow, claims to have surmounted the former difficulty at least. Further, the Great Western Railway is experimenting with an arrangement, partly mechanical and partly electrical, which claims to have overcome all the difficulties hitherto experienced.

The electrical track circuit, as employed for the purposes of automatic signalling [25], is another solution of the problem. Several inventors have demonstrated their ability to establish electrical communication between the signals and engine of an approaching train, viâ the track, and so to give audible or visual indications of "danger" in the "cab" of the locomotive itself.

27. ELECTRIC TRAIN STAFF "CATCHER" APPARATUS, G.W.R.

Staff and Tablet Working. The regulation of the traffic on single-line railways is accomplished either by an electrical train staff or tablet apparatus. staff or tablet, suitably inscribed, is delivered to the engine-driver at station A, and constitutes his authority to occupy the main track between A and B. On reaching B, he surrenders the tally, and receives another one, which gives him the right to the road between B and C. The tallies, in any desired numbers, are kept at each of the two

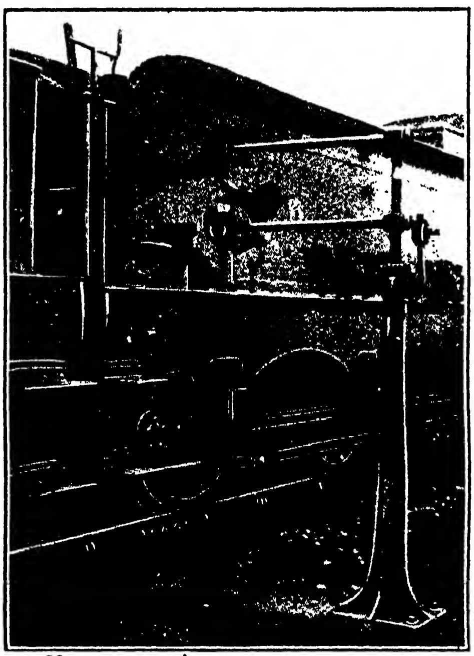
stations, and are locked in a cabinet, automatically controlled through electromagnets by an apparatus in the cabinet at the other station. And a staff or tablet being taken out at one station, a second one cannot be taken out at either station until this first one has been returned to the magazine at one station or the other. Thus, to get two trains in the same section at the same time is impossible. One line wire is sufficient for all purposes—namely, operating the staff or tablet instruments [26], giving code signals on bell, and for telephonic communication. When it is required to work permissively a single line equipped with the staff apparatus the following method can be adopted with perfect safety. Each staff can be made up of three portions coloured distinctively. The end portions, coloured red and blue respectively, are denoted as "tickets;" while the centre and fundamental portion, coloured yellow, is called "staff." When it is desired to send three following trains from station A to station B, an entire staff is withdrawn from a magazine in the ordinary manner. The first and second driver each take a ticket, and see the staff. The third driver will take the staff. It is physically impossible to replace the staff in either instrument until the three portions are screwed together, and until this is done both instruments remain locked.



28. WHITAKER'S ELECTRIC TABLET RECEIVER
Special apparatus

Exchanging Apparatus. On some lines, in order to avoid stopping at stations to discard one tally and pick up another, what are called staff "catchers," or tablet "snappers," are employed. A "catcher" [27] usually denotes an apparatus for exchanging the full-sized staff instruments, which are especially equipped with ring-handles. It is a very simple contrivance. By the side of the line is fixed a post, with an arm projecting to the driver, and shaped to receive the staff for the section the train has just passed through. A driver hangs the staff by its handle on to this arm, which projects from a leather padded target, in order to absorb the force of the blow. A few yards farther on is another post with a pocket into which is placed the staff for the section in advance. The driver plucks out his staff as he passes the post. At night the target-arm and fresh staff are made prominent by means of lamps, carried on a separate post in the case of the former, and bracketed to the second staff post. With this exchanging contrivance a train need slow down to only about 20 miles per hour.

It has long been customary to exchange electrical train tablets, which are small discs looking like quoits, at higher speeds by hand. The tablets are placed in pouches furnished with wire hoops, and through the latter the driver and signalman respectively thrust their arms as the train speeds by. But the practice is a somewhat risky one, hence several automatic tablet exchangers or "snappers" have been devised.



29. WHITAKER'S COMBINED TABLET OR MINIATURE STAFF RECEIVERS AND DELIVERERS ON ENGINE AND ALONGSIDE TRACK

Whitaker's Tablet Exchanger. A very ingenious "exchanger" [29] has recently been invented by Mr. A. Whitaker, and is in use on the Somerset and Dorset Railway.

The locomotive tender is equipped with a catcher which slides in and out in a bracket, and is thrown out when it is required either to catch or discard a tablet. The aluminium tablets are placed in leather pouches furnished with rings. By the side of the track are placed columns having one or two different kinds of arms, according to whether the column in question is for setting down, picking up, or exchanging tablets. If the last-named, two arms are necessary, the upper one being the setting down arm, and a replica of the fish-tailed catcher on the tender, the jaws of which have three triggers. A tablet to be discarded is carried in a slot at the back of the tender catcher, and is snapped off by the ring passing through the jaws of the catcher by the side of the track, while a tablet to be picked up is hung from its ring on another arm, and snapped up by the tender catcher. The arms normally stand in—that is, are parallel with the track, and when to be used are thrown out by levers. An outstanding feature of the apparatus is, however, the automatic return of the arms to the normal position directly the process has been effected. Otherwise, the fact of the arms being left to project

diagonally so close to a train would be attended with serious risks. The "snapper" performs its work at a speed of sixty miles per hour.

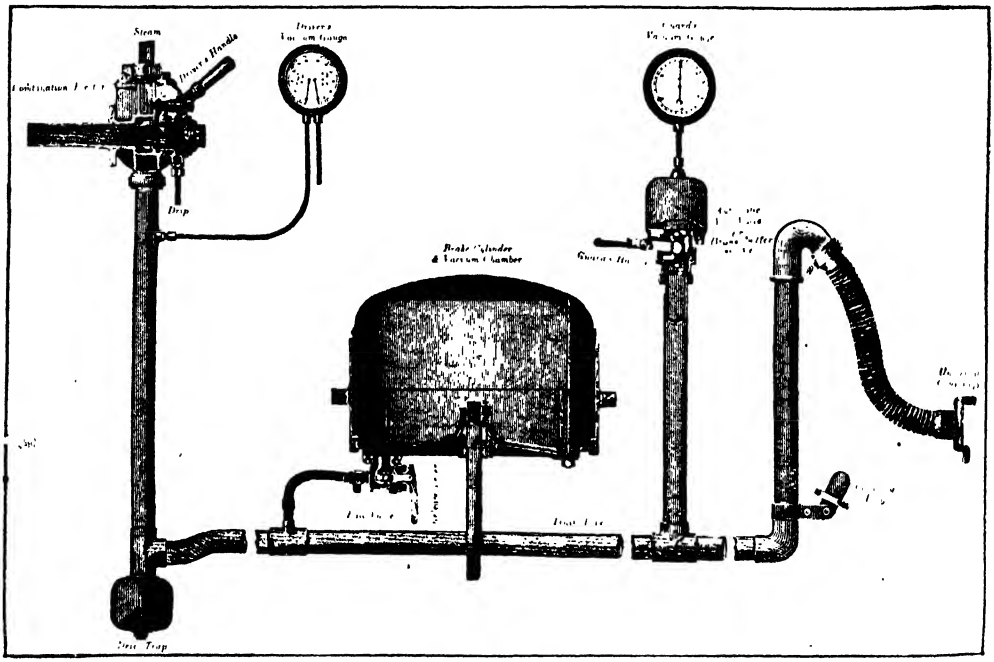
In one particular instance, however, it was not found practicable to place a receiver by the side of the track; it had to be located in the six-feet way, thus necessitating a special design. With this type of receiver the arm is set vertically [28] for an approaching train, and drops down vertically—backwards—instead of revolving horizontally, directly the catch off the tender is effected.

In many cases, by the use of electrical train staff and tablet instruments, together with exchanging apparatus, the facilities for working the traffic are so improved that the doubling of single lines and the consequent capital expenditure may be postponed for years.

gradually evolved from the hand-operated screw brake that formed the earliest method of retarding the motion of trains.

The basis of a continuous automatic power brake is an apparatus fitted to each wheel of every vehicle composing a train, so that every engine, tender, and vehicle has its own store of brake force ready for instant use, while its action is such that if every or any coupling in the train separate, the brake of each vehicle is automatically and instantaneously applied. The brake is capable of application by the engine-driver and by any of the guards.

Unfortunately, British railways have been unable to agree upon uniformity of brake system. At the present day 59 companies are returned as using the automatic vacuum, and 17 companies the Westinghouse automatic air brake.



30. ORDINARY VACUUM AUTOMATIC BRAKE

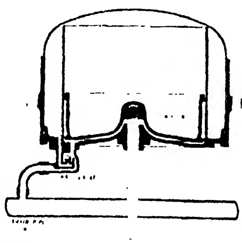
Railway Brakes. A fact little realised by ordinary railway passengers is that the attainment of the present high speed of our trains was made possible only by inventions of suitable means of controlling them. In itself, the ability of trains to travel at high speed would have been not only a useless but a dangerous thing had it not been accompanied by such improvements in railway brakes as enabled drivers and guards to control the tremendous energy set up by heavy trains travelling at high velocities.

The history of railway brakes is a long and complicated one, which cannot be related here. Suffice it to say that the continuous automatic power brake, the compulsory equipment of which to all passenger trains was brought about by the Railway Regulation Act of 1889, was

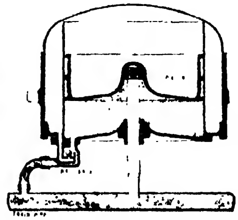
The "Ordinary" Vacuum Automatic Brake. This brake stops the train by the application of brake blocks to the tyres [33] in the same way as the ordinary hand brake. The levers, however, which apply the blocks are moved by a piston working in a cylinder, the piston deriving its power from the pressure of the atmosphere. It is continuous, each vehicle carrying its own brake cylinder, which is connected to a pipe running from end to end of the train, and through this pipe the action of the brake cylinders is controlled on the engine. A combination ejector, consisting of two ejectors known as the "large" and the "small"—the latter being placed inside the former, and worked continuously, while the "large" is worked by the admission of steam—exhausts the air out of the continuous pipe and the cylinders. The brake is applied by the

admission of air into the train pipe, and released by the withdrawal of the same through the ejector.

The engine having been coupled to the train, and the hose couplings connected between the tender and train, and also between the coaches, and the one at the end of the train having been placed upon the plug, the driver admits steam to the small ejector, which soon exhausts the train pipe and cylinders to a vacuum of from 20 in. to 24 in., or the large ejector may be used if the vacuum is required to be obtained more rapidly. The small ejector must be kept at work continuously to maintain the vacuum. To apply the brake, the driver moves the handle of the combination ejector in the direction marked "On," thus admitting air to the train pipe and to the bottom of each cylinder, which lifts the pistons and so pulls the blocks to the wheels. The air cannot pass to the top of the piston, as it is prevented by the



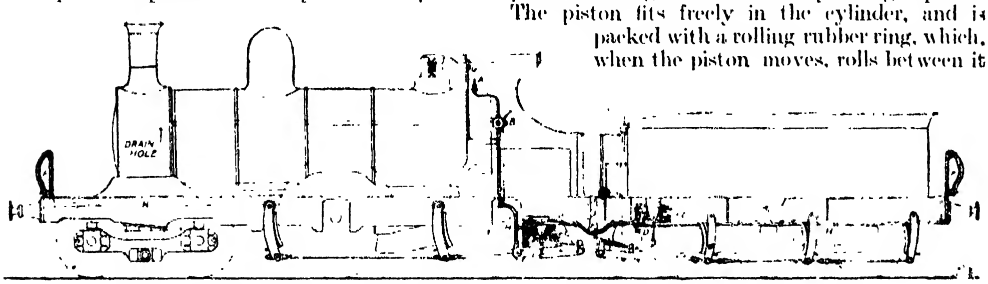
31. VACUUM BRAKE, "ON"



32. VACUUM BRAKE, "OFF"

vacuum, say from 5 in. to 10 in., which should be recreated slowly as the train comes to rest by placing the handle in "Running Position." To apply the brake quickly the handle must be moved to the position marked "On," thus fully opening the air valve. The guard can apply the brake by pressing down the handle of his valve, the "brake setter-valve," thus admitting air and applying the brake throughout the train, which it will stop even if the engine remain under full steam. When a rapid application is made by the driver, the guard's valve opens automatically, letting in air from the van, thus increasing the rapidity of application, and it closes again after the brake has been fully applied.

Arrangement of Brake Cylinder and Vacuum Chamber. The brake cylinder and vacuum chamber is shown in section in 30, self-contained in the vacuum chamber as applied to carriages, and is the only fitting required. The piston fits freely in the cylinder, and is packed with a rolling rubber ring, which, when the piston moves, rolls between it

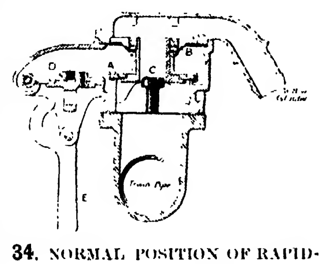


33. AUTOMATIC VACUUM BRAKE AND CONNECTIONS ON ENGINE AND TENDER

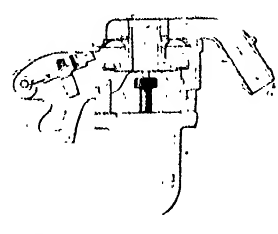
screw-stop valve B. Combination ejecto Brake cylinder . Ball valve E. Drip trap F. od coupling G. Vacuum g H. Train pipe Vacuum chamber

ball in the ball valve. The power of the application is controlled by the amount of air let into the continuous pipe.

To release the brake, the handle must be returned to "Running Position," when the air let in to apply the brake will be removed through the small ejector; or it may be released more quickly by pushing the handle in the direction marked "Off," and so admitting steam to the large ejector. The brake having been applied, the pressure of the blocks on the wheels may be increased or diminished at pleasure without removing them, and also without reducing the full reserve power of the brake, which is always at command for an emergency stop. Ordinary stops should not be made by a violent application of the brake, but by a destruction of



34. NORMAL POSITION OF RAPID-ACTING VALVE



35. RAPID-ACTING VALVE OPENED AND BRAKE APPLIED

and the cylinder, making a perfect packing without friction. The piston rod is coated with brass and works through a brass bush, and a packing rubber prevents air from passing the rod. This rod should be kept clean by wiping with a dry cloth, but no oil or grease must ever be used. At the bottom of the cylinder is attached the ball valve, the branch of which is connected by a small hose pipe to the train pipe. This valve is of the most simple construction, as there is only one moving piece, and that being a small brass ball, having a rolling action in a horizontal position, has consequently no friction. The spindle with release lever is added for the purpose of withdrawing the ball from its seat when it is required to release the brake by hand—for instance, when coaches are detached

from the engine. This spindle is made air-tight by a small diaphragm, the pressure on which when a vacuum is created pulls in the spindle and allows the ball to go freely to its seat.

The action of the cylinder is as follows. The air is drawn out through the train pipe from the bottom of the piston direct, and from the top by passing the ball. To apply the brake, the air is let into the train pipe, and it then passes to the under side of the piston, and, being prevented from entering to the top by the ball, lifts the piston, and so applies the brakes with any amount of force according to the quantity of air let in. Fig. **31** shows "Brake on," and **32** shows "Brake off."

A drip trap is placed on the train pipe at the bottom of the down pipe from the ejector so that any moisture will drain into it. It is fitted at the bottom with a self-acting ball valve, which opens when all the vacuum in the train pipe is destroyed and allows the water which may have collected to run out.

Before starting, the driver must see that the gauge indicates at least 18 in. of vacuum, and that not less than this amount is maintained during the journey and while standing at stations. The vacuum is created by admitting steam to the small ejector by means of the steam cock on the combination ejector. The guard also must see by the gauge in his van that the proper amount of vacuum is maintained, or report otherwise to the driver.

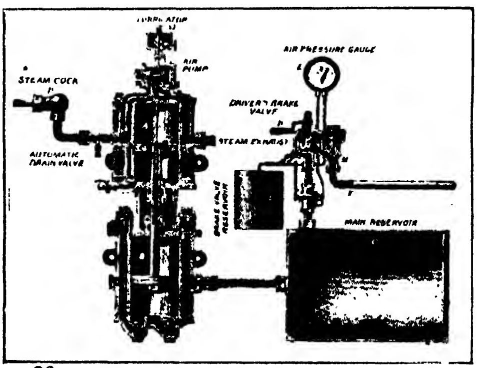
Rapid-acting Vacuum Brake. The rapid-acting vacuum brake — which can be used either as a "rapid-acting" or an "ordinary" vacuum automatic brake — consists of the addition of a rapid-acting valve. This appliance is mounted on the train pipe as near as possible to the brake cylinder, and is connected to the latter by the usual flexible hose.

The normal or "running" position is shown in **34**. A vacuum is maintained on the underside of the valve, A, and the top side of the diaphragm, B, the atmospheric pressure being free to act on the top side of the valve, A, and the under side of the diaphragm, B; but on account of an excess of pressure the valve, A, is held tight upon its seating.

When a rapid action of the brake is required, air is suddenly admitted to the train pipe and thus to the under side of the valve, A, then the pressure acting on the under side of the diaphragm, B, is sufficient to cause it to lift the valve, A, and allow air to pass full bore both to the brake cylinder and to the train pipe, as shown by **35**. Immediately the brake is "full on" the valve falls to its normal position by gravity.

To obtain a graduated application of the brake, air in moderate quantities is admitted to the train pipe, and the area of the passage around the peg, C, is proportioned so that it will allow the necessary amount of air to enter the brake cylinder, and so obtain a simultaneous action of the brake on every vehicle throughout the train.

Westinghouse Automatic Air Brake. Air pressure is the power employed for working the Westinghouse brake. Each locomotive carries its own air compressor, which is driven by the steam from the boiler of the engine, and compresses air to a pressure of about 80 or 85 lb. to the square inch, or, in the case of the quick acting brake, to 90 or 95 lb. When the locomotive is coupled to the train this compressed air, with which the main reservoir has been charged, is turned on to the main pipe running through hose coupling the whole length of the train, and thence through branch pipes leading to auxiliary reservoirs carried by each carriage. Thus, when the train is ready to start, the whole system of reservoirs and pipes is charged with an equal pressure of air, which is ready at any moment to act instantaneously upon the brakes by means of a device known as *the triple valve*. The following advantages and principles of operation are secured by this method of employing compressed air: (1) The power is continuous throughout the whole length of the train and can be applied to all vehicles either by the driver from the engine or by the guard from any part of the train. (2) The action is automatic, instantaneous, and simultaneous. It applies itself with full force to every vehicle should the train separate or should a rupture of a vital part of the apparatus occur. (3) The brakes are applied by a *reduction* of air pressure, purposely or accidentally produced. (4) The brakes are released by an *increase* of air pressure which can be produced by the driver only by means of the air compressor on the engine.



36. WESTINGHOUSE QUICK-ACTING BRAKE. PARTS APPLIED TO LOCOMOTIVES ONLY

We shall now proceed to describe in detail the operation of the Westinghouse quick-acting brake, references being made to the accompanying figures [**36**–**38**] showing sections of the various parts.

Parts Applied to Locomotives. Every engine is fitted with the following parts [**36**]:

The *steam air pump*, A, B, which compresses the air; its steam cock, P; and lubricator, O.

A *main reservoir*, C, for storing the air necessary for releasing the brakes and recharging the auxiliary reservoirs.

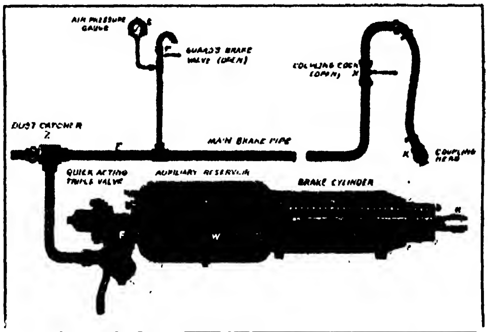
A *driver's brake valve*, D, which regulates the flow of air from the main reservoir into the brake pipe for charging the train and releasing the brakes, and from the brake pipe to the atmosphere for applying the brakes.

Parts Applied to Tenders, Carriages, and Vans. A *triple valve*, F, by means of which the instantaneous action is produced, in conjunction with a *reservoir*, G, in which is stored the compressed air for applying the brakes.

A *brake cylinder*, H, with pistons and rods connected to the *brake levers* and *blocks*.

A single line of *pipe*, E, called the *brake pipe*, extending the whole length of the train.

Each van has a valve or cock, T, connected to the brake pipe, and a gauge S, to indicate the pressure of air. By opening his valve a guard can stop the train, even against the will of the driver, if necessary.



37. WESTINGHOUSE QUICK-ACTING BRAKE. PARTS APPLIED TO TENDERS AND CARRIAGES

Operation of Brake. The pump [36] being started by opening the steam cock, P, and admitting steam to the cylinder, air is forced from the cylinder, B, into the main reservoir, C, which is connected to the driver's brake valve, D.

When a train is to be charged—the hose couplings between the carriages having been united and the engine connected to the train—the compressed air stored in the main reservoir, C, is turned into the brake valve over to the left. It then fills the brake pipe, and flows through the branch pipe on the engine and tender and each vehicle to the triple valve, F [37], thence by a groove, and past a piston into a reservoir, G, where it remains until the brake has to be applied. Uniform air pressure then exists throughout the train, except in the brake cylinders, H, the brakes being off; and the pressure per square inch is shown on the gauge, L, connected to the brake pipe.

So long as this pressure is maintained the brakes are kept off, as the passage from each reservoir to its cylinder remains closed by the slide valve; but letting the air escape from the brake pipe causes the triple valve pistons and slide valves to move towards the left and to uncover the passages to the cylinders. The air stored in the small reservoirs, G, then flows into the cylinders, H, and forces out the brake pistons and rods, thus applying the brakes. From the foregoing it will be seen that the driver can, by turning the handle of his brake valve, reduce the pressure in the brake pipe, and thus apply all the brakes.

Releasing the Brake. The brakes are taken off by reopening the passage from the main reservoir, through the driver's valve, and thus restoring the pressure in the brake pipe; this moves the triple valve pistons towards the right with their slide valves, and places the cylinders, H, in communication with the atmosphere by means of the exhaust cavity in each of the valves; the air used in the cylinders is thus allowed to escape, and the brake pistons and rods are pushed back to their places by springs inside the cylinders.

The driver's valve, D, shown in the diagram [36] is of the improved construction, with equalising arrangement. A small reservoir, U, is coupled to the nipple on the left of this brake valve.

Emergency Stops. The description so far explains the ordinary use of the brake. In an emergency, when the shortest stop possible is required, the brake valve handle should be thrown full over to the right, which movement lets out the air quickly from the train pipe. This sudden reduction of pressure makes the first triple piston and slide move the full stroke, with the effect that some of the air from the train pipe, together with the air from the reservoir, passes direct to the brake cylinder, H. The reduction thus made in the train pipe helps the next triple valve to start, and so on to the end of the train. This action is so rapid that the brake is actuated by the driver in 2½ seconds to the end of a train of 50 vehicles, not less than 1,500 ft. long.

The release of the brakes is made as previously described. The triple valve cock plug [37] and handle, Z, have three positions. When the handle is down, the triple will be in ordinary or quick action; when halfway, it is cut out; and when right up, in ordinary action only.

The ordinary Westinghouse brake, which works on the same principle but carries a simpler form of triple valve, is used where emergency short stops are not likely to be required. The high-speed brake is an improvement on the quick-acting brake, invented in order to graduate the high pressure between brake blocks and wheels, so that this shall be gradually reduced as the train slowed down, thus preventing skidding and undue wearing of the wheels. It carries a reducing valve, which gradually reduces the pressure as the speed decreases.

Evils of the Dual Brake System. The dual brake system is a fruitful source of inconvenience and additional cost, and sometimes, indeed, of danger to the safe working of a train as well. All the coaches of every Anglo-Scottish train have to be equipped with both the vacuum and air brakes, because the English companies concerned use the former and the Scotch the latter. Further, most of the railways are compelled to have a number of passenger train vehicles, such as family saloons, horse boxes, carriage trucks, etc., fitted with both systems of automatic brakes for the purpose of working through to "foreign" lines, while, again, companies which favour the vacuum brakes are bound to keep a number of engines fitted with Westinghouse apparatus, and *vice versâ*.

THE MYSTERY OF SOLUTION

Properties of Solutions. Colloids and Crystalloids. Gaseous Ions. What We Have Learned and How Far We Have Progressed

By Dr. C. W. SALEEBY

THE facts of solution and the facts of double decomposition, when fully considered, lead us to revise the idea that the dissociation of the electrolyte is due to the passage of electricity through it. It can be shown, indeed, that the electricity is not *used up* in dissociating the molecules of the electrolyte. There is already a good deal of freedom amongst the ions of the solute, or substance dissolved, even before the electric current passes. What the electricity does is merely to sort out the ions and force them to move against the resistance of the water. As to what solution really involves we cannot say. The ions of the solute must have relations which we cannot define with the molecules of the solvent, but they are, at any rate, independent of, or dissociated from, each other.

The dissociation theory does more than give us a complete explanation of the electrical and osmotic properties of solutions, or at least of aqueous solutions. It actually enables us to explain, in great degree, the chemical properties of such solutions - that is to say, it enables us to correlate their chemical and their electrical properties. The very solutions which exhibit the highest chemical activity are solutions of electrolytes—salts and acids— and their chemical activity is the activity of their ions. There are some chemical reactions in which "the electric charges on the ions seem to be the determining factors of the whole process."

Colloids and Crystalloids. But even yet we have not exhausted the chief aspects of the subject of solution. We can distinguish broadly between two large groups of substances. On the one hand, there are those which are crystalline in form, like salts in general, and for purposes of this comparison such bodies are classed as *crystalloids*. On the other hand, there are many bodies, most of them of organic origin, such as white of egg, which are not crystalline, or not definitely crystalline, and which markedly contrast with the crystalloids in respect of certain physical properties. These we call *colloids*, from the Greek *kolla*, glue, and *eidos*, likeness. The most outstanding distinction, perhaps, between these two groups of substances is that the crystalloids diffuse rapidly through water, whilst the colloids move slowly or not at all.

While the majority of inorganic substances are crystalloids, there are many exceptions, and under certain definite conditions compounds of iron, gold, silver, arsenic, bismuth and mercury can be obtained in colloidal form. If, now, we take a mixture of crystalloids and colloids dissolved in water and place them within a parchment or some similar membrane, the crystalloids will diffuse through while the colloids are completely arrested. Since the membranes of the body are colloidal we can readily guess that these facts must be very frequently and very importantly illustrated in physiology. In the living body, also, important consequences must result from the fact that there are two distinct classes of colloids: those—such as gelatin—which, when dissolved in water, can be made to "set," and afterwards redissolve, and those which, once thrown out of solution, remain insoluble. The first class of colloids are said merely to *set*, but the second class to *coagulate*. The first may be called *reversible* and the second *irreversible*.

Our Conception of a Solution. Again, we find that different parts of our subject become interwoven with one another. In the case of the irreversible or coagulable colloids we find that their precipitation is greatly aided by the addition of the minutest quantities of the solution of a salt or other electrolyte, and, furthermore, it has been lately shown that the coagulative power of the electrolyte has a definite relation to the valency of its basic or metallic ion.

We are now able, perhaps, to form some kind of picture of a solution in terms of the dissociation theory. We cannot form any picture of the relation of the solute to the solvent, but at least we begin to understand the state of the solute itself.

Says Mr. Whetham: "A certain number of the dissolved molecules are regarded as dissociated into charged ions, which wander, free from each other, through the liquid, perhaps by successive combinations with solvent molecules in their path. When an electric force is applied, though still moving sometimes in one direction and sometimes in another, the ions on the whole drift in the direction indicated by the force, and we may therefore imagine that two processions of oppositely charged ions pass each other, drifting in opposite directions through the solution. When there is no electric force, the ions are subject to no steady drift, and must move sometimes in one direction, sometimes in another, as the chances of their life direct. Any one ion will sometimes be passing from one solvent molecule to another, carrying its electric charge with it: sometimes it will come across an ion of the opposite kind in such a way that combination occurs, and, for a time, an electrically neutral molecule is formed. By collisions of unusual violence, or by other means, this molecule will soon be dissociated, and its ions again set free from each other, to be handed backwards and forwards by the solvent molecules as already described."

The Nature of a Nerve Impulse. Having framed such a conception, Mr. Whetham shows how it is possible to explain the fashion in which chemical valency and coagulative

power are correlated. A distinguished physiologist, Mr. W. B. Hardy, F.R.S., has shown how electric conditions affect the behaviour of solutions of colloids in water. His results seem to show that colloid particles can exist in solution only when they are electrically charged. If the experiment is so arranged that the charge is neutralised, coagulation immediately occurs. In the case of colloids travelling with the current, it is always the acid ion that causes coagulation, or, in general, it is the ion possessing a charge of opposite kind to that of the colloid particle, and therefore neutralising it, which determines its coagulation. It seems highly probable, not merely, as Mr. Whetham says, "that a wave of this electrolytic coagulation is the physical accompaniment of a nerve impulse," but that it *actually constitutes* the nerve impulse. It need scarcely be said that anything which throws light upon the nature of a nerve impulse is helping us to solve one of the most profound and important problems in all science.

The Nature of a Colloid Solution. It has lately been supposed that the peculiar behaviour of colloids as distinguished from crystalloids in solution is due to the circumstance that colloid solutions are not really solutions at all. It has been supposed that the colloid really exists not truly dissolved in the solvent, but merely in the form of solid particles suspended in it. Particles of quite appreciable size can be detached by various means in some colloidal solutions. The question, however, like most of the others we are considering, is still under discussion. At any rate, it is evident that there is some very marked molecular distinction or inter-molecular distinction between colloids and crystalloids in general. Now, the molecules of colloids are, as a rule, very much larger indeed than those of crystalloids. With this in our minds we may understand the following distinction, as suggested by Mr. Whetham: "It seems likely that the forces which are involved in crystalloid solution are of the nature of those classed as chemical or molecular, while, when colloids dissolve, the actions between solvent and solute are conditioned also by the phenomena studied under the names of capillarity and surface tension. It is not likely that any sharp line of demarcation can be drawn; though as the size of the dissolved particles increases, the importance of the chemical forces probably diminishes, and that of the capillary force grows."

Gaseous Ions. Having discovered the existence of ions in liquid solutions, let us turn and see whether any parallel facts can be detected in gases. Under ordinary conditions, a gas is not a conductor of electricity, and thus the leakage of electricity through the air surrounding a telegraph wire, for instance, is very small indeed. An electroscope, however, will detect an appreciable amount of such leakage. We find, moreover, that under quite a number of different conditions gases can be made capable of conducting electricity in a marked degree. Some of these conditions may be noted.

The mere heating of a gas may cause it to conduct electricity. Recent contact with incandescent metals, the neighbourhood of flames or radium and other radio-active substances, and of glowing carbon, the influence of ultraviolet light bubbling through water, passage over molten phosphorus, the influence of the Röntgen rays or the cathode rays—all of these agencies have the effect of ionising the gas so that it becomes a more or less efficient conductor of electricity. The term ionisation is adopted because we find ourselves justified in supposing that the change in condition of a gas, whereby it becomes a conductor, depends upon the production or presence in it of ions comparable to those first described by Faraday in the case of electrolytic solutions.

What is Gaseous Conductivity? The first fact to recognise is that the ionising agency produces a change in the gas, which persists, more or less, after the agency has been withdrawn. These gases coming from a flame retain their conductivity for several minutes, and furthermore display properties which lead us to suppose that the conductivity of the gas is not a mere state of it, but depends upon the presence in it of material things.

For instance, we find that the conductivity of the gas is a thing that can have its position altered in space. It can be blown about from one place to another. On the other hand, again, it can be filtered from the gas, so to speak, for if we bubble the gas through water or filter it through a plug of glass wool the conductivity is found to have disappeared.

A key to the nature of the something which is present in the conducting gas is afforded by its behaviour nder the influence of an electric field, which destroys its conductivity. We must suppose, then, that the ionised gas contains charged particles perfectly comparable to those which we have already studied in the case of solutions. These must be both positive and negative, since the gas, as a whole, has no electric charge.

Gaseous ions differ in certain ways from the ions of an electrolyte. They have only a brief persistence after the ionising agency is removed. This fact may be explained on the assumption that positive and negative ions soon recombine with one another, and that they also lose their charges by contact with solid bodies around them. The fact that these ions do not persist explains the reason why, in this case, the amount of electric current that can be conveyed is not proportional, as it is in the case of solutions, to the electric force.

The Speed of Gaseous Ions. The speed with which these ions move has been measured in various ways, and is found to be very much higher than in the case of the ions in an electrolytic solution. "At atmospheric pressure, under a potential gradient of one volt per centimetre, the velocities of different ions vary from about three-quarters of a centimetre per second in the case of carbon dioxide to about seven centimetres per second in the case of hydrogen. The velocity of the negative ion is

in general appreciably greater than that of the positive ion, the ratio, unity for carbon dioxide rising to 1·24 for air and oxygen."

The velocity of the positive ions is inversely proportional, as we might expect, to the pressure of the gas. That of the negative ions, however, increases so rapidly as the pressure is decreased that physicists are now led to believe them to possess more complexity of structure at high pressures than at low pressures. This is one of the keys to the nature of these ions.

The Nature of Gaseous Ions. We have already satisfied ourselves as to the nature of the ions in a liquid. In the case of chloride of sodium, for instance, we regarded them as consisting of atoms of sodium and chlorine respectively. But gaseous ions are different. They may be molecular or atomic or sub-atomic; and the conclusion to which we are forced is that the last is the true explanation in the case of the negative ions. The first difficulty was to estimate their dimensions, and the results of the experiments which have been made on this point lead to the conclusion that the normal process of gaseous ionisation consists in the detachment from an atom of gas of a minute particle, called by Professor J. J. Thomson a *corpuscle*. "At extremely low pressures the corpuscle constitutes the negative ion, and the atom or molecule from which it has been separated forms the positive ion. As the pressure rises, neutral molecules become attached to the ions, probably by virtue of the electric forces, and collect round the original ion, which constitutes the nucleus. These complex systems form the ions of gases at atmospheric pressures."

Thus we have reached the admirable result that the negative ions of a gas at low pressures are none other than the corpuscles or electrons of which we have heard so much in this and its companion course. The conclusion is verified when we attempt to estimate the absolute mass of these ions and discover that it corresponds to the mass of electrons as ascertained in other ways.

Large Gaseous Ions. We have seen that at atmospheric pressures and the like ions may be of very considerable size—much larger indeed than molecules. Mr. C. T. R. Wilson, a distinguished worker at the Cavendish Laboratory, has been enabled to demonstrate to the eye the existence of these large ions by means of some very striking experiments. It has long been known that the condensation of drops of water in the air is very greatly aided by the presence of particles of dust, which form nuclei around which the water can condense. What Mr. Wilson did, then, was to obtain air containing an abundance of water vapour, but practically destitute of all dust. In such air sudden cooling consequently yields scarcely any drops of water. Precisely the same conditions, however, yield a dense cloud of drops, which can be readily seen, *if the air has first been ionised*. The explanation of this is that the ionisation has consisted in the production of a number of particles of greater than molecular size which, just like particles of dust, act as nuclei for the condensation of the water vapour. Mr. Wilson's work has enabled Professor Thomson to study the amount of the electric charge upon a gaseous ion. We can measure the current conveyed through a gas, and we know that its amount must depend upon (1) the number of the ions, (2) their velocity, and (3) the quantity of the charge upon each. Mr. Wilson's method enables us to ascertain the number of the ions, and since the other factors can also be estimated the amount of their charge is revealed. It is probably identical with the ionic charge in the case of liquid electrolysis.

Positive Ions. Having recognised the vastly important conclusion that the negative ions of a gas are none other than our old friends the electrons, let us consider more carefully the positive ions. Very striking indeed are some of the fashions in which they can be produced. The mere heating of a platinum wire, for instance, causes it to emit positive ions. These are various in size, some consisting, perhaps, of molecules of the gas surrounding the wire, and some consisting of molecules of platinum. When the wire is made hotter and hotter, however, negative rather than positive ions are given out. In general, low temperature and high pressure favour the production of positive ions, while the reverse conditions favour the production of negative ions.

But platinum is not exceptional in this respect. Other metals behave similarly, and so does sodium vapour. Indeed, *solid electrically-charged matter is given out by all kinds of substances when their temperature is sufficiently high*. Carbon is noteworthy in this respect. These facts are of general physical interest, evidently, but they are also of remarkable interest in relation to some of the greatest of cosmic phenomena. Glowing carbon abounds in the envelope of the sun, and this must constantly emit corpuscles, leaving a positive charge upon the sun. If, then, the temperature of the sun be locally raised, as must undoubtedly often happen, a stream of corpuscles must be rapidly shot out from the sun in all directions. Their impact upon our atmosphere at these high speeds will suffice to make certain of its gases luminous; and this, as we have already briefly noted elsewhere, is thought by Arrhenius to explain the phenomena of the Aurora Borealis.

Electricity in Solids. We have to conceive, then, of the passage of an electric current through liquids and through gases as not a continuous but a particulate affair, the electricity being handed on in units by means of the material motion of the particles composing the liquid or the gas. The same conclusion has to be reached when we consider the passage of electricity through solids; so much the worse, perhaps, for our conventional notion of the constitution of a solid! It is far less solid than we have thought. Indeed, the conduction of electricity through a metal must really be conceived no longer as conduction at all but as *convection*. The reader will remember the contrasting use of these two words in our study of Heat.

TOOLS FOR MEASUREMENT

Standards. Rules. Surface Plates. Straightedges. Squares. Bevels. Levels. Compasses. Calipers. Gauges. Vernier and Micrometer Instruments

TOOLS
continued from page 4586

By JOSEPH G. HORNER

As in other branches of engineering practice, each great class or group of measuring tool has given birth to numerous variations in form. Rules, calipers, gauges, and the rest, each number scores of kinds, so that exact definition becomes necessary in mentioning any one of these articles. With increasing differentiation and growing complexity the work of manufacture has become highly specialised in the hands of various firms, some of whom now limit their productions to a few kinds of articles only.

The chief difficulties inseparable from the measuring tools are two in number—that of accuracy of manufacture, and that of its preservation in service. These two matters have engaged the best faculties and labours both of mathematicians and mechanics, and the men who measure and test in the shops owe more than they suspect to others who have originated methods of measurement and test, and produced instruments of precision. Few men who handle a pair of gauges at the lathe, or planer, or bench, or who cut a screw thread and measure it with a micrometer or gauge, suspect how much of history lies behind those simple instruments—history which we do not propose to consider. At present we are concerned more with the application of old principles to new tools.

The Main Divisions. The tools used for measurement may be conveniently divided into two very broad groups, in which, as we might suspect, there is some slight overlapping. One includes the tools employed for marking out or settling dimensions directly, with reference to absolute dimensions. To this group belong the rules, scales, compasses, dividers, and allied forms. The other embraces those which are employed for measuring or checking by the contact of rigid parts, possessing a certain degree of known accuracy. In this great group are included all kinds of gauges, besides straightedges, squares, levels, bevels, etc. Some of these are, however, used also for marking out and checking. And the gauges are all derived originally from the absolute measurements of the rule. Thus, one group of measuring instruments is adjustable, while the other is not. In the movable group, dimensions are taken by inspection, and in the fixed group by the sense of touch or contact. This is a most important difference, for although the latter might seem to be the most accurate possible, yet it is not so in fact. It is the most sensitive, but the finest measurements ultimately have to be referred to micrometric divisions, notwithstanding that the sense of touch is capable of detecting differences as minute as any measuring machines will indicate.

There is therefore a fundamental difference between measurements taken by the divisions on a rule and those taken by fixed and unalterable gauges. The first is the older, the second is the modern. The first is lessening, the second grows, until in some departments of modern machine shops a common rule is rarely used or seen. If this rule is employed for some details, it is only for comparatively rough measurements, and not for really accurate work. For no two persons can take a measurement precisely alike with a rule, because the sense of sight alone is trusted, and this is deceptive. He is a very accurate workman who can read within a hundredth part of an inch from a rule, and this is a very coarse dimension. Further, it is obvious that there is very much of measurement which cannot be taken with a rule at all. A rule is adapted for taking a dimension only along a plane external surface. Cylindrical and spherical surfaces, the dimensions of irregular outlines, the mutual coincidence of any portions of work which have to fit one another perfectly, without being tight on the one hand or sloppy on the other; the accuracy of screw threads, and much more of a kindred character cannot be determined with a rule. In all modern workshops, therefore, the tendency is more and more towards the abolition of the rule for all except the very roughest work, and the substitution of various gauges in its place.

Standards. The question of standards does not much concern the workman, although it is of first importance to the manufacturer. We have travelled far since the barleycorn, the cubit, the length of the foot, the handbreadth, and so on were standards suited to the needs of agricultural folks. Accurate measurement became possible only when a national standard of length was fixed, using a bar of metal of a definite material, which had a definit length at a definite temperature. Such is the national British standard preserved in the Houses of Parliament.

The present English standard dates from 1824, when the yard bar made by Bird in 1760 was legalised. But that bar was destroyed by the fire in the Houses of Parliament in 1834, and a new one was made from five existing copies. It is termed "Bronze No. 1," kept in the Houses of Parliament. About forty-four copies were made in bronze and distributed among various public bodies, and these are the standards from which manufacturers have made their own standards for private use. The story of these bars is an interesting chapter in the history of manufacture. Their accuracy at a definite temperature lies within a few millionths of an inch of absolute dimensions. They are never touched for the purpose of making copies from them, and many precautions are taken to prevent alteration in the length, and flexure. The metric standards, which are based upon the supposed length of a ten-millionth part of an arc of the earth's meridian, have no virtue by reason of being based upon a natural measurement, even supposing the length taken were correct, which it is not. There is no need to seek a standard in reference to any natural dimension. The important point is to have a recognised standard which can be easily verified at any time, and this the British standard affords.

But to have such a standard is one thing, its application to the varied requirements of engineers and those engaged in constructive work is another. When the first standard was made a century and a

half ago the methods of measurement in use were utterly crude and coarse by comparison with those of the present day. The 2-ft. rule and the common calipers were the measuring instruments chiefly employed. Those were the days when large screws were cut by chipping and filing, when small ones were cut with solid dies, when cylinders were ground out and not bored, when no standard screw threads were in existence, when there were no planing machines or shapers, no gauges, no milling, or machine grinding, and when $\frac{1}{16}$ in. and $\frac{1}{8}$ in. were fine dimensions.

The era of modern accurate measurement began with Whitworth, but its development has far exceeded anything which his most sanguine visions could have anticipated. Yet in showing that the most refined and accurate measurements must rely on the sense of touch and not on that of sight for their appreciation, and that for definite measurements to be read off they must be read in degrees of revolution of a micrometer screw, he pointed the way to all subsequent improvements in measuring instruments. His plug and ring gauges, and his famous measuring machine embodied these principles, and were the precursors of other contact gauges of special types, and of special measuring instruments, and micrometer calipers.

Intermediate Standards. The methods by which dimensions are transferred from the original standards to the intermediate ones, or copies, are too abstruse for a brief description here. It must suffice to say that no instruments of measurement are ever permitted to be brought into actual contact with the original standards, because that would involve wear. Lengths are therefore transferred by means of microscopic readings from line divisions, and by means of light reflectors from end measures. The intermediate standards which are made and kept for reference in manufactories generally take the form of gauges—that is, instead of having a yard bar, or a metre bar, subdivided into lines, a gauge bar or some one of the numerous types of gauges, each of which gives an end measurement only, estimated by contact and touch, is used. For obvious reasons these are more trustworthy in the hands of workmen than the fine divisions on a standard rule would be, because the former can be *felt*, while in the reading of the latter errors will arise, and a vastly larger time would be occupied in the latter than in the former. When it is necessary to determine exact line measurements in a modern shop, in order either to test a gauge, or to ascertain or to work to an odd dimension for which there is no gauge made, then the micrometer caliper is used for small dimensions, or the measuring machine for larger ones. Each of these types is the offspring of Sir Joseph Whitworth's millionth of an inch measuring machine.

The Rule. We begin our description of the working instruments of measurement with the rule. This is made for reading direct measurements as estimated by the eye, and for taking dimensions from with compasses and similar tools. The forms of rules vary with the requirements of many trades. Those of wood are used chiefly by the woodworking crafts, but metal ones mostly by metal-workers, who are partial to the short rules of 4 in., 6 in., and 12 in. in length, which can be carried in the pocket. Folding rules are not used when very accurate results are desired. The graduations on rules are marked generally, though not invariably, on both sides, and only some of the main divisions of inches are finely subdivided. Large numbers of fine divisions and of fancy divisions are confusing. Only those in frequent use need be given, as
$\frac{1}{32}$ in., $\frac{1}{64}$ in., and $\frac{1}{100}$ in. are less often wanted. A small, separate rule may be kept with these divisions on, and a separate rule for decimal, and for metric divisions. Many rules are made specially narrow to go into confined spaces; others are made flexible to bend round curves. Rules are often combined with squares, the blade being graduated. In doing accurate work measurement should not be taken from the end, because that is subject to wear. It is better to start from one of the inch divisions and read.

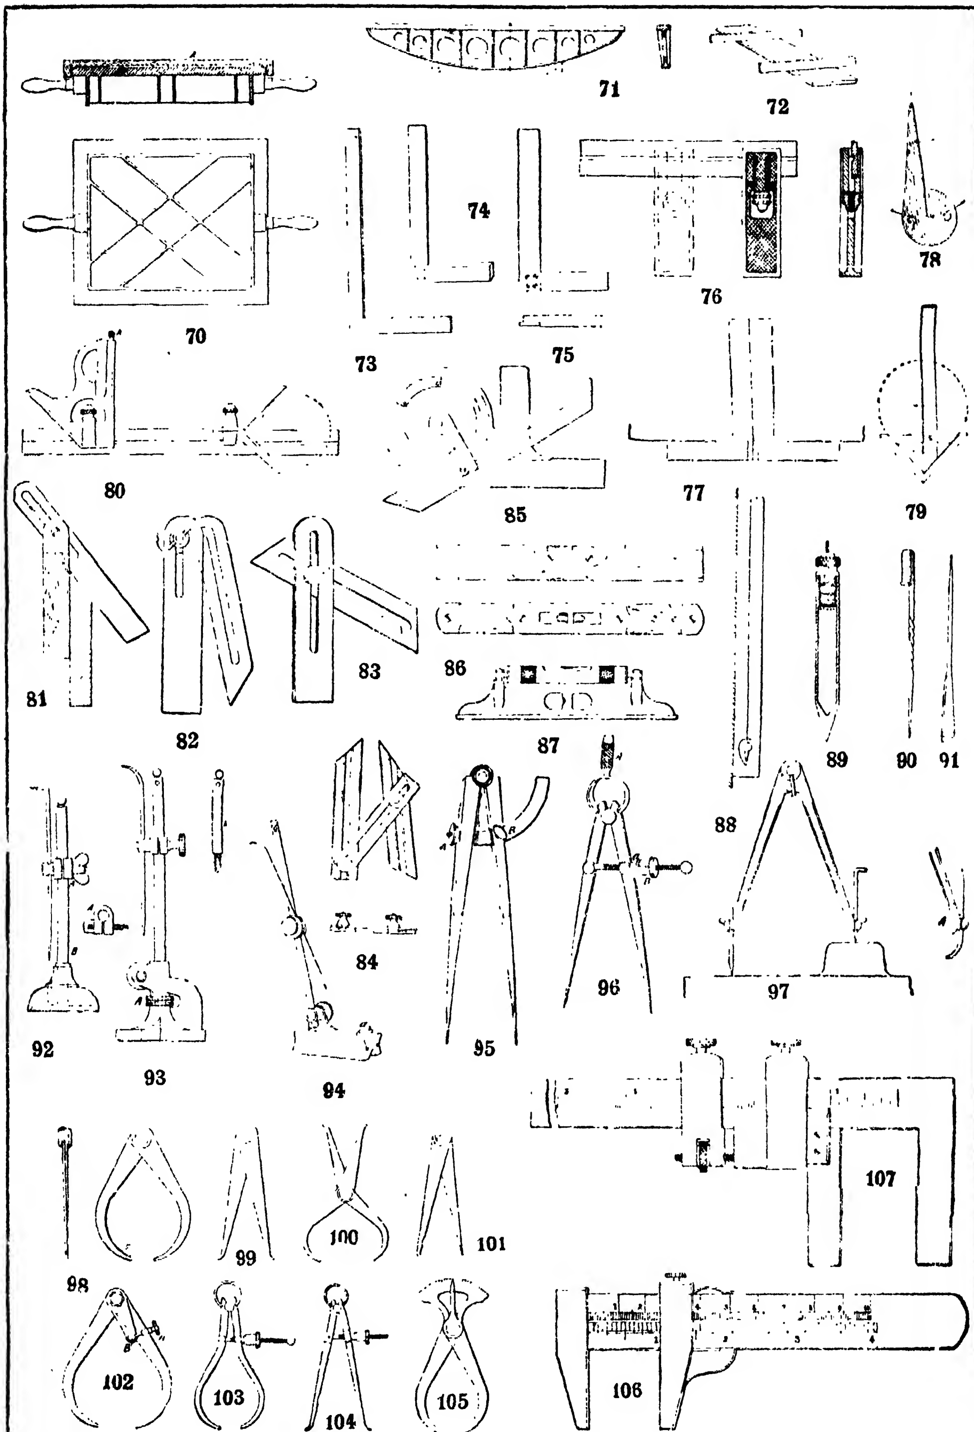
Tapes, Rods, and Scales. Tapes are flexible rules, convenient when lengths of many feet have to be measured. They are indispensable to land surveyors and builders, and to a limited extent are used by engineers for measuring large circumferences and laying out long dimensions. But they are not accurate enough for very precise work, because their length varies with alterations in temperature, and, moreover, they can be stretched by a pull. For accurate lining out, rigid rods of yellow pine, about 2 in. square in section, and properly seasoned, are used and divided off into feet and the coarser subdivisions on a length of from 5 ft. to 10 ft., the ends projecting an inch or two beyond the neat lengths. Then a brass rule, finely divided, is sunk into the first foot division. End measurements are not taken, but only those from the edge, thus the rule never wears. Lengths shorter than the rule may be readily taken, and those of greater length, by moving the rule endwise, with practically no risk. When fine fractional dimensions are required, in these, as in other rules, the reading is taken backwards—that is, from the termination of a 12-in. division which is not finely divided back to the first foot (or, in common short rules, to the first finely-divided inch).

Scales are used for laying out on or taking dimensions from drawings which are made to some proportion less than exact size. They have been described in the course on DRAWING FOR ENGINEERS. They are not used so much in the shops as they were, because now more detailed drawings give views to actual dimensions than was formerly the case. Even when drawings are made to some smaller scale, dimensions are nearly invariably figured on.

The rule is often combined with other instruments which contain provision for contact measurement, as in the slide caliper rules, which will be better illustrated when we consider the forms and uses of calipers.

Surface Plates. There is a large group of tools which are not employed for actual measurement, but for marking and testing the truth of surfaces, centre lines, and edges. This group includes all straightedges, surface plates, squares, bevels, levels, plumb bobs, and allied forms. Though they have this one feature in common, they differ widely in forms.

A plane surface is one of the most difficult figures to produce, and the genius of Whitworth was required to show how alone it can be done. He substituted scraping for the older method of grinding, and showed that in order to originate an accurate surface three surfaces must be mutually corrected. For though it is obviously easy to make one surface coincide with a second one, it does not follow that either is accurate. If No. 1 is concave, No. 2 will be convex, or vice versâ. But if three plates are prepared, and Nos. 2 and 3 are fitted to No. 1, and then No. 2 and 3 to each other, and then No. 1 to Nos. 2 and 3, this process of mutual correction



VARIOUS SMALL TOOLS

Beam caliper

can be continued until all the plates are as true as the limitations of the materials themselves will permit of. The final corrections are extremely minute, and carefully localised, as indicated by the contact of the merest film of oil interposed between the plates. The plates themselves [70] are ribbed to lessen chance of flexure, and are supported on three points only. As in the measuring tools, so in these plates, some are kept only for the correction of the actual working plates, which are distributed about the benches, and all alike are covered [70] A when not in use. These plates are used for testing the truth of surfaces that are required flat, either for bolting up to others, or for sliding. They are often employed as a base for lining out work on, though that is not a legitimate function, because all occasion of unnecessary wear should be avoided.

Straightedges. There is no essential difference in the surface plates and straightedges. The latter must be originated in the same way as the surface plates. But either can be, and is, derived from a standard surface plate known to be true. A straightedge, however thin its edge, has sensible thickness, and therefore its edge must be a true plane, or free from winding. The larger shop straightedges of several feet in length [71] are often two or three inches in width on the edge, and are really narrow surface plates, only the length vastly exceeds the width. These are of cast iron, deeply ribbed, often with feet as shown by dotted lines, and got up by scraping, and are used for scraping large machine slides by and as standards for the production of smaller straightedges. When used for testing the slides of heavy machines the straightedges are held up in the crane-sling, face downwards, and lowered on to the work for trial.

These larger straightedges are generally cambered, as shown, to lessen chance of flexure. But those of moderate and small dimensions are parallel. They are made in metal and in wood. Two parallel straightedges of equal width are *winding strips*, or *parallel* strips [72], and they are used to check the winding of plain surfaces or that non-plane condition in which one or more portions stand higher than others. The value of the winding strips is that, being longer than the width of surface being tested, they magnify the inaccuracies, which are readily seen on sighting along over the top edges.

In testing work with the straightedge, chalk for timber, and red lead in oil for metal are generally used, to show by transference of the chalk or lead from the edge to the face of the work the parts where contact occurs. This contact should be light. Hard pressure and rubbing not only distort, but wear the edges unduly. Also a straightedge should be held vertically, and not tilted at an angle to show the light, which is not a reliable position.

Squares. The numerous squares and bevels are combinations of straightedges, the squares being two straightedges fixed at right angles, the bevels with angles capable of variation. The requirements of mechanics are so extensive that each group includes several designs and sizes.

There are two kinds of squares—the *try*, or *trying square*, formed of two blades at right angles, and the *set* square, the web of which is continuous. The first is used for testing both external and internal angles, chiefly the first: the second for internal angles only. Some try-squares have the *stock* and *blade* of equal thickness [73], but usually the stock, or shorter arm is of greater thickness than the blade [74] as being more convenient in use, the edge of the stock affording a steady, maintaining the blade straight and square across the material. This is sometimes exaggerated by forming a broad flange on the stock, so that the square will stand upright. Being wide, it will not scrape up the sand in foundry moulds, in which work it is specially used.

Variations in trying squares occur chiefly in dimensions, and methods of fitting the blade to the stock. The first have a very wide range, from 2 in. or 3 in. to as many feet. The feature which controls the second in the modern squares is the nature of the provisions for securing the blade and stock. The old plan, and that most common still, is to cut a saw kerf down one end of the stock, insert the blade [74] and rivet it up. But the two cannot be detached again for correction due to wear, nor is it certain that the edge of the blade is pulled up to a good bearing. Hence devices exist for accomplishing both. Blades are screwed in or on their stocks with tapered screws or split screws, which pull the blade against its shoulder, and which may or may not be supplemented by plain screws. In some squares the blade is fitted against an open face [75]. Another provision sometimes made is that for adjusting the blade transversely to its stock [76] which can be appreciated when a blade is too long or too short to go into a recessed situation. A clamping bolt is fitted in the stock, and the blade is grooved to receive the hooked head of the bolt.

A square is tested by setting its stock against an edge known to be true, and by scribing a line on a face coincident with an edge of the blade. If, on reversing the position of the stock, the same edge coincides with this line, the square is true; but if not, then the square is inaccurate by half the amount of difference [77].

Set Squares. These are always thin, made of wood, or metal, or vulcanite. They are used to test internal angles. A subsidiary utility is that of combining certain common angles between the hypotenuse of the angle and the right angled edges. These are 45 deg., or else 60 deg., and 30 deg. The transparent celluloid squares are useful for the draughtsman, because they permit of seeing lines and figures on the drawing beneath them.

Tee Squares. These differ from the trying squares, in that the stock is prolonged to right and left of the blade, since this type is used only flatwise by draughtsmen against the edge of a board.

Centre Squares. These are squares only in name. The working edge of the blade makes a tangent to any regular arc against which it is laid, and therefore coincides with the centre of the arc, which centre is located by the intersections of lines obtained from two or more settings of the square. These are made of wood, with pins to make contact with the edge of the arc [78], and with metal edges set at angle of 45 deg [79]. In another form, seen to the right in 80, the instrument is made to fit a rule, which thus becomes the blade. The instrument to the left in 80, also clamped to the rule by the same device as that shown in 76, combines a square, a bevel of 45 deg., and a spirit level. A plain scriber is also screwed into the frame at A for use when detached.

Bevels. Bevels are also incorrectly termed *bevel squares*. They are used for laying off and checking angles, which, however, are not marked on the bevels, but obtained from a protractor. They comprise a rigid stock, and an adjustable blade, which is tightened at any angle by means of a screw.

The objection to the common bevel [81] is that in small angles the inner edge of the blade com

so far down the stock that the available length of the blade is much shortened. To remedy this is the reason for the *offset* design [82], in which the available length of the blade is the same at all angles. The long open slot also in the common bevel is objectionable when checking the edges of very thin material, and this is absent in the offset type. In **83** the stock is slotted as well as the blade, so that by moving the latter down the slot, either side of the bevel can be used, which is impossible in **81** or **82**. The combination bevel with three blades [**84**] provides a wider range of utility than the ordinary type. The ends of the blades are also ground to definite angles.

Protractors. These, also termed *bevel protractors*, have the angles set out on the face. The common form is a plated half disc divided round into degrees, from which a bevel is set, or lines marked off directly. But many instruments include a blade adjustable round a graduated plate [**85**] with a vernier reading.

Spirit Levels. These [**86**] are used for testing the general level of surfaces, not in the same sense as surface plate tests, but for setting up a surface known or assumed to be true in a truly horizontal position. They are employed by many trades, but chiefly in the departments of building and engineering.

Levels are mostly short, measuring less than 1 ft. in length. Unless a surface were perfectly true, these lengths would be insufficient to afford a fair test to the general horizontal accuracy of a surface several feet in length. They are therefore laid upon the top edge of a parallel straightedge, long enough to extend over the surface to be levelled, so averaging all slight inequalities. Sometimes the level and straightedge are permanently united, which is a good plan where the work done in a shop is of a uniform character.

Levels used in the ordinary manner wear in time on the base, and so cease to indicate truthfully. Then, if the instrument is turned end for end, the one-sided positions of the bubble must be alike on reversal if the surface is true. But some levels contain provision for adjustment [**87**] to compensate for wear, in the shape of nuts which clamp lugs in which the ends of the bubble tube terminate. The ordinary rigid levels must have their base corrected now and again.

The woodworker uses chiefly levels with wooden stocks [**86**], the metal-worker with those of metal [**87**]. The wooden ones are generally protected with brass plates next the ends. The bubble tube is sunk into the wood and covered with a brass plate with a central bridge. In some metal instruments the tube can be turned round in a casing of brass for protection [**87**]. Many levels have a side sight; the ordinary wooden ones can only be seen by looking down directly on the top. Combination levels are those which have provision for testing the truth of perpendicular faces in addition to horizontal. They contain two bubble tubes at right angles in one stock. Some levels have a vee'd base, which allows them to be used on shafts or tubes.

Plumb Bobs. These are for testing the vertical truth of faces and centres, and depend for their action on the suspension of a pear-shaped weight with a point from a cord. This may be used alone, or in combination with a straightedge, termed a *plumb rule* [**88**]. In one type, a hollow tube with a pointed end is filled with mercury [**89**] which comes to rest quicker than a bob of lead, and is smaller for a given weight.

Marking and Dividing Instruments. Sharp-pointed instruments of various kinds occupy an important place in the work of measurement. These include scribers, surface gauges, compasses, dividers, trammels in various designs, which are constantly being used by mechanics working in wood and in metal. Lines must be *scribed*—that is, scratched or cut, and centres must be pricked or *popped* to be permanent and unobliterated by the usage of the shops, and to be accurate enough to cut by. The finer the lines the better, so long as they are visible, because a thick line has sensible width, which is objectionable.

The Scriber. This is the instrument by which lines are drawn, guided by the edges of squares and straightedges. One end is a point [**90**], the other is often a knife edge [**91**]; **90** is the engineer's scriber, the hook at the opposite end being often made to hang the instrument over the pocket-edge of the trousers; **91** is the form used by woodworkers, the knife edge cutting like a chisel into the wood.

Surface Gauges. Mount a double-ended pointed instrument in a support, and the surface gauge, or *scribing block*, in its crudest form results. For the steady block affords a rigid support to the scriber, and the latter can be adjusted vertically, and traversed along the faces of work, scribing lines as it goes; hence one of the utilities of the marking-out table with its true face. In this way any number of horizontal parallel lines can be scribed at all heights within the range of the surface gauge. All the differences in these tools are matters of detail, differences in plain commonplace tools and those of high precision. These variations consist chiefly in the mere adjustment and pinching of the scriber holder by a thumbscrew, and the employment of finely-pitched or micrometric screws for effecting the adjustments. These take various forms in the hands of different manufacturers, the result being that positive and exact minute dimensions can be obtained by divisions on the instruments themselves. These are a great advance on the old blocks, which had an upright piece, against which was clamped a flat slotted scriber. The scribers are made of round rod in most cases now. Three forms out of many are illustrated in **92**, **93**, and **94**. In **92** the scriber stem is carried in a split lug, A, tightened with a screw and wing nut around the scriber, and on the stem or pillar, B, which is supported on a steady base hollowed underneath to leave an annulus only of bearing surface. This block, in common with others, has a hole in the base to permit of passing the scriber down to form a depth gauge. In **93** a refinement occurs in the form of the milled nut at A, which by means of a finely-threaded screw inside the base affords a fine adjustment to the height of the pillar, and saves troublesome tapping of the scriber to make minute alterations in the height of point. There are several other methods of effecting fine adjustments. Fig. **93**, B is an extension piece for increasing the range of the instrument. A high-class universal gauge is shown in **94**. The stem is pivoted in a lug in a heavy base, so that it can be set in any position between the vertical and horizontal. The base is vee'd to fit circular bodies as well as flat faces. Friction springs retain the stem in position while making adjustments, and also the scriber in its clamping boss. Pins at *a* are fitted to be pushed down below the face of the base; when the base can be slid along the edge of a surface plate to mark lines on a horizontal face. Many scribing blocks have rules fitted, some have a micrometer, making them very precise instruments of measurement.

Dividers, Compasses, and Trammels. These instruments are used both for dividing and for marking arcs of circles. Hence they occur in a large range of dimensions and degrees of precision; from those adjusted by the hands merely and clamped with screws, to those in which the adjustments are micrometric in fineness and precision. In strictness there is no essential difference between the dividers and compasses, because many of the latter combine the finely-threaded screw of the former. But commercially the dividers are classed as those which are opened by a spring, and closed by a wing nut and screw; and compasses are either clamped with a screw pinched on a quadrant or have in addition a fine adjustment or screw; or have neither, comprising legs and hinge only, with or without a clamping screw in the hinge. Thus **95** is a compass, **96** dividers. Fig. **95** is the best form of common compass, because it combines the fine screw adjustment at A in addition to the clamping wing nut at B. The dividers [**96**] differ from the older kinds in having a spring loop separate, and only attached to the legs instead of being in one with them. There is a knurled stem, A, which renders it easier to handle and twirl the instrument than by holding the spring itself. The nut at B is also an improvement on the solid nut, because when the legs are sprung together a little with the left hand the nut frees itself from the thread, and can be slid along instantly, instead of being turned through the whole distance. On releasing the legs, the nut grips the threads again. The nut, B, is like a split chuck, its nose being coned to match a coned ring, *a*. When *a* presses its cone on the nose of A, the latter is compressed inwards sufficiently to engage with the screw threads; when free from the coercion of *a*, its elasticity causes it to open outwards.

Most compasses have rigid legs, but some have also supplementary points [**97**]. The advantage of the latter is that the points, moving in pivoted holders, can be set perpendicularly, however much the legs may be spread, and also that the points may be set in different planes to suit centres or arcs which are not in the same plane. Often these combine calipers with points, being situated at opposite ends [**97**] A, the legs being pivoted to the main legs, still with advantage of perpendicular setting. In other forms this combination exists in the *compass calipers*, or *hermaphrodites*.

Trammels. These are for larger radii and centres than can be obtained with compasses. The trammel heads slide along and are adjusted and clamped on a parallel beam of wood or metal, and designs vary. Some have a fine screw adjustment on one head, some combine provision for inserting a pencil in a tube on one head; but generally two points only and clamping screws are included.

Calipers. The basis of all the contact gauges is the common adjustable caliper, comprising two legs adjustable round the pivot, and capable of taking either external or internal dimensions. The length is then read off on a rule or a gauge. Any common calipers can be used for taking external or internal dimensions. But it is more convenient to have two instruments, the former [**98**] bow-legged to pass over large diameters, the latter [**99**] straight to go into small bores and spaces. These constitute the two types on which modified forms are fashioned, with or without capacity for fine screw adjustment. Sometimes the two instruments are combined in one on opposite sides of a central pivot [**100**], in which case both pairs of points should give the same dimensions. This type is also useful for measuring chambered recesses, the straight legs being passed through and opened out, when the size is measured from the curved legs lying outside; it would otherwise be impossible to record the dimensions, because when the calipers are removed from the chamber, they must be squeezed inwards, and the size is therefore lost. Hermaphrodites, or compass calipers [**101**] are not true calipers, but they have one pointed compass leg and one caliper leg. Their value consists in scribing lines from edges, guided by the caliper leg moved round or along the edges. Centres can also be found when plugs are inserted in rough bores preparatory to marking out for boring, etc.

Calipers of the foregoing forms are adjusted finely by tapping lightly one leg against a rigid body. But others include screw provisions for such adjustments, by which much time is saved. Thus in 102 a fine screw, A, with a knurled head, moves in a nut, B, at the end of the plate attached to the joint. Figs. **103** and **104** are variants on the type of compasses shown in **96**, both in regard to the fitting of the nut to the screw, and in having a spring head. Though in most cases the caliper must be set on a rule or gauge to read the dimension taken, some instruments combine a quadrant rule [**105**], or sometimes a straight rule on the side opposite to the legs, on which the dimensions can be read off. These forms are not popular, but the same principle in other guises—that of the caliper rule and vernier, and micrometer calipers—are largely employed.

The Gauges. Though in the calipers the sense of touch indicates when they are in actual contact with the turned work on opposite sides of its diameter, this device is not an ideal one, because the rule still affords the final test of truth, the calipers being laid directly upon the divisions of the rule in order to determine the size required. This, therefore, is not in strictness a mode of measurement obtained by the sense of touch, since the rule becomes the check, which is of an ocular kind. In order that the system of measurement by touch shall be strictly carried out, the caliper must be checked not on the rule, but against a fixed and rigid standard such as another caliper, or a gauge. To this the objection may be made that it would involve an expensive series of fixed gauges, because the number of dimensions required would be numerous, and this would be true in a degree. The system is expensive in its first inception, but it conduces to such great economies ultimately that all firms who run their shops on modern lines adopt it. The simplest case which occurs is that in which there are two gauges for any one dimension—namely, external and internal—so that while one is used for testing the accuracy of external parts, the other is employed similarly for internal parts which have to correspond. Or if there is no such correspondence, a definite dimension is secured at once, with a degree of precision which cannot be obtained by reference to a rule. Modern systems of measurement are thus both absolute and relative. That is, a dimension may be worked to fractional portions of the inch, or it may be made to correspond with another dimension. In each of these cases the methods followed to-day are essentially those of Whitworth, and though the devices adopted in each case are different, yet the verification in each depends on the sense of touch. To the first or absolute class belong the caliper rules, vernier, and micrometer calipers, to the second the fixed gauges.

But the division into rule measurement and contact measurement is not of a hard and fast character. Many instruments combine the two functions, as the micrometer and vernier calipers.

Caliper Rules. The simplest caliper rules comprise a beam with a fixed jaw at one end [106], and another jaw which can be slid along the beam, and adjusted and clamped to give any width of opening within the range afforded by the length of the beam. The latter is divided out like a rule into English or metric subdivisions, or both. These are sometimes made in wood, but mostly in metal, and fill a useful place in the shops, but they do not admit of measurements of higher precision than the rules do. They simply save the trouble of taking separate measurements, and comprise a caliper grafted on a rule.

A refinement on the caliper rule is the so-called *caliper square* or *beam caliper* [107], which is a stage between the rule and the vernier types, points in which will be noted in connection with the latter.

Vernier Calipers. For very fine measurements the vernier is applied to the caliper rule, or beam caliper, or vernier caliper, producing a most valuable instrument. Its design and construction is shown applied in **108**, and the vernier is enlarged in **109**.

Each inch along the bar or beam is divided into ten parts, and each tenth into four parts, so that each inch has forty divisions. The sliding jaw of the caliper carries the vernier, A, on which a length equal to 24 divisions of the main bar is divided into 25 parts [109], or 20 parts in **108**. Clearly, therefore, each division on the vernier in **109** is shorter than each division on the bar by one twenty-fifth part of the fortieth of an inch, in other words, by ·001 in. When the zero mark on the vernier and the bar coincide, the caliper is set to 1 inch. Any other distance, excepting those at the cardinal divisions, 2 in., 3 in., etc., is taken by the distance to which the zero scale is moved to right or left of the zero on the bar, or the inch divisions on the same. The distance to right and left is counted as the number of divisions the zero point on the vernier has been moved, say, from the zero point on the bar. The number of divisions counted to where one is found that corresponds with one on the bar will be the number of thousandths to be added to the distance read off on the bar itself. Calculation is facilitated by calling the tenths (·100), one hundred thousands, and the fortieths, twenty-five thousandths (·025).

In the illustration [109] the vernier has been moved to the right $1\frac{2}{10}$ in., or 1·20 in. The sixth line of the vernier coincides with a line on the scale (indicated by the arrow), so making $\frac{6}{1000}$, or ·006 in., to be added to the reading from the scale, making the total reading one, and two hundred, and six thousands inches, or 1·206 in.

Around this vernier caliper several designs are evolved. Generally provision is made for fine adjustment of the sliding head by means of a fine screw in a second sliding head, B [108]; also in the beam calipers [107], which is brought up and pinched at a convenient distance away from the head to which the loose caliper jaw is attached. Other devices are used in Continental designs. Many of these calipers are made with compass points on the side opposite to the caliper jaws. Also inside and outside calipers are formed on opposite jaws.

The other great group of calipers, the micrometer type, differs from the vernier in the method of obtaining fine divisions, which involves a different shape.

Micrometer Calipers. In this design the principle is that of the Whitworth measuring machine—namely, the subdivision of the pitch of a finely pitched screw by equal divisions on a circular wheel. Obviously, for a movement of each arc of division on the wheel the screw moves a jaw through a corresponding division of the pitch, which is therefore a definite dimension, however fine it may be. The principle is worked out in a different manner in the micrometer calipers than in the larger measuring machines, and they do not read to so fine dimensions. The following is a description of the Brown and Sharpe micrometer [110], typical in the main of others.

Fig. **110** gives views of the same instrument in external perspective above, in longitudinal section below, with a ratchet stop to the left [111]. The figures on the horseshoe are decimal equivalents, for ready reference. The spindle A is movable to and from the anvil B, and between these the work is measured. A is actuated by the fine screw C. D is the barrel, in one with the horseshoe arm E. The screw fits in a nut, F, which enters a recess in the barrel. A similar threaded nut, G, affords additional support to the screw, and is used to take up wear. It is threaded externally to fit a screw cut in the end of the barrel D, and with one cut in a lock nut, H. The screw threads in G and H are finer than those of the main screw, C, for exact adjustment. A ring, I, encircles the plain spindle A. It has a split tapered boss threaded externally to take the sleeve, J, with a knurled head. This clamps the split boss around the spindle A, locking it after setting. A variation in the position of J is shown in the upper and lower figures.

These calipers measure to $\frac{1}{1000}$ in. The screw has forty threads per inch. The graduations on the barrel, some of which are seen at *a* in the upper figure, in a line parallel with the axis of the screw, are also forty to the inch, beginning at *O*. Each division, therefore, corresponds with the longitudinal distance traversed during one revolution of the screw. The bevelled edge of the thimble adjacent is graduated into 25 parts. As 40×25 equals 1,000, each movement of the thimble round one division advances the screw $\frac{1}{1000}$ in.

Very Fine Measurements. Smaller readings can be taken by estimating by the eye a half or a quarter of a division round the thimble, so that a half or quarter thousandth can be estimated very accurately. But for finer divisions a circular vernier is embodied. It has 10 divisions, which occupy the same space as nine divisions on the thimble. When a line on the thimble coincides with the first line on the vernier, the next two lines differ from each other by one-tenth of the length of a division on the thimble, and so on. Hence, when the thimble is turned so that a line on it coincides with the second line of the vernier, the thimble has moved one-tenth of the length of one of its subdivisions, or $\frac{1000}{10} = \frac{1}{10000}$.

As it is possible to vary the amount of pressure on the instrument, and thus obtain varying readings, a ratchet stop [111] is fitted to some calipers. It is a ratchet, A, with a spring pawl, B. If more pressure is exercised than that which suffices to set the instrument, the ratchet slips past the pawl and stops the further turning of the measuring spindle. When opening, the pawl catches the ratchet and prevents slip.

Variations in this type of caliper by various makers consist in different methods of taking up the wear on the screw for the purpose of re-adjustments after long service, some making it on the

anvil, some on the thimble. Also in the comparative fineness or coarseness of the readings, in the range of dimensions available, and in the graduations in English or metrical dimensions. Other variations are the combination of two calipers in one head for different ranges of dimensions, or for two dimensions nearly alike, as for slack and driving fits. Others are made for special functions only, as for measuring screw threads, wires, tubes, sheet metal, etc. Another distinction is that between small and large types, which involves a difference in design.

Large Micrometer Calipers. The small micrometers do not usually exceed 2 in. maximum capacity, but larger ones are made of horseshoe and beam types for larger dimensions. In these the range of the micrometer screw movement is still small, not exceeding 1 in. usually, but the larger dimensions are obtained by the large size of the horseshoe in the one case, and of the length of the beam in the other, along which a movable head can be set in several positions.

Fig. **112** is a large horseshoe caliper, with a micrometer spindle to the right. The anvil to the left has provision for taking up wear with two ring nuts, and two other anvils (one of which is shown separately at A) are supplied for sizes which the 1 in. range of the micrometer cannot accommodate. The longest anvil would, for instance, measure from 3 in. to 4 in., the next one 4 in. to 5 in., and the shortest 5 in. to 6 in. Beam micrometers are shown in **113**, **114**. The main inch divisions are obtained by clamping the main head, A, with its set-screw, B, by the line on the bevelled edge at *a*. The adjusting block, C, is clamped also near A, in order that the exact setting of A to the inch divisions may be effected by the milled head, D, operating a fine screw. The micrometer then gives parts of the inch.

In **114** the head is set precisely by means of a plug, A, pushed through a hole in both head and beam. The plug is hardened, and the holes are bushed with hardened steel. Each separate hole in the head matches its own in the beam for every inch, thus spreading the total wear over the six holes and simplifying the work of manufacture, since, when a set of plug-holes are lapped out correctly they are done with, and the next holes are treated—a much simpler job than trying to make a single hole in the beam answer for all the settings.

From these leading instruments many others have been derived, or their underlying methods have been grafted on common tools in order to render them instruments of high precision. They include several kinds of depth gauges and rod gauges, which in their crude forms every workman has to make use of in measuring depths below a surface, or diameters of bores, or distances between opposed faces in situations where the common rule or calipers cannot be introduced or would not be suitable. The vernier and the micrometer both appear in these instruments, varied in their methods of application according to the ideas of different firms.

Rod Gauges. Fig **115** is a high-class rod gauge with micrometer readings at the right hand, an immense advance on the gauges made by workmen. The principle is identical with that of the micrometer calipers—namely, a finely-threaded screw, A, and a divided head, B, the graduations of which are read as they pass the arm C. The screw D clamps the setting, if required, by means of a brass anvil pressing on the micrometer screw. To increase the range of the instrument, extension rods, E, are fitted in a socket, and clamped with a screw, F. Other types of these gauges are made with the screw entirely concealed and protected.

Depth Gauges. Fig. **116** is a high-class micrometer depth gauge, which can also be used as a rod gauge on being detached from the foot, A, to which it is screwed, with a hardened contact piece then inserted in the screwed end. This end, B, contains the micrometer screw and the bevelled edge at *a*, the circular divisions corresponding with the thimble in **110**, and reading to thousandths of an inch. The stem or rod, C, is graduated in inches and quarter inches. The sections to the left show the splits for taking up wear.

Fixed Gauges. These all have one feature in common—the embodiment of a rigid unalterable dimension. They occur in numerous forms in cylindrical and flat types, and in various degrees of accuracy, relatively coarse and fine, and in standard and in limit sizes. Some of the most refined mechanical methods are involved in the manufacture of these instruments, including hardening and extremely fine grinding, so that degrees of accuracy range from the coarse $\frac{1}{1000}$ in. to the very fine $\frac{1}{100{,}000}$ in.

Much work in engineers' shops has to be accurate within $\frac{1}{100}$th of an inch, a very great deal within from $\frac{1}{500}$th to $\frac{1}{1000}$th of an inch, and finer. Now, it is easy to observe $\frac{1}{100}$th of an inch by sight alone; it is not possible to estimate $\frac{1}{1000}$th, much less $\frac{1}{10000}$th by the eye. And although $\frac{1}{100}$th is visible to the eye it is not practicable to work to that dimension by setting the rule against the work. In all these fine measurements, therefore, the sense of touch is relied on, and the means used are afforded by gauges ground to precise dimensions required.

Plug and Ring Gauges. In their simplest form these consist of one plug and one ring [**117**, **118**] of the same dimensions. That is, the plug can be just inserted within the ring if a very fine film of oil is interposed without any slackness in fitting. The oil is necessary, because if not applied the one would *seize* or hold so fast within the other that the two could not be separated. Such gauges are termed *standard*, because of exact sizes, as $1\frac{1}{2}$ in., 2 in., or 3 in., no more and no less, within the degree of accuracy mechanically possible.

Now, it is not difficult to see that with these ring and plug gauges absolutely rigid, with no possibility of springing or yielding to pressure, and made to fit each other absolutely, that a piece of tissue-paper, a tangible representation of $\frac{1}{1000}$th part of an inch, could not possibly be inserted between the two gauges, and therefore if work is turned and bored exactly by these gauges, then it will fit within something less than the thickness of the tissue-paper, and that the latter therefore is a coarse dimension.

In one way, however, such gauges might be made to pass work so that there should be two or three times that difference in the thickness of paper. If one gauge were employed at one temperature, and the other at a temperature considerably higher or lower, then when the work should be brought together under normal conditions of temperature, the parts so fitted would not correspond. This at once indicates another element of which consideration must be taken. Then, further, something depends on the nature of the surfaces which are turned, or, when exceedingly fine fitting is concerned, which are ground; whether they are done very smoothly or rather coarsely.

There is another matter which shows how extremely close the fitting of the metallic surfaces can be made. It is quite possible to fit them so well—a plug within a ring—that though they can be slid in while dry, they cannot be separated again. The metallic contact is, in fact, so close that molecular adhesion takes place, and separation must be so forcible that the metal will be striated and torn out by the pressure. But before that occurs the precision of the fitting will have gone past the $\frac{1}{1000}$th part of an inch, with which we started for the purpose of illustration; in fact, as then mentioned, that, though extremely fine if judged by the carpenter's rule, is much exceeded in the engineer's shop, gauges being made to the $\frac{1}{5000}$th part, and the coarser ones to $\frac{1}{2000}$th part of an inch.

Mr. Viall has stated that gauges can be made within a limit of ·00002 in., but makers will not guarantee that they will be within that limit six months after manufacture, since steel changes, "goes and comes." But they can be made and guaranteed to remain for an indefinite period within ·0001 in. He also states that when measuring standard plugs by the aid of the Browne and Sharpe measuring machine, differences of ·00002 in. can be readily felt by those who are not experts in measurement, while by those who are, differences of ·00001 can be readily detected. It is possible to make *working* gauges within a degree of accuracy measured positively by $\frac{1}{30000}$th part of an inch, thirty times less than the thickness of tissue paper! The finest film of gold leaf that floats in the air is about that thickness. Limits of $\frac{1}{50000}$th part are also guaranteed in the best gauges, used for reference.

Limit Gauges. Standard gauges do not measure all the degrees of fitting that are necessary. Thus, for example, the fit of a shaft in the boss of a wheel in which it has to be keyed is a tight, or *driving* fit, or a *force* fit; that is, the shaft must be driven in, or pressed into its bore. But a shaft journal rotating in a bearing must be an easy fit, or a slack or *running* fit, otherwise it would not revolve. But there are also several degrees in slack or running fits, dependent on the classes of work, and ranging from a free fit without any slackness to a fit at the other extreme with $\frac{1}{64}$ in., or $\frac{1}{32}$ in., or even $\frac{1}{16}$ in. of slack. Now, the workmen using standard gauges have to make these various allowances over or under gauge sizes, which results in want of uniformity and some waste of time occupied in making trial fits. This is inconsistent with a system of good fitting, and is impracticable in an interchangeable system. Out of this has arisen the growth of the *limit* or *difference* gauges, in which the *limits*, or *limits of tolerance*, suitable for all classes of manufacture are embodied. These are larger or smaller than standards by the difference required in shafts and their bearings, or in degrees of driving fits. The difference is made in the plug, and not in the ring. Two sizes are generally now made on the ends of one plug, one being a "go in," the other the "not go in," and marked respectively – and +.

Snap Gauges. This term is applied to the flat gauges. These are made in exact fits, and to limits like the plug and ring gauges, and in a range of limits. They also occur in numerous designs—single-ended [119, 120], of horseshoe type [121], and with external and internal gauges at opposite ends of the same bar [122]. The working faces are hardened and ground. Flat and plug limit gauges are shown in 123.

With regard to the difference in the cylindrical and the flat forms, the first named are generally used to check turned and bored work, the ring being slipped over the shaft or spindle, the plug being inserted in the hole of the pulley or wheel. The gauges make contact all round their circumferences, and so check the circular truth as well as diameter, but they cannot be used between two shoulders, such as a journal, the only gauge applicable being one with an open side. For the finest testing the flat gauges give more accurate results, because they have not such large surfaces in contact. This is in harmony with the fact that narrow points are always used in rod gauges. Any width beyond that required for actual contact is superfluous.

The gauge principle, with or without limits, is embodied in other forms, for tapered work, and for testing screw threads, the latter being shown in 124. The upper gauge gives the size of the hole before the thread is cut in it (equivalent to the *tapping size*), and of the thread at the opposite end. The lower tests the screws, and is adjustable by the setting screws to fit the plug accurately, or with a definite amount of slack. The two pins in the body of the gauge prevent lateral twisting of the parts; there is sufficient elasticity in the body to open or close the threaded hole slightly.

Measuring Machines. The basis of all the high-class gauges is found in the measuring machines, which firms keep for testing purposes, and to maintain a check upon gauges in use. Some of these machines are marvellous pieces of mechanism measuring to $\frac{1}{100000}$th part of an inch or less. The famous Whitworth machine, which measured to the $\frac{1}{1000000}$th part of an inch, was the predecessor of later types. The machine had a screw of 20 threads to the inch, which was turned by a worm wheel of 200 teeth, the latter being driven through a worm from a wheel graduated into 250 parts. Hence a movement through one division corresponded to a traverse of $\frac{1}{20} \times \frac{1}{200} \times \frac{1}{250} = \frac{1}{1000000}$th in. This is an example of a machine that does not find scope in practice, but there are plenty of machines measuring to $\frac{1}{100000}$th of an inch. Fig. 125 shows a recent type, made by the Newall Engineering Co. Ltd., Warrington, which measures to $\frac{1}{100000}$th in. The bed carries two heads, A and B, the former having the measuring screw and its disc. As this screw has a traverse of only 1 in., settings must be made from the distances between the heads. Standard end measuring rods are used for this purpose, or a microscope is fitted on the head A to read the graduations on a rule attached to the side of the frame. The screw is rotated quickly by the knurled knob C, or slowly by D, the latter being carried in a rocking lever attached to the screw spindle, and pushed away from a bar, E, by the screw D. The large wheel, F, is divided, and rotates under the indicating bar seen at the top. A compensating device is provided for counteracting the errors in the pitch of the screws, errors which cannot well be eliminated. On the head B a device is fitted which ensures that the end pressure on pieces being measured shall be uniform in all cases. A spirit level is applied in such a manner that it magnifies the movement of the measuring points 4,000 to 1, so that any contraction or expansion of the piece being measured is detected.

Continued from page 4618

POULTERERS AND GAME-DEALERS

In provincial towns the poulterer pure and simple is still to be found in considerable numbers, but in the larger towns and cities, especially of England, he is usually also a cheesemonger, or a fish merchant. In London, for instance, there are probably not more than a dozen men, or firms, who keep open shop solely for the purveying of poultry; but in country towns many good livings are to be made without the cheese, fish, or bacon adjuncts. It follows, therefore, that the conditions of buying and selling—particularly of buying—differ considerably according as the business to be done is in the metropolis or other large centre, or in a country town, with no large central markets like Smithfield and Leadenhall. However, the reader who is interested in this branch of trade may get hints to aid him, whether he purposes starting in the country or in the metropolis. The main idea, however, is to help the man who desires to start in a provincial town or in a suburb to retail poultry and game.

The Primary Essentials. The steps taken to learn the business are simple, but important. There is no regular apprenticeship to the trade. The youth starts his career as errand-boy in the establishment of a poulterer with a good-going business. When not engaged in delivering goods to his employer's customers he is taught how to pluck, clean, and truss fowls, how to skin and clean rabbits and hares, and, generally, how to make the produce ready for the counter. Some men become very expert in plucking—an art not so easy as it looks—nine fowls an hour soon becoming not much of a task for them. Skinning rabbits is much more easily learned, and 100 animals per hour may be skinned by an expert. A period of two years should suffice to teach the lad the elementary principles of the trade, but his experience has to be considerably widened before he can qualify as a poulterer.

Starting Business. Assuming that the young man has acquired an all-round acquaintance with these essentials, and has a capital of about £50 in hand, he may safely embark on his account in a country town, or in a suburb where the necessity for a poulterer and game-dealer is indicated. Of course, in a large city, or in the metropolis, such a capital would be inadequate, provided nothing but poultry and game were intended to be sold. For the business, in London let us say, can be done only in a good-class neighbourhood, where it would be imperative to spend at least three times fifty pounds in fitting-up the shop alone. In the West End, or in any fashionable quarter, the shop of a poulterer has usually elaborate tiled walls and floors, with marble counters and marble window slabs. But the man we have in mind at the moment is the ordinary person with a modest capital and an overwhelming desire to attain to the marble slab stage by honest effort and industry.

Fitting-up. Even in a country town, however, the neighbourhood selected must be a good one. A business thoroughfare, with other good shops in the vicinity, is the place for a shop, and one should endeavour to get a shop which, though not necessarily large, should have plenty of air. A "through draught," although rather trying to the shopkeeper, is a very desirable thing in a poultry shop, for it tends to the preservation of goods which are particularly liable to go "higher" than is desirable if kept for even a short time in a close atmosphere. A lofty, airy shop, with plenty of room in the window should, if possible, be taken, and the fittings required are not a large item. All that is really necessary in this way for a start is a few bars, wooden or steel (wooden for preference), from which the rabbits and hares are suspended. These should be fixed along one side of the shop, while on the opposite side are erected several wooden shelves, on which the fowls, etc., are placed. A counter, a wooden block (for chopping off rabbits' feet, etc.), a chopper, knives, scales, and a spring balance complete the shop paraphernalia, with the exception of a few shelves with hooks screwed into the edges for hanging goods in the window, which ought likewise to have a tiled bottom. The whole of the fittings should cost not more than £15 to £20.

Stock. Of recent years cold storage has revolutionised this as well as other provision trades. Not so many years ago the poulterer depended solely upon home supply for his goods. Nowadays the foreign supply has considerably exceeded the "fresh" in many lines and the foreign trade is growing annually. In a country town even now the main supply of the retailer comes from the surrounding country districts. He buys his poultry and game from the farmers, trappers, gamekeepers, or others authorised to sell game in the neighbourhood, or from gentlemen's estates somewhere within the United Kingdom. But the big towns and cities are now supplied by the foreign game that is shipped daily to the London markets. This foreign produce includes geese, turkeys, and pigeons from France, and fowls from Italy. In the summer season the last-named are sent, chilled, packed in boxes of 12 and 24, but come loose in the winter.

Ptarmigan comes from Norway and from Russia. The country last named also supplies black game, hazel hens, capercailzies, Manchurian partridges, ordinary partridges, and geese, fowls, ducks, and turkeys—all frozen. From Holland wild fowl are obtained; and the Australasian produce includes rabbits, hares, and poultry. America exports to us frozen poultry and game, and, incidentally, our Transatlantic cousins have taught us something regarding the method of packing. The Americans were the pioneers of perfect packing and grading, and their example is now being followed by our own Colonies. Fowls of different grades are packed in wooden boxes, each compartment being made to fit the fowl, so to speak, and not only can the poultry be exhibited with ease, and the minimum of handling, but the weights of each can be depended upon as approximately correct. Canadian turkeys are imported, plucked, graded, and packed in cases of 18 or 24 birds, according to size, tissue paper being placed between the birds and a layer of straw on top. Canada also sends chickens, dressed, to commission merchants in Great Britain and live chickens to importers. Quails are imported in great numbers from Egypt and Algeria, and pheasants and partridges from Austria. Fresh goods are supplied largely to the London markets from Lincolnshire, Cambridgeshire, Norfolk, and from Ireland. A large turkey trade is done with Norfolk.

Laying in Stock. Still keeping in mind the young man with an intimate knowledge of his business and a capital of £50, the question of buying for an opening stock should not be difficult. Knowing the precarious nature of the goods, he would be careful to lay in only a very small stock at first, launching out as he gauged the wants of his neighbourhood. In a country town he would buy direct from the rearers, poultry being bought alive. To start in a small shop his first order would be something like the following. The prices are merely approximate, and vary according to the season of the year and the district.

——	Average Cost.	Average Retail Price.
2 doz. chickens and fowls	£2 to £2 4s.	2s. 3d. to 3s. each
12 pairs rabbits ..	15s.	6d. to 1s. each
½ doz. pigeons (wild)	3s. 6d. to 4s.	10d. to 1s. each
½ doz. ,, (tame)	3s. 6d.	8d. to 1s. 2d. each
½ doz. ducks	10s. 6d. to 12s.	2s. 3d. to 3s. 6d. each
10 doz. eggs	10s. to 20s. (according to season)	1s. to 2s. 6d. per dozen

An enormous trade is now done in Ostend rabbits. These are bought at the London market at from 4s. 4d. to 4s. 8d. per stone of 8 lb. Australian rabbits costing in London from 6¼d. to 6½ each have a large sale in poorer class neighbourhoods at any price from 7½d. to 10d. each. Good English rabbits cost from 8d. to 10d. wholesale, and retail at from about 10d to 1s. 3d., according to size and condition Bordeaux pigeons are shipped to this country in boxes of "sixes," "eights," and "fours." The "fours" are usually large-sized birds and may cost the retailer from 1s. to 1s. 2d. each; the "eights" cost about 1s. 1d., and the "sixes" 10d. each. Eggs are bought in London usually by the 100—120 going to 100. Irish ducks cost usually from 2s. 3d. to 2s. 9d, while good English ducks are dearer—2s. 9d. to 3s. 6d. being average cost. These are naturally finer varieties than the ducks in the table and bear a proportionately greater profit. The fluctuations in price vary greatly, of course, according to the supply and the demand.

Should he happen to open about the Christmas season (which usually lasts from November to the end of February), the retailer would order two dozen turkeys, costing, perhaps, 8d. to 1s. per lb., and selling at 10d. to 1s. 3d., and half a dozen geese, at a cost of 5d. to 6d. per lb., to retail at 8d. to 10d. This takes no account of game, which would perhaps be best left till it was seen how the business was going. Of course, the poulterer in a metropolitan suburb, or a provision merchant who wants to add a poultry department, would simply go to the Leadenhall or Smithfield markets and select his stock from the wholesale merchants there. In such a case he would find that foreign produce is cheaper than the home-fed. For instance, Italian turkeys would not cost more than 6d. to 8d. per lb.; Russian geese would be 4d. to 5d. per lb. and so on; but the quantities mentioned would make a creditable opening in either case. The beginning of November is a good time to start.

Selling Game. As the business seemed to be going all right, the beginner would presently apply for a game-dealer's licence, without which he cannot sell game. To sell poultry (by which is meant pullets, chickens, fowls, ducks and ducklings, geese and goslings, and turkeys), rabbits, woodcock, quail, snipe, or landrail, no licence is required, but to deal in British or foreign game a £2 licence is necessary, annually renewed not later than July 1st. The term "game" includes hares, pheasants, partridges, grouse, and black game. The dealer has also to observe the "close times," and to take care that he does not sell or buy game ten days (one day inclusive, and the other exclusive) from the day on which it becomes unlawful to kill such game. He should note, therefore, that the shooting of game is as follows:

Grouse begin August 12th, end December 10th; partridges begin September 1st, end February 1st; pheasants begin October 1st, end February 1st; wildfowl and landrail begin August 1st, end March 1st; black game begin August 20th, end December 10th. The sale of hares is prohibited from March to the end of July.

The country poulterer would contract for supplies with some gentleman or gentlemen who had estates in his neighbourhood, or somewhere near. The town buyer would get his stock from the recognised markets. The usual wholesale prices are somewhat as follows, with the usual variations in season and supply: Grouse, 4s. to 7s. per brace; pheasants, 1s. 10d. to 5s. per brace; partridges, 2s. to 3s.; hares, 1s. to 3s., according to size. Foreign hares cost from 1s. to 1s. 9d. each; Manchurian

partridges, 10d. to 1s. each; and Russian partridges, 1s. to 1s. 6d. each. The retail prices for grouse vary from 5s. to 8s. 6d.; pheasants, 3s. to 6s. 6d.; partridges, from 2s. 6d. to 3s. 6d.; and hares, from 2s. to 4s. (British), and 1s. 6d. to 2s. 6d. (foreign).

Prices and Profits. The produce mentioned is that in regular sale, and what would preferably be stocked by the beginner. But these by no means exhaust the stock which the poulterer and game-dealer with a large connection requires to keep. As time went on, and the business developed, he would probably have to stock some of the following:

Stock.	Average Cost Price.	Average Retail Price
Blackcock	2s. 3d. each.	3s. to 3s. 6d. each
Grey Hens	1s. 9d.	2s. 6d. to 3s. each
Larks	1s. per dozen	1s. 9d. per dozen
Plovers (golden) ..	10d. each	1s. 3d. each
Plovers (ordinary)	7d. each	10d. each
Ptarmigan	7½d. each	10d. to 1s. each
Snipe	10d. each	1s. 2d. each
Teal	10d. each	1s. 4d. each
Widgeon	10d. to 1s. each	1s. 9d. each

These are mainly for high-class trade, and would be added as required. The business is a fairly profitable one, as will be seen, but allowance must be made for waste, as the stock is perishable. The stock, even in a country business, must be turned over four times a week. The man in the metropolis can keep small stocks, and buy in the markets every day, if necessary. The general and best rule in buying is to pay as you go, and the selling should be for cash as far as is possible. Of course, where credit is given, and in some family businesses it is inevitable, a larger profit must be secured than when cash is paid. The average profit must be about 30 to 40 per cent. on the turnover, and a safe rule is to aim at having a clear profit of not less than 12½ per cent. after paying all expenses.

PROVISION MERCHANTS

Although the provision merchant frequently carries on his separate business, handling bacon, hams, cheese, butter, eggs, margarine, polonies, potted meats, meat pies, sausages, and so on, these goods are also very commonly dealt with by the grocer [see page 3041], occupying one whole side of his shop—the "provision side"—and a separate window. The trade demands considerable knowledge and experience—unless conducted in a very small way—and, indeed, constant daily supplies from a wholesale house, which does practically all the work except the actual retailing. Thus, bacon may be bought ready washed and dried, and pork may be bought in "lengths," pork pies ready-made, and so on. Many a good shop has started in such a small way; but such small shops are hardly to be dignified as provision shops. The provision side of a grocery business, or the provision trade proper, is one in which good profits are made by those who understand their business thoroughly, and are able not only to sell, but to buy well, taking advantage of the frequent and rapid turns of the market; but as the market fluctuations cut both ways, there are few retail businesses in which so much risk is run by the inexperienced or where money is so quickly lost. Within the last three or four years prices of bacon and cheese have been ruling abnormally high, and profits have been difficult to secure.

Starting in Business. As regards capital, selection of shop, etc., the general remarks under the head of Grocery will apply, and it is unlikely perhaps that a novice will start in the provision trade without grocery, although he may certainly do well to give the former side of his business special attention and prominence if there is a promising opening in the neighbourhood he has selected for his venture.

Arrangement of Shop. The provision side and window should be that which gets least sun. Given this condition, it is often found convenient to allot the right side of the shop to provision, and the left to grocery. The "Practical Grocer" gives the following details of a "provision fitting" for a shop. "The provision fitting would be, say, 12 ft. long, 18 in. deep at bottom, and 11 in. above counter height. The fitting would have a marble counter shelf 18 in. wide, and under same would be fitted uprights and shelves, with spaces for eggs, etc. Above the counter shelf the wall would be lined to a height of 2 ft. with marble, or an imitation tile (on zinc) can be executed at much lower cost. The centre of the fitting would be provided with two iron bars and two hangers for hanging sides of bacon upon. At each side of the centre would be provided three shelves for tinned goods, and a moulded cornice, and the whole hung up to ceiling above on iron rods. From the end of the provision fitting to the end of the shop would be provided a fitting for Italian goods, jams, pickles, sauces, etc. This fitting would be 12 ft. long, 18 in. deep at counter height, and 11 in. above. The lower part of this fitting could be used for other goods. Across the back of the shop would be provided a fitting with shelves and lockers for sundries."

The *provision window* usually has a marble bed, and a common plan is to have a marble shelf about 8 in. wide placed at the back of the window, with a mirror at the side. The window may have sliding sashes, so that it can be dressed from outside if desired. A light, decorated iron frame with marble shelves may be put in the middle and circular stands at the sides, with porcelain stands for "pure butter" and "margarine" respectively, and art-coloured majolica pedestals and pots for palms or ferns to give a cool and fresh effect.

Storage. A good cellar, dry, cool, and well ventilated, is very necessary. Refrigerators or ice-boxes are also useful. They are much used in America, for instance, on account of the heat. To keep butter free from dust and fresh there is nothing better than boxing in the butter stand completely with plate-glass fixed on the counter. Sparkling glass, polished marble, etc., have much to do with making a shop attractive to the customer. The window should be dressed thoroughly and attractively every morning. Cleanliness everywhere is, of course, essential

in a provision shop. Cheese should be stored in a cool cellar, on shelves specially made for the purpose, as it is necessary to turn them over occasionally to prevent cracking and "sweating." Bacon needs unceasing vigilance, especially in summer. A place with plenty of good ventilation is best for storing bacon. It should be bought once a week, if possible, as much of it is mild-cured nowadays, and a quick sale is required. Fresh eggs should be kept in a dry, cool place, free from any odour which would be capable of impairing their flavour.

Treatment of Stock. In the profitable handling of provisions, unremitting care and minute attention to detail are essential. Be careful *always* to avoid overstocking, which means certain loss from shrinkage and deterioration. All goods should be weighed, checked, or counted when received, and claims promptly made for damages. Eggs, for example, are a very common subject for claims upon railway companies. Eggs may be tested for freshness in various ways. In the Paris markets eggs are tested by means of a glass of brine made by dissolving common salt in water in the proportion of a pint to each 2 oz. of salt. An egg to be tested is dropped into the glass. If perfectly new laid, it sinks to the bottom; if more than a day old, it does not rest on the bottom; if five days old, it floats. In this country the wholesale method of testing eggs is by what is called "candling." A box is arranged so as to exclude light, excepting a strong light thrown through the eggs under examination by means of a lamp. The light thus projects an illuminated image of the egg upon a mirror, wherein a fresh egg appears unclouded, while a bad one shows a dark spot; the larger the spot the older the egg. Eggs that have been preserved, as eggs now frequently are, by means of a solution of water-glass, should always be examined thus before being sold. If a proper candling lamp is not available, one may be constructed by cutting an oval hole, the size of an egg, in a piece of black cardboard nearly a foot square. Place the egg against the hole, and look through it at a strong light. If the egg be dark or show spots, it should be rejected. In unpacking eggs, sort them out into small, medium, and large, and price accordingly.

Butter. In buying butter, Danish rules the market, though Normandy and Brittany take first rank for fresh in London and the South of England. Irish has greatly improved, and fine grades run the Danish close, and, it is to be hoped, will at no distant date excel it, in the English market. But the Danes have managed their trade remarkably well, and excel in uniformity and regularity, while no expense is spared in ensuring rapid transportation and delivery in the markets here. Some English farm butter is excellent, but the supply is so badly regulated that, as a rule, it does not count. In contracting for Danish, it is by no means uncommon to agree to pay the wholesale agent a fixed sum per cwt. over the current Copenhagen quotation, this quotation being fixed officially every Thursday, and regularly published in the current trade papers. The Copenhagen Committee have now arranged, since March 29th, 1906, that the quotation shall include the "overprice," so as to avoid the confusion which previously arose. Bacon, eggs, etc., are sold wholesale subject to specified conditions of sale fixed by the wholesale associations. Of these conditions the retail buyer should inform himself by studying the trade annuals.

Handling Provisions. The following miscellaneous hints on handling provisions are practical. In cutting up bacon, avoid accumulating bits; bad cutting by inexperienced hands will prove detrimental. Weigh closely and reckon correctly. Best cuts command ready sale at profitable prices; make ends or unsaleable cuts low to clear. Label hams with weight, and price directly on receipt with both bacon and hams, work out cost and profit occasionally by actual "results"; it is astonishing how often these are different from what is looked for. Cheese and butter should also be tested for shrinkages and estimated accordingly. Do not have too much cheese in cut at a time, or dryness and deterioration will be the consequences; a fresh appearance is the best salesman. Take tastings from the inside of a wedge. Butter should be kept as fresh and firm as possible. A speciality should be made with butters of finest quality, and they should be sent out in nicely worked-up rolls and prints. Keep cut lard neatly wrapped in parchment covering, according to requirements; this prevents loss from hasty weighing. Avoid sending out bad or broken eggs. Cooked hams, pork pies, sausages, etc., are profitable side lines if quick sales can be effected; otherwise they are best left alone. Ticket everything, and sell at marked prices only. Take stock often, advertise judiciously, endeavour to obtain your customers' confidence, and a good paying provision trade is assured.

Warranties: Water in Butter. While the law specially affecting the sale of provisions is dealt with below, it is necessary to point out here that in purchasing provisions great care is needed. The Board of Agriculture is empowered by the Sale of Food and Drugs Acts to fix authoritatively the quantity of moisture permissible in butter, and has decreed (1905) that not more than 16 per cent. shall be allowed unless the excess is declared to the purchaser. Consequently it is necessary that the retailer be on his guard against buying butter with more than 16 per cent. of water. A simple method of estimating the percentage of water in butter is practised in the Cork and Limerick markets, and is accurate enough for practical purposes, although, of course, it is not a proper analysis. It requires only a small saucer-shaped vessel, a small spirit or gas lamp, and a cheap set of scales and weights such as apothecaries use. A piece of butter is weighed and then heated in the saucer over the lamp for a few minutes, with constant stirring, until no more steam is observed to arise from it. After being allowed to cool, the butter is weighed again, and the loss of weight shown gives the amount of water which was in the butter. A specific warranty should always be obtained when buying butter.

also for cheese, lard, and margarine. It is the law that not more than 10 per cent. of butter fat shall be found in margarine. To any warranty the signature or initials of the guarantors must be appended.

Staff. Provision hands receive about the same wages as first grocery hands, and should be the best and most experienced men available in a shop. In engaging a manager for a shop where margarine is sold it is not unusual to stipulate by signed agreement that he shall respect and observe all the requirements and provisions of the Margarine Act, and sometimes that he will indemnify the employer against penalites or losses occasioned by neglect or irregularity in exposing for sale or retailing margarine. Some employers direct in their shop rules that margarine and cheese shall be "ironed," or tested by the managers as to their quality before being placed on the counter for sale, and that the butterman shall frequently wipe the provision scale plate to keep it free from water and scrupulously clean. It is forbidden to re-wrap margarine on the provision side after it has been sold in the legally prescribed wrapper; if a customer wants it wrapped again so as to hide the label, she is asked to take it across the shop to the grocery counter and have it done there.

Profits. A provision merchant who analyses results in his various business departments gives the following as gross profits: Bacon, 11 per cent. profit, and stock turned over at least every fortnight, or twenty-six times in a year; hams, 13 per cent., but turned over twelve times only; cheese, 12 per cent., stock turned over eight or ten times (cheese profit is usually higher than this); salt butter, 10 or 12 per cent., turned over twelve to twenty times; fresh butter, about 12 per cent., stock turned over nearly twenty times; tinned meats, 15 per cent., but turned over four to six times, which, however, is not so frequent as it ought to be.

Laws as to the Sale of Provisions. The Sale of Food and Drugs Acts, the Margarine Act, and the Merchandise Marks Act impose very special liabilities on the retailer who deals in provisions and demand therefore his careful study and observance. The prejudice caused in the minds of his customers by a conviction under these Acts is usually greater loss than the actual penalty. To deal with the last-named Act first, it is under the Merchandise Marks Act that traders have been prosecuted for selling ham not from Scottish pigs as "Scotch hams," and bacon not bred in Wiltshire as "Wiltshire bacon." In the trade "Wiltshire cut" appears to be thought allowable, but bacon that is not cured in the Wiltshire district must not be sold as "Wiltshire," or trouble is sure to follow. The offences defined by the Act are applying to goods "any false description," or having in one's possession for sale any goods to which any forged trade-mark or false trade description is applied; and the expression "false trade description" means a trade description which is false in a material respect as regards the goods to which it is applied. The Food and Drugs Act and the Margarine Act apply mainly to the provision dealer because of the great amount of adulteration that has in the past prevailed in butter. The main forms of such adulteration are the admixture with butter of margarine, the wilful addition of water beyond the legal or the natural quantity, and the admixture of neutral fatty substances such as coconut oil. Cheese also is liable to be adulterated, or rather, imitated, "filled" cheese having become so common in the trade that it had to be dealt with specially by the Sale of Food and Drugs Act, 1899, under which it must now be sold as "margarine cheese."

What is "Food"? This enactment expressly declares that "for the purposes of the Sale of Food and Drugs Acts, the expression "food" shall include every article used for food or drink by man, other than drugs or water, and any article which ordinarily enters into or is used in the composition or preparation of human food, and shall also include flavouring matters and condiments." Under the previous Act of 1875 some foods, etc, escaped the law—egg powder and baking powder, for instance, which are now covered. The main sections of these important Acts seek to protect the food of the people by prohibiting the mixing of injurious ingredients with food; prohibiting the sale of articles of food not of the proper nature, substance, and quality; prohibiting the abstraction of any part of an article of food before sale and selling such without notice to the purchaser; defining butter, margarine, and margarine cheese and regulating their sale; empowering the authorities to examine at the ports and elsewhere and take samples of analysis, and so on. Section 3 of the Act of 1875 enacts that "no person shall mix, colour, stain, or powder, or order or permit any other person to mix, colour, stain, or powder, any article of food with any ingredient or material so as to render the article injurious to health," and no person shall sell any such article, under a penalty not exceeding £50, thus regulating the use of preservatives and colouring matters such as copper in tinned peas and boric acid in milk and butter. If a retailer is summoned under the section mentioned he can escape by proving that he did not know that the article was injurious to health, and could not with reasonable diligence have obtained that knowledge. Section 6 of the same Act, the principle one under which proceedings for adulteration are taken, directs that "no person shall sell to the prejudice of the purchaser any article of food or any drug which is not of the nature, substance, and quality of the article demanded by such purchaser, under a penalty not exceeding £20."

What is Permitted. No offence is committed (1) where any ingredient not injurious to health has been added because required for the production or preparation thereof as an article of commerce in a state fit for carriage or consumption and not fraudulently to increase the bulk, weight, or measure of the food or drug, or conceal the inferior quality thereof; (2) where the drug or food

is a proprietary medicine or the subject of a patent in force, and is supplied in the state required by the specification of the patent; (3) where the food or drug is a compounded medical prescription; and (4) where the food or drug is "unavoidably mixed with some extraneous matter in the process of collection or preparation." Either the employer or the assistant may be summoned and fined under this Section 6, but there is an important protecting section which declares that there is no offence in selling an article of food mixed with any matter or ingredient not injurious to health, and not intended fraudulently to increase its bulk, weight, or measure, or conceal its inferior quality, "if at the time of delivering such article or drug he shall supply to the person receiving the same a notice, by a label distinctly and legibly written or printed on or with the article or drug, to the effect that the same is mixed."

Butter. It might be supposed that this would apply to butter, the "bulk" of which is increased by the addition of water or milk; but such butter is (1905) allowed to be sold in shops where the fact of such admixture of milk is brought to the purchasers' knowledge by notice, just as diluted whisky or milk is, on the strength of ruling by the High Court that a sale cannot be to the "prejudice of the purchaser" under Section 6 where the seller brings to the purchaser's knowledge the fact that the article sold is not of the nature, substance, or quality he demands.

"If," said the Court, "the alteration is brought to the knowledge of the purchaser, and he chooses to purchase notwithstanding, it can never have been intended that such a transaction should be interfered with." It is questionable if the public generally realises that the butter is not pure, but the merchant who puts up his ticket with "milk-blended" butter will probably explain as seldom as possible. You can bring the alteration to the purchaser's knowledge in any way you please so long as you do it in some way; and this is why, in some hotel bars the legend may be read: "All spirits sold here are mixed." The same protection applies to goods such as butter or milk. When margarine is sold, that fact must be conveyed to the purchaser's knowledge by wrapping it in a special wrapper, prescribed by the Margarine Act and the Sale of Food Act, 1899; but if margarine is supplied when "butter" has been asked for it is necessary also to give the customer a verbal intimation.

The Margarine Act. The Margarine Act defines as "butter" the "substance usually known as butter, made exclusively from milk or cream, or both, with or without salt or other preservative, and with or without the addition of colouring matter." As already mentioned, the Board of Agriculture, which is empowered to fix standards, has added to this that butter shall not contain more than 16 per cent. of water if it is to be presumed genuine. The Act then declares that "the word 'margarine' shall mean all substances, whether compounds or otherwise, prepared in imitation of butter, and whether mixed with butter or not, and no such substance shall be lawfully sold, except under the name of margarine, and under the conditions set forth in this Act." To this definition the Food and Drugs Act, 1899, added that margarine containing more than 10 per cent. of butter fat shall not be sold at all—the object being to prevent the sale of those "mixtures" that are peculiarly liable to be passed off as butter. This latter Act also defines as margarine-cheese "any substance, whether compound or otherwise, which is prepared in imitation of cheese, and which contains fat not derived from milk"; and this article, margarine cheese, has to be sold under the same conditions as margarine.

Selling Margarine. The retail dealer who exposes margarine for sale must attach "to each parcel thereof so exposed, and in such manner as to be clearly visible to the purchaser, a label marked in printed capital letters, not less than one-and-a-half inches square, 'Margarine.'" It is also best to place the lump or lumps of margarine so exposed for sale on a slab bearing the word "Margarine." Then, when handing margarine to a customer the retailer must be careful that it is in a paper wrapper on which is printed the word "Margarine" in capital block letters, not less than half an inch long, and distinctly legible, and with no other printed matter appearing on the wrapper. In the same way "margarine cheese" must appear solely on the wrapper of imitation cheese. Condensed, skimmed, or separated milk must be labelled "machine-skimmed milk." Under the Margarine Act an invoice is a warranty, so that if the provision dealer has bought what he believed to be butter, and it is called "butter" (not "Danish" or "Irish" merely), on the invoice, the production of this invoice will exonerate him if the substances prove not to be genuine.

CONDIMENTS

Sources and Manufacture of Salt. The Salt Mines of England. Uses of Salt. Vinegar. Pepper. Mustard. Ginger. Spices

Continued from page 4569

By CLAYTON BEADLE and HENRY P. STEVENS

ALTHOUGH eaten with foods, condiments cannot be regarded as true foods, as their food value is almost negligible, many (such as pepper, mustard, and spices) being largely composed of indigestible fibre. They may, however, be regarded as adjuncts to food, and are taken in comparatively small quantities, with the idea of stimulating the appetite. Most of them contain a small proportion of a very active ingredient. Thus pepper contains a resin, "piperin"; mustard, a volatile oil; and spices similar oils, which give to the condiments their peculiar flavours. These active ingredients are so powerful that they would act as poisons if taken in really large quantities. Acetic acid, too, can only be taken in the diluted form as vinegar. In virtue of the chemical nature of the active ingredients, many condiments act as food preservatives, especially salt and the spices.

Common Salt. Although most condiments can hardly be regarded as necessities, common salt is certainly an exception. It is one of the essentials for our health preservation.

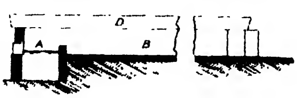
Nature has endowed this country with salt supplies second to none, both in quantity and quality. Salt is brought to the surface either in the form of clear liquid, as *brine*, or as dry rock, known as *rock salt*. Cheshire brine yields for every imperial gallon 3 lb. 2 oz. of dry salt. Roughly, 1,000 gallons of brine produce 1 ton of dry salt.

The brine is said to run under the earth in channels, and to collect in the lowest part of the geological basin at a depth of about 130 ft., whence it is pumped to the surface. It is supposed to result from the rainwater percolating to the rock salt and dissolving it. Where fresh water reaches the surface of rock salt, either at the outcrop or through fissures in the outlying marl, brine is formed

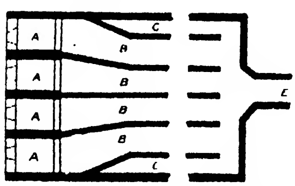
The brine has the following average composition:

Substances	Northwich.	Droitwich.	Stoke Prior.
	Per cent.	Per cent.	Per cent.
Sodium chloride ..	25·222	22·452	25·492
Calcium sulphate ..	·391	·387	·261
Sodium sulphate ..	·146	·390	·594
Magnesium carbonate	·107	·034	·034
Total solids ..	25·866	23·263	26·381

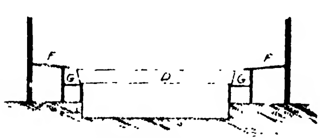
Brine is pumped by two plungers from a depth of 64 yards through an 8-in. pipe, and delivered to an enormous wooden cistern measuring about 36 ft. by 32 ft. by 10 ft. deep. From this tank the brine passes through pipes to the evaporating pans.



1. SETTING OF SALT-PANS (Longitudinal section)



2. PLAN OF FLUES OF SALT-PAN



3. TRANSVERSE SECTION OF SALT-PAN

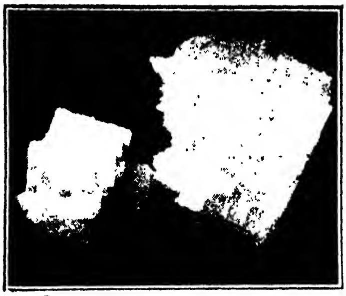
4. RAKE 5. SKIMMER 6. MOULD

The Salt-pans. The pans are made of steel, measuring about 36 ft. by 24 ft. by 20 in. deep, rest on brickwork, and are heated underneath by coal fires. A battery usually contains from five to ten pans. For examples of ordinary pan settings, see **1, 2,** and **3**. This type of pan has one flue, B, for each fireplace, A, and blank places, C, over which the salt in the pan can be scraped to the side without fear of overheating. D is the salt-pan, and E the flue to drying-room; F F the hurdles, and G the floor, on which the workman stands. Each pan in the particular works we are describing has two fires, divided by a partition wall running halfway to the back of the pan. In order to ensure even distribution of heat, there are five draughts, as they are called, divided by four parallel walls running halfway from the back. Brine is conveyed continuously to the evaporating pan, gentle ebullition takes place, and enormous volumes of steam pass off from the surface and disappear up the ventilators in the roof. The temperature of the brine is maintained at about 220° F.

As the water evaporates, an incrustation of crystalline salt is formed on the surface, which, as it gets heavy, settles in the cooler end of the pan. The crystalline deposit of pure salt so formed is drawn to the side of the pan by means of a rake [**4**]. The salt is then lifted out of the pan by means of a skimmer [**5**], a perforated scoop about 18 in. diameter. The excess of liquid drains through the perforations and the contents of the skimmer are transferred to a wooden mould consisting of an open box [**6**] tapering from one end to the other (length, 22 in. and 8 in. by 8 in. at large end), standing on its smaller end.

Drying and Packing the Salt. When a number of moulds have been filled and allowed to set, they are inverted, tipped out, and conveyed to the drying-room. The ordinary size block weighs 28 lb. (80 to the ton). Each pan produces 4 tons in 12 hours (equal to about 50 tons a week).

The drying-room is heated by the waste heat from the furnaces, which passes through long, square, iron flues, 4 ft. by 4 ft., placed on the floor level, on and around which the blocks are stacked. The temperature of the drying-room varies from 120° F. to 150° F. The blocks take six to fourteen days to dry, according to the temperature and weather. The dried blocks now pass through a munching machine, and then through a pair of rollers, and finally through sieves, until the required grain of salt is obtained.



7. BAY SALT (One-third scale)

The dry salt is carried by "elevators" to the top of the building, whence radiate, octopus-like, shoots or feeders, reaching to all parts of a large packing-room where girls are busily employed filling *damp*-proof paper packets, which consist of two sizes, and contain 1½ lb. and ¾ lb. respectively of table salt. This is never touched by hand from beginning to end.

Preparing Fishery Salt. The preparation of salt for the preservation of food, such as fish salt, is made somewhat differently from that of table salt. It has to be coarse and distinctly granular for sprinkling between layers of fish in boxes or barrels, as, if too fine, it would melt too rapidly.

For *fishery* salt, the brine in the pans is evaporated at from 90° F. to 120° F., according to the quality to be produced. The lower the temperature the coarser the grain, and the slower the operation.

There are several qualities of fishery salt, distinguished according to coarseness. The first grade of salt is named Second Fishery, a degree coarser is Best Fishery; next higher grade is X Fishery, a still better quality is XX, and the highest of all, and the coarsest, is Bay Salt [7].

From 22 to 25 tons per pan per week is the average production of fishery salt.

8. ROCK SALT FROM ADELAIDE MINES (One-third scale)

The Salt Union supplies 90 per cent. of the salt used in Great Britain for fish-curing. The pans owned by them have a capacity of about 1,000,000 tons per annum. The attempt to oust the pure natural article by salts obtained from sea-water evaporated by the sun's rays in hot climates is likely to end in failure, as, in addition to the great inferiority in composition of the latter, there is a liability to the formation of a fungus on fish which does not take place with the pure article. Sea-water also contains many organic ingredients that militate against the proper preservative action of salt.

The following analysis will show the difference in composition between the Cheshire fishery salt and the foreign sun-evaporated sea-water:

Ingredients	Cheshire Second Fishery	Foreign
	Per cent.	Per cent.
Chloride of Sodium (pure salt)	97·32	89·21
Moisture	1·72	[illegible]·82
Sulphate of lime	·85	1·48
Sulphate of magnesium ..	·—	3·15
Chloride of magnesium ..	·08	·95
Insoluble matter	·03	·39
	100·00	100·00

Where Rock Salt is Found. The geological position of rock salt occurs between the coal formation and the lias in the new red sandstone of the Triassic series. The great rock salt formation of England occurs within the red marl, or red sandstone. At Northwich, in the valley of the Weaver, rock salt is found in two chief beds, the top being about 87 ft. thick, and the bottom 90 ft. The top bed is 126 ft. below the surface.

The mining is done from the bottom of the layer of the thick bottom bed, where the best salt is found. The natural beds are about 2 miles long by 1½ miles wide.

A Large Salt Mine. To support the weight above, it is necessary to leave pillars of salt equal to about one-twelfth the area of the mine. This is done by leaving enormous pillars (somewhat larger at the bottom than the top), 10 yd. square and 25 yd. apart.

The rock salt raised as blasted from the Adelaide mines belonging to the Salt Union, Ltd., at Marston, Northwich, is called "Prussian Rock," when brought to the surface, and the larger pieces resemble enormous blocks of granite and porphyry. In places it contains veins of deep brown or amber colour [light portions, 8], grading to pale transparent salmon tint [dark portion, 8] and in some parts it is as transparent as glass and very pure, and crystallised in large cubes [9]. If taken at base of vein, one occasionally finds attached pieces of stone [see right-hand bottom corner of 10]. In other places the caverns are bristling with needle-shaped crystals not unlike the familiar sal-ammoniac [11], and in some few places it is opaque and white, falling to pieces between the fingers as though Nature had already prepared it for coarse fishery salt [12]. The mine at Marston is 336 ft. deep. It is approached by a perpendicular shaft about 9 ft. wide by means of a bucket which emerges into a cavern 30 ft. high. This cavern is the largest rock mine in Great Britain. Its walls and domes are bristling with crystals of rock salt in the various varieties referred to above. This chasm has entirely resulted from the removal of enormous quantities of salt rock, about and around which there still exist almost limitless supplies.

The Mining of Rock Salt. In order to obtain the rock salt a horizontal incision is made in the wall of the rock 7 in. from the base, the incision being 4 in. deep and 28 in. wide. This is performed by a machine resembling a very substantial circular saw with two-way teeth arranged

9. SALT CRYSTAL FROM ADELAIDE MINES (One-half scale

round its circumference. The machine is driven by compressed air laid on to the mine, and is moved forward by means of a grab. The cut is made slightly downwards so that the floor appears in ridges. The progress of the work depends largely upon the hardness of the rock, which varies considerably at different points. To prepare the rock to receive the charges for blasting, holes are produced by means of an iron pole called a *chisel*, that is rod-shaped and tapering towards the end, which is beaten out to a spear-shaped head. This is thrust into the rock and turned until the required depth is reached. In this hole a charge is inserted and fired by the aid of a fuse. Sometimes the charges merely crack the rock and at others they remove several tons. Thus, if large pieces are wanted, a small charge is put in vertically by which the face of the rock is just cracked and the necessary sizes are removed with a pick. If small lumps are required, a large charge is put in in a slanting direction, which blows the face of the rock to pieces.

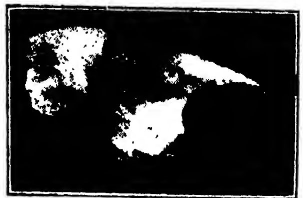
In addition to their mines at Northwich and Winsford, in Cheshire, the Salt Union have mines at Carrickfergus in Ireland, and they have also white salt works at Northwich, Winsford, Middlewich (Cheshire), Stoke Prior and Droitwich (Worcestershire), Middlesbrough (Durham).

11. ROCK SALT IN NEEDLE SHAPED CRYSTALS (One-half scale)

The Uses of Rock Salt. The rock salt is ground to a powder and supplied in bags for agricultural purposes. It is exported in lumps for refining and conversion into table salts. It is placed unground in the stalls of oxen, who greedily lick it as an adjunct to their food. Brine is used in large quantities in the "Solvay" process for the manufacture of alkali; white salt and rock salt in the "Leblanc" process for the production of soda and salt cake [see Acids and Alkalis], also in copper smelting. As such it forms the basis of several of our most important industries, which are dealt with at full length under different sections. Brine also plays a very important part in the process of refrigeration [see Food Preservation]. The following list gives the various uses to which salt is put:

- Scouring
- Removing discolorations
- Washing greasy bottles
- Removing inkstains from carpets and tablecloths
- Removing wine stains
- Carpet cleaning
- Dissolved in spirit for removing grease spots
- Washing silk handkerchiefs
- Mixed with oil for furniture polishes
- Cleaning straw matting
- Cleaning brooms
- Disinfecting
- Cleaning slimy sponges
- Cleaning stained hands
- Cleaning copper (with lemon added)
- Making a fire burn up
- On frozen roads
- Consolidating roads
- Destroying insects in gardens
- Destroying vermin in manure heaps
- Weed killing
- Doctoring horses, cattle, and sheep
- As food for cows to improve milking

12. OPAQUE ROCK SALT (One-half scale)



10. ROCK SALT WITH ATTACHED STONE (One-half scale)

- With food for cattle to improve appetite and digestion
- With poultry food
- With all foods deficient in salt
- As medicine
- In brine baths
- As an antidote to poisons, snake and dog bites
- Improving the burning of paraffin
- Preserving potatoes
- Salting down vegetables before cooking
- Removing animalculæ from raw vegetables, such as watercress
- Salting butter
- Bread making (added to flour)
- Plugging tobacco pipes
- Eating with fruit
- Preserving meat
- Extracting frost from frozen vegetables
- Detecting poisonous mushrooms
- Preserving milk
- Preserving eggs
- Curing hams and bacon
- Fish curing and preserving
- In liquid form, as a fire extinguisher
- Laying dust
- Assisting disintegration and weathering of soil
- Absorbing and retaining moisture on the ground, and therefore as a preventitive of drought
- Assisting the soil to absorb ammonia for crops
- Purifying land
- Placing land to cattle to crop closer
- Increasing clover crops
- Checking or preventing potato disease
- Sweetening and preserving fodder, and preventing mouldiness in it

No distinction has been made between *stove* salt, etc., and *rock* salt in the above enumeration, but it may be taken generally that salt from brine is always used in connection with human food and household purposes, and ground rock salt for all others, except where colour and a high degree of purity is of paramount importance.

Natural Vinegars. Genuine vinegar has been defined as the "product of the alcoholic and acetous fermentation of vegetable juice or infusion." That is to say, it is obtained from some vegetable extract which is allowed to ferment, first with the formation of alcohol, which is then converted into acetic acid. Vinegar so prepared will consist of a solution of acetic acid with various vegetable juices and colouring matters. To this class belong the true malt vinegars, prepared from malt or a mixture of malt and barley. The materials are finely ground and *mashed*—that is, extracted repeatedly with small quantities of hot water till all soluble matters are removed. The clear liquors are run off into a vat, where yeast is added, so that fermentation sets in; carbon dioxide gas is given off, and alcohol formed in the liquor. This alcohol has to be further oxidised to form acetic acid, for which purposes some means is adopted to expose it effectually to the oxygen of the air. The action, however, would be slow were it not for growth of a peculiar fungus, or "vinegar plant" (*Mycoderma aceti*). Either the liquor is allowed to trickle over twigs on which the vinegar plant grows, or the liquor passes through barrels on the sides of which the plant has developed. So prepared, *malt* vinegar has a peculiar and pleasant odour, due to the presence of small quantities of organic substances known as *aldehydes*, *esters*, etc., and it is coloured brown owing to the presence of organic colouring matters formed

13. SCRAPED GINGER

in the process. Small quantities of vinegar are also prepared from inferior wine, but very little prepared in this manner is met with in this country.

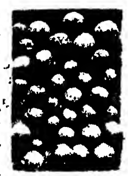
Artifical Vinegars. In contrast to these natural vinegars are the artificial *wood* vinegars, prepared by doctoring a solution of acetic acid obtained by distilling wood and small quantities of caramel, other substances being added to imitate the colour and appearance of *malt* vinegar. A great deal of the vinegar sold is prepared in this way from acetic acid, and at times illegally labelled " malt vinegar." At one time the so-called distilled or *white* vinegar was prepared by distilling the malt vinegar. It is difficult to see what advantages were gained by doing this, as the vinegar so prepared is indistinguishable from diluted acetic acid. A small quantity of sulphuric acid used to be regularly added to the vinegar with the idea that it helped to preserve it. Such an addition is now illegal, and must be looked for in analysing a sample. On evaporating a small quantity of vinegar in a platinum dish to dryness, the solid matter will have a tendency to carbonise even at 100° C. if sulphuric acid be present. Hehner evaporates 50 c.c. to dryness with 25 c.c. of N/10 (NaOH) which is ignited at a low temperature; 25 c.c. of decinormal hydrochloric acid is then added, and the dish warmed to drive off the carbon dioxide. The solution is filtered off from any residue and now contains the free acid originally present in the vinegar, which may be titrated, using phenol phthalein as an indicator in the usual manner.

An opinion can be formed as to whether a sample of vinegar is genuine malt vinegar or not by a combination of tests, such as specific gravity, total solids, nitrogen, phosphoric acid and acetic acid. The latter can be directly estimated by titrating the vinegar with decinormal soda and phenol phthalein as an indicator. Every cubic centimetre of N/10 (NaOH) is equivalent to ·006 grammes of acetic acid.

Pepper. Two varieties of pepper are commonly met with—*black* and *white* pepper. Both are obtained from a climbing plant, the *piper nigrum*, often trained like hops or vines to grow on poles. As soon as the berries show signs of turning red they are picked off and dried. *Black pepper* consists of this dried unripe fruit, in the form of rounded berries about one-fifth of an inch in diameter. The outer covering is then blackish brown and wrinkled and contains a seed of a yellow brown or grey colour. This seed, from which the outer coating has been stripped, forms *white pepper*. For this stripping the fruit is soaked in water in order to soften the husk or outer covering, which is then removed by rubbing. These outer husks possess some of the characteristics of the seed, and are used to a certain extent for flavouring. It will be seen therefore, that the distinction between black and white pepper lies in the fact that the former consists of the seed contained in its husk or outer covering, while the latter is hulled and contains only the kernel. The peculiar pungency characteristic of pepper is due to the presence of an acrid resinous substance, besides which it contains small quantities of an oily body termed *piperin*, starch, and cellulose or woody fibre. The following table represents the average proportions of certain substances in black and white pepper (Clifford Richardson):

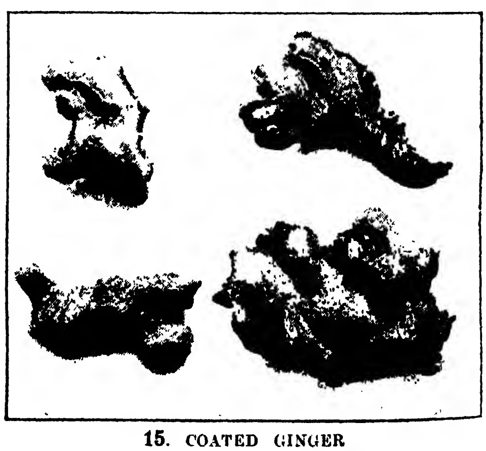
Substances	Black	White
	Per cent.	Per cent.
Water	8 to 11	8 to 11
Ash	2·75 to 5	1 to 2
Volatile oil	·1 to 1·75	·5 to 1·75
Piperin and resin	7 to 8	7 to 8
Starch	32 to 38	40 to 44
Fibre	8 to 11	4·11 to 8
Albuminoids	7 to 12	8 to 10

The manufacture consists in grinding the corns and separating the ground particles by means of sieves. It is found that most of the active constituents are contained in the finely-divided particles, the coarser particles containing mineral impurities and forming an inferior product.



14. PIMENTO

Analysing Pepper. The analysis of pepper is made chiefly for the purpose of detecting adulterants, and much ingenuity has been expended by unscrupulous dealers in incorporating with the pepper substances which are not easily discovered by the analyst. Besides the coarser mineral adulterants, such as china clay and starch, substances such as ground olive stones and *long pepper* may also be added. The difficulty of the analyst is considerably increased by the fact that samples of genuine pepper vary considerably in chemical composition among themselves. The analyst has to rely chiefly on his microscope. Thus, foreign starch will have a different appearance to that peculiar to pepper itself. Any large addition of fibrous material, such as ground olive stones, may be detected by estimating



15. COATED GINGER

the celluloso or crude fibre; thus, unadulterated white pepper may average, say, 6 per cent., black pepper 9½ per cent. Long pepper will contain as much as 21 per cent., and ground olive stones 60 to 70 per cent. Unfortunately, authorities differ a good deal even here, not only on account of the variation in composition of genuine samples, but in the methods employed in estimating fibre.

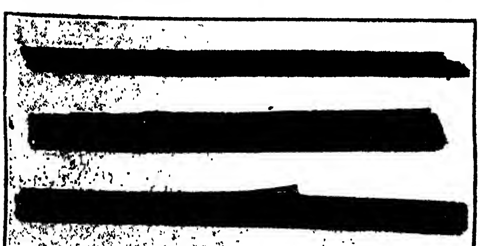
Cayenne Pepper. *Cayenne* pepper is obtained from the dried ripe fruit of the *Capsicum fastigiatum* and *Capsicum annum*, which grow in the tropical parts of Africa and America. The pods are orange-red in colour, perhaps ½ in. or so in length, having a shrivelled appearance. Inside are small white, rounded seeds. It owes its peculiar properties to a body known as capsicum, which is colourless, and has a very acrid taste. In addition to this, cayenne pepper consists of fibres and small quantities of fats and resin, but it is noteworthy that it contains no starch; for analysis the chemist must rely mostly on its microscopical appearance.

Mustard. There are two plants which furnish us with the raw material for the manufacture of mustard—namely, the *black* and *white* mustard plants (*Sinapis nigra* and *alba*), yielding respectively black and white mustard seeds. Both plants are found growing wild in most parts of Europe, the white mustard rather more in the south. The seeds differ a great deal in appearance. The white are about one-twelfth of an inch in diameter, and of a palish yellow colour, while the black seeds are considerably smaller, only about one-fifth of the weight of the white ones, and reddish to dark brown in colour. It is only the black mustard seeds which produce the peculiar volatile oil with the penetrating, pungent odour known as *allyl isothiocyanate*, so irritating to the nose and eyes. It is formed when the seeds are macerated with water. It is, however, a curious fact that the addition of white mustard increases the yield of the volatile oil.

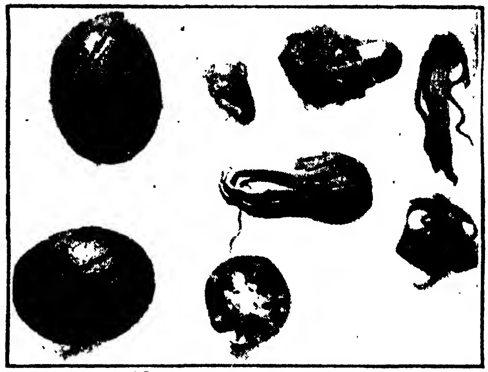
17. CARDAMOMS

To prepare mustard powder, a mixture of the two seeds is crushed between rollers and ground up. The product is then passed through sieves and an impure mustard flour obtained. This flour is then subjected to a second sifting operation, and the product is ready for the market.

The *allyl isothiocyanate* exists in mustard in combination as glucoside (*Potassium myronate*), which is split up in the presence of moisture by a ferment, *myrosin*, also found in the seeds. White mustard contains myrosin, and therefore aids the formation of allyl isothiocyanate, although it does not itself contain any of the glucoside. If you wish to prepare some of this volatile oil you merely require to macerate the black seeds with water, and



18. CINNAMON



16. NUTMEGS AND MACE

after standing for a time, distil, when the oil will pass over with the steam.

In addition to this volatile oil, mustard seeds contain some 35 per cent. of a fixed oil or fat, which is practically odourless and tasteless. There are also present albuminoids, from 25 per cent. to 30 per cent., cellulose, and about 1 per cent. of sulphur. Mustard, however, contains no starch, so that this possible adulterant is easily detected.

The following are the figures obtained in a number of analyses of genuine mustards (Clifford Richardson):

Water	..	3 to 7	per cent.
Ash ..	..	4 ,, 6	,, ,,
Volatile oil	..	·5 ,, 2	,, ,,
Fixed oil	..	31 ,, 37	,, ,,
Starch	..	None	
Fibre ..	..	5 ,, 18	,, ,,
Albuminoids		25 ,, 32	,, ,,

Adulterants of Mustard

In addition to starch, other adulterants which have been detected from time to time are turmeric, cayenne pepper, buckwheat, flour, clay, gypsum, and other mineral matters. Some mustard is poor in oil, being prepared from "mustard cake," the residue left after pressing the oil from the ground seeds. The amount of oil is easily estimated by extracting with ether. [For further details and a description of other processes see ANALYTICAL CHEMISTRY.]

Starch is easily detected by boiling with water, and then testing with iodine. Other adulterants may be detected by estimation of the fibre, albuminoids, ash, and other constituents.

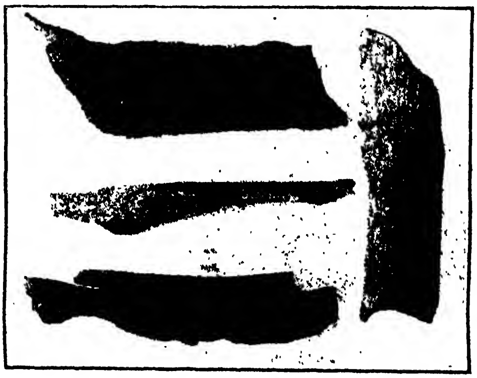
Ginger. Ginger is the dried root, or, more correctly, *rhizome*, of the ginger plant (*Zingiber*), which is a native of India, but has been introduced into a number of other countries, such as Jamaica, Africa, and Japan. The best qualities come from Jamaica. It is prepared by scraping off the outer skin, washing and drying in the sun, and forms rounded, elongated pieces, branching off from one another [13]. The usual colour is a pale buff, but sometimes the outer skin is not removed, "coated ginger" [15], or the scraped root is whitewashed with chalk or chloride of lime to preserve it from the attacks of insects. The peculiar odour of ginger is due to a volatile oil, amounting to about ¼ per cent. of the weight of the root. The pungent taste is due to another constituent. In general, the composition of ginger varies a good deal; it contains resins, starch, fibre, and mineral matters. The following figures will give an idea of the

results obtained in the analysis of several samples (Permain):

	Per cent.
Ash (not including sand)	3·1 to 5·0
Ash soluble in hot water	1·8 „ 2·7
Ether extract (oil and resins)	2·5 „ 5·0
Alcoholic extract after treatment with ether (resins, etc.)	2·7 „ 3·4

Fraudulent practice in dealing with ginger is mostly confined to the sale of the "exhausted" product—that is to say, ginger which has been ground up and the essential constituents removed by digesting with weak spirit for making essences, etc. This form of adulteration is the more difficult to detect as the appearance of the ginger is not altered. A good test for exhausted ginger consists in determining the alcoholic extract after treatment with ether. This should average about 2·8 per cent., while exhausted gingers may average 1·4 per cent. (Dyer.)

Spices. Among the spices, Caraway Seeds are the dried fruit of the *Carum carui*, and contain about 5 per cent. of a volatile oil. Cloves are the dried calyx and flower buds of the *Eugenia caryophyllata*, a sort of myrtle which grows in Zanzibar and the West Indies. As in other spices, they owe their peculiar flavouring properties to a volatile oil, of which they contain up to 16 per cent. Allspice or Pimento [**14**] is the small, dried berry of another variety of myrtle, the *Pimenta officinalis*. It contains about 4 per cent. of an oil similar to oil of cloves. Being cheaper, it is sometimes used to adulterate the latter. Mace is the outer coat or *arillus* of the Nutmeg, the fruit of the nutmeg tree, *Myristica fragrans*. Fig. **16** shows a nutmeg in shell, with the coating of mace, pieces of the mace stripped off, and also the shell broken open with the nutmeg inside. Nutmeg contains 6 per cent. of a pungent volatile oil, and mace about 4½ per cent. of a volatile oil. Cardamoms [**17**] are the dried ripe seeds of several plants, and include the so-called "grains of Paradise." In the illustration two shells have been cut open, showing the black seeds inside. They contain the usual volatile oil and resin. Cinnamon [**18**] is the bark of several allied trees, the best of which comes from Ceylon. The bark is stripped off in spring and autumn. It contains up to 1 per cent. of an essential oil to which it owes its flavouring properties. It is sometimes adulterated with Cassia [**19**], the bark of trees of the same genus, but of inferior value. Cassia is easily distinguished from true cinnamon, the latter consisting of thin curled pieces from which the outer and inner coats of the bark have been removed, while cassia forms thick pieces, consisting of the entire bark.



19. CASSIA

Adulteration of Spices. Spices are very frequently adulterated, sometimes by the substitution of an inferior article, such as pimento for cloves or cassia for cinnamon, and also by the addition of various other waste materials, such as sand, gypsum, walnut and coconut shells ground up, ground olive stones, mustard husks, pepper refuse, etc. These adulterants are readily mixed in with the ground spice, it is therefore much better to buy the whole spice and grind it as required for use. But even then certain adulterations may be effected. Thus cloves may be mixed with an undue proportion of stalks, or the material may be exhausted to remove the essential oil, as in the case of ginger. Under such circumstances, chemical and microscopical analysis alone can supply us with the required information.

Methods of Analysis. In conclusion, we will indicate briefly the methods adopted in analysing the condiments mentioned in this article. Moisture is determined by drying the finely powdered samples at 100° to 105° C. till no further loss in weight takes place. Ash is determined by igniting 2 to 5 grammes in a platinum crucible, and weighing the residue. The ash should be white, or nearly so, and free from black spots due to incompletely burnt particles. Oil and fatty matters are determined by extraction with ether in a Soxhlet. By means of this apparatus ether vapour rising from a flask in which it is made to boil is condensed, and drips on to the substance to be extracted. It is necessary that the solvent used should be volatile like ether. The fibre, or *crude fibre*, as it is sometimes termed, is obtained by taking the residue after extraction with ether, and boiling it (say 2 grammes) with 200 c.c. of 1¼ per cent. sulphuric acid for half an hour, washing free from acid, and then boiling with 200 c.c. of 1¼ per cent. of caustic soda for half an hour, after which the material is washed with water till free from alkali, dried at 100° C., and weighed. The residue is then burnt to ash, and the weight of the ash subtracted from the weight of the dry residue; this gives the weight of the fibre, which, multiplied by 50, gives it in the form of percentage on the original substance taken. For albuminoids, 1 gramme of the substance is heated with 10 c.c. of nitrogen-free, strong sulphuric acid, until the black carbonisation products are completely destroyed and the liquid is white. This operation is hastened by adding 8 grammes of potassium sulphate, which raises the boiling point of the liquid so that it can be heated to a higher temperature. It is best to use special flasks made of Jena glass. When cold, the residue is taken up with water into a large flask, and distilled with soda. The nitrogen of the albuminoids, which has been converted into ammonia by the heating process, now passes over, and is absorbed in a definite quantity of decinormal sulphuric acid. When the distillation is complete, the excess of acid is titrated back. The number of cubic centimetres of decinormal acid neutralised by the ammonia multiplied by ·875 will give the percentage of albuminoids in the original substance.

PARALLELOGRAMS

Sides, Angles and Diagonals of a Parallelogram. Rectangles Simple Propositions referring to Quadrilaterals. Propositions on Parallels. Loci

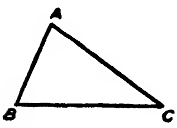
By HERBERT J. ALLPORT, M.A.

Proposition 22. Theorem

If one angle of a triangle is greater than another, then the side opposite to the greater angle is greater than the side opposite to the less.

Let ABC be a $\triangle$ in which $\angle$ABC is $>$ $\angle$ACB.

It is required to prove that AC is $>$ AB.



Proof. If AC is *not* greater than AB, either

AC = AB

or AC is $<$ AB.

Now AC cannot be equal to AB, for then the $\angle$ABC would equal the $\angle$ACB (*Prop.* 5), and the hypothesis states that this is not so.

Neither can AC be $<$AB, for then the $\angle$ABC would be $<$$\angle$ACB (*Prop.* 21), and again the hypothesis states that this is not so.

$\therefore$ since AC can neither be equal to nor less than AB, AC is $>$ AB.

PARALLELOGRAMS

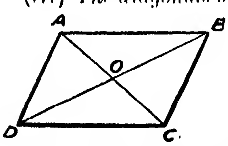
Definitions. A *parallelogram* is a quadrilateral figure whose opposite sides are parallel.

A *diagonal* of a quadrilateral is a straight line joining opposite angular points.

Proposition 23. Theorem

In any parallelogram

(i.) *The opposite sides are equal.*
(ii.) *The opposite angles are equal.*
(iii.) *Each diagonal bisects the parallelogram.*
(iv.) *The diagonals bisect each other.*



Let ABCD be a ▱, and AC, BD be its diagonals, intersecting at O.

It is required to prove that

(i.) AB = CD, and BC = AD.
(ii.) $\angle$ABC = $\angle$ADC, and $\angle$DAB = $\angle$DCB.
(iii.) $\triangle$ABC = $\triangle$ADC in area.
$\triangle$DAB = $\triangle$DCB in area.
(iv.) AO = OC and BO = OD.

Proof. (i.) Since AB is $\parallel$ to CD and AC meets them

$\therefore$ $\angle$BAC = $\angle$DCA (*Prop.* 12);

and, since AD is $\parallel$ to BC and AC meets them

$\therefore$ $\angle$ACB = $\angle$DAC (*Prop.* 12).

Hence, the two $\triangle$s ABC, ADC have two $\angle$s of the one equal to two $\angle$s of the other, and they have also the side AC common to both.

$\therefore$ $\triangle$ABC = $\triangle$ADC in all respects (*Prop.* 19).

$\therefore$ AB = CD, and BC = AD.

(ii.) Since $\triangle$ABC = $\triangle$ADC in all respects

$\therefore$ $\angle$ABC = $\angle$ADC.

Again, it has been proved that

$\angle$BAC = $\angle$DCA and $\angle$DAC = $\angle$BCA.

$\therefore$ the whole $\angle$DAB = the whole $\angle$DCB.

(iii.) We have already proved that the area of $\triangle$ABC = area of $\triangle$ADC.

In the same way it can be shown that $\triangle$s DAB, DCB are equal in area.

(iv.) In the $\triangle$s AOB, DOC

$\angle$BAO = alternate $\angle$DCO (*Prop.* 12)
$\angle$AOB = $\angle$COD (*Prop.* 3)
AB = CD (by i.)

$\therefore$ $\triangle$AOB = $\triangle$DOC in all respects (*Prop.* 19).

$\therefore$ AO = OC, and BO = OD.

Corollary 1. *If one angle of a parallelogram is a right angle, all its angles are right angles.*

In the figure, since AD is $\parallel$ BC and AB meets them

$\therefore$ $\angle$DAB + $\angle$ABC = 2 right $\angle$s (*Prop.* 12).

Hence, if one of these $\angle$s, say $\angle$DAB, is a right $\angle$, the other must also be a right $\angle$. But the opposite $\angle$s of a ▱ are equal.

$\therefore$ all the $\angle$s must be right $\angle$s.

Corollary 2. *If two adjacent sides of a parallelogram are equal, all the sides are equal.*

Definitions. 1. A parallelogram whose angles are right angles is called a *rectangle*.

2. A rectangle whose sides are all equal is called a *square*.

3. A *rhombus* is a parallelogram whose sides are all equal, but whose angles are not right angles.

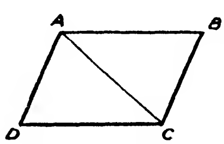
4. A *trapezium* is a four-sided figure having *two* of its sides parallel.

Proposition 24. Theorem

If one pair of opposite sides of a quadrilateral be equal and parallel, the quadrilateral is a parallelogram.

Let ABCD be a quadrilateral in which AB is equal to CD, and also $\parallel$ to CD.

It is required to prove that ABCD is a ▱.



Proof. Join AC.

Then, since AB is $\parallel$ to CD and AC meets them

$\therefore$ $\angle$ BAC = $\angle$ DCA (*Prop.* 12).

Hence, in the $\triangle$s ABC, ADC,

AB = DC,
AC is common to both $\triangle$s,
$\angle$BAC = $\angle$DCA.

$\therefore$ $\triangle$s are equal in all respects (*Prop.* 4).

$\therefore$ $\angle$BCA = $\angle$DAC.

But these are alternate $\angle$s.

$\therefore$ BC is $\parallel$ to AD (*Prop.* 11).

Hence, ABCD is a ▱.

The student should find no difficulty in proving the following propositions for himself.

1. *If the opposite sides of a quadrilateral are equal, the quadrilateral is a parallelogram.*

2. *If the opposite angles of a quadrilateral are equal, the quadrilateral is a parallelogram.*

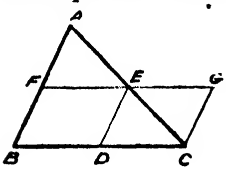
3. *If the diagonals of a parallelogram are equal, the parallelogram is a rectangle.*

4. *If the diagonals of a quadrilateral bisect each other, the quadrilateral is a parallelogram.*

Proposition 25. Theorem

The straight line which joins the middle points of two sides of a triangle is parallel to the third side and equal to half of it.

Let ABC be a Δ, and let E and F be the middle points of AC and AB respectively.



It is required to prove that FE is $\parallel$ to BC, and that FE $= \frac{1}{2}$ BC.

Proof. Through C, draw CG $\parallel$ to BA, to meet FE in the point G.

Then, since FA is $\parallel$ CG, and FG meets them,

$\therefore \angle AFE = \angle CGE$ (*Prop.* 12).

Also, $\angle AEF = \angle CEG$ (*Prop.* 3).

$\therefore$ the Δs AEF, CEG have two $\angle$s of one equal to two $\angle$s of the other, and side AE = side CE.

$\therefore$ they are equal in all respects.

$\therefore$ CG = AF.

But AF = BF.

$\therefore$ CG = BF.

Hence, the figure BCGF has one pair of sides equal and parallel.

$\therefore$ BCGF is a $\square$ (*Prop.* 24).

$\therefore$ FE is $\parallel$ to BC.

Again, to prove that FE $= \frac{1}{2}$ BC.

Bisect BC at D, and join DE.

Then, since DE joins the middle points of two sides of the ΔABC, $\therefore$ DE is $\parallel$ to the third side AB.

$\therefore$ BDEF is a $\square$.

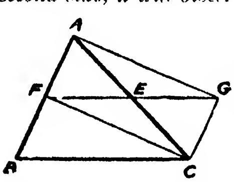
$\therefore$ FE = BD (*Prop.* 23).

But BD $= \frac{1}{2}$ BC

$\therefore$ FE $= \frac{1}{2}$ BC.

Proposition 26. Theorem

If through the middle point of one side of a triangle a straight line be drawn parallel to a second side, it will bisect the third side.



Let ABC be a Δ, and let F be the middle point of AB. Through F draw FE $\parallel$ to BC, meeting AC at E.

It is required to prove that E is the middle point of AC.

Proof. Through C draw CG $\parallel$ to BA, meeting FE at G. Then

BCGF is a $\square$.

$\therefore$ CG = BF (*Prop.* 23).

But BF = FA.

$\therefore$ CG = FA.

Hence, since CG and FA are equal and $\parallel$,

$\therefore$ figure FCGA is a $\square$ (*Prop.* 24).

$\therefore$ the diagonals AC and FG bisect each other (*Prop.* 23), so that E is the middle point of AC.

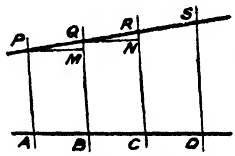
Proposition 27. Theorem

If a number of parallel straight lines cut off equal portions on one straight line, they will also cut off equal portions on any other straight line.

Let AP, BQ, CR, DS be parallel straight lines which cut the line AD so as to make AB, BC, CD equal to one another.

Let PS be any other straight line, cutting the parallels at P, Q, R, S.

It is required to prove that PQ, QR, RS are equal to one another.



Proof. Through P and Q draw PM, QN, $\parallel$ to AD, and meeting BQ, CR at M and N respectively.

Then ABMP and BCNQ are $\square$s.

$\therefore$ PM = AB, and QN = BC (*Prop.* 23).

But AB = BC (*Hyp.*).

$\therefore$ PM = QN.

Again, since PM and QN are $\parallel$, and PR meets them,

$\therefore \angle QPM = \angle RQN$ (*Prop.* 12);

and since QM and RN are $\parallel$, and PR meets them

$\therefore \angle PQM = \angle QRN$ (*Prop.* 12).

$\therefore$ in the Δs PQM, QRN,

$\angle QPM = \angle RQN$

$\angle PQM = \angle QRN$

and PM = QN.

$\therefore$ Δs are equal in all respects (*Prop.* 19).

$\therefore$ PQ = QR.

In a similar way it can be proved that QR = RS.

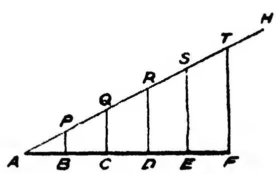
$\therefore$ PQ, QR, RS are all equal.

Proposition 28. Problem

To divide a given straight line into any number of equal parts.

Let AF be the given straight line, which it is required to divide into, say, five equal parts.

Construction. Through A draw a straight line AH, in any direction. Starting from A, mark off five equal lengths, AP, PQ, QR, RS, ST. Join TF. Through P, Q, R, S, draw straight lines $\parallel$ to TF, cutting AF at the points B, C, D, E. (This is done with the aid of set-squares.) Then AF is divided into five equal parts, AB, BC, CD, DE, EF.



Proof. A number of $\parallel$ lines PB, QC, RD, etc., cut off equal portions from the line AH. (*By construction.*)

$\therefore$ they cut off equal portions from the line AF (*Prop.* 27).

$\therefore$ AB = BC = CD = DE = EF.

Loci

The *locus* of a point is the line which it traces when it moves according to some given law. For example, if a point moves so that it is always a constant distance from a given fixed point it traces the circumference of a circle (*Def.* 11). The locus of the point is therefore the circumference of a circle whose centre is the fixed point, and whose radius is the constant distance.

INSURANCE AS A CAREER

Various Branches of the Profession. Life and Industrial Insurance. How to Become an Actuary. The Institute and Faculty of Actuaries. Examinations

Following on BANKING from page 4590

By W. A. BOWIE

THE business of Insurance consists of the receipt by the insuring office of a sum of money, termed the premium, in consideration of its undertaking to pay a larger sum upon the happening of a certain contingency to the person or property insured. The premium is estimated after consideration of any available statistics relating to the kind of risk which is to be insured against. Let us take an example. From statistics relating to the ages at death of certain observed persons, a table showing the probability of death can be constructed, and upon this table life assurance premiums may be calculated.

The Scope of Insurance. Or, from the record of past experiences of fires in a certain town and in certain classes of property, we can approximately fix premiums which should cover the risk of fire in the same town for the several kinds of property. A moment's thought will show over how wide an area of the world's business the province of insurance extends. Every ship on the sea runs risks hourly which the insurance expert must consider; and every street accident reported by the police is an item in the statistics which govern the fixing of an adequate premium in the great business of insurance against personal accident. It is practically impossible for any one man to be an expert in every department of insurance work, but the profession is one which calls for the exercise in its higher branches of considerable brain power; and many of its developments have proved of fascinating interest to some of the foremost mathematicians of past generations.

We give it as a personal opinion, based upon a wide experience covering many years of work in England and Scotland, that an insurance career is well worth entering upon in the case of a young man with a good education, a fair amount of brains, and an earnest desire not only to do the work assigned to him but to qualify himself by all available means.

Growing Opportunities. While, during the twenty years ending with 1905 the number of first-class insurance offices in the United Kingdom has decreased by amalgamation rather than increased by new ventures, the number of important branches created in the metropolis and the provincial towns has been so great that fresh chances for young men of ability and proper training have been very much extended. A young man who enters a large insurance office is often at a loss to know how to direct his studies, and our aim is to encourage him not only to master the department in which he is placed, but so to cultivate his education in the general subject of insurance that, as he rises to more responsible work, his outlook will be wider and clearer. An example will suffice to show what we mean.

A boy is a clerk in the head office of a large company and is attached for a year or two to the department responsible for the writing out and issue of fire policies. This is only one of a dozen departments of a fire company, but the boy will find that practically all the books and methods of working may, if he likes, come under his observation. He will find, almost invariably, that by exercising a little courtesy towards his superiors he can obtain an answer to any question he may ask concerning their own departments. By reading lectures and papers bearing on these other departments he will form a fair idea of the general lines of work which, on the day when he is promoted to one of the smaller branches of the company, with three or four departments in his charge, will be of considerable use to him. Here let us advise the student to read as many as he can of the papers delivered by experts before the insurance institutes of the United Kingdom, the best of which are published as annual volumes entitled "Journal of the Federation of Insurance Institutes of Great Britain and Ireland." There are, besides, many papers not included in these collections which would well repay perusal. Most of these publications are to be found in the libraries of the various insurance institutes, and in the head offices of the larger companies.

A knowledge of shorthand often brings a young clerk into close contact with one of the chiefs in the office, and, if he has the ability to rise, the youth will often be picked out for some occasional special service. A good knowledge of arithmetic is indispensable.

The chief branches of the business of insurance are *life*, *fire*, *marine*, *accident* and *contingency*.

Life Assurance. We will take first the life branch, which has been most highly developed on scientific lines. The theory of life contingencies may almost be said to be an exact science, and its study as applied to insurance constitutes an entire branch of the profession. A young man who enters a life office may, if he is quick at figures and fond of mathematics, think it worth while to study in order to pass all the examinations necessary to become an actuary. We shall come later to discuss the lines on which he should proceed in order to reach this coveted position. Many young men, however, who promise to develop good business capacity may be altogether unsuited for the higher branches of mathematical work. For them a position as secretary or manager may be the goal.

Life Office Work. Let us look first at the *non-actuarial departments* of a life office. A youth must quickly make himself acquainted with the methods of securing proposals and dealing with the policies issued. The proposal forms have to be scanned to see that no irregular answers are given; and the variety of policies issued, with the precise phraseology used in each case, should be noted. Any special conditions endorsed on the back of policies are of great importance, often modifying the contract, or charging extra premiums for special risks. Insured "lives"—the insurer is known in the insurance office as a "Life"—sometimes transfer their policies in security to a bank or a private individual. The transaction is called an *assignment*, and notice of it is generally given to the company.

Questions of title often arise as to whom the policy really belongs, and the correspondence with the persons interested in the matter is generally well worth study. It may be pointed out here that it is highly essential that a clerk should early learn to compose a good letter. The writing of a few essays in a literary society is a capital aid to the cultivation of a good style. Every young man should make a point of reading both the letters received and the copies of the answers which will have been filed. The correspondence, which is generally free to the clerks, is an education in itself and will show an expert manager's methods of dealing with difficult matters as they arise.

The methods of attending to the collection of renewal premiums should be closely observed, particularly the precautions taken to see that one premium is paid before notice for another is despatched. The student will also become thoroughly acquainted, not only with his own company's prospectus and table of rates, but with those of other companies as well, noting special conditions as to bonus distribution, foreign residence, surrender values, and the like.

Office Books and Accounts. It is very important that a careful record of all transactions in connection with each policy be entered on the registers, and the sooner a clerk becomes familiar with the use of each book in the office the better for his prospects. He must know the principles of bookkeeping [see CLERKSHIP] and how they are applied to the accounts of the departments of his own office. He should notice how premiums on new and renewal policies are debited to agents and collected by them; how agents' commissions are allowed and paid, and how all financial transactions are brought by skilful summary, at the end of six months or a year, to a focus in a single statement called a *Revenue Account*.

Claims. Life offices are concerned not only with receiving money, but with the payment of sums on the death of the insurer, or, perhaps, on his reaching a certain age. The aim of the office should be to meet a claim as promptly as possible, and for this purpose to grant every facility to the persons interested. Many a good fresh insurance has been secured by the ready settlement of a claim. A study of the causes of death, and of the original medical report when the insurance began, will often reveal how some weakness undetected at the start has been the cause of ultimate death; or the family history may show that there is a tendency to premature death from certain causes which have affected the insured as well as his family. It is always helpful to notice with what skill the chief medical officer and the actuary or manager have dealt with hazardous lives, and how far their action has been justified.

Loans and Investments. The lending of money does not generally come much before the office staff. The directors and the manager deal with questions of immense importance when, at the board table, they decide how many thousands of pounds are to be safely invested. But the study of the investment ledger and of the annual balance-sheet will show a learner on what careful lines a British board of directors puts money by. Care is always observed that no speculative securities are bought, even if they yield a high rate of interest. The securities purchased must, however, yield a good and safe return. Fortunately a life office can lend money for long periods, and therefore it is often approached by those who do not wish their mortgages to be disturbed so long as the interest is duly met. A war, or great stagnation of trade, may often depreciate the value of first-class securities, and an insurance company must be careful not to put too high an estimate upon stocks in its balance-sheet. In 1903, for instance, Consols and other first-class investments had depreciated to such an extent that many insurance offices were compelled to write off as a loss sums running into thousands of pounds, because their securities had fallen below the current selling value. Some companies undertake the granting of loans combined with life assurance on security of comparatively small houses, and a wide field is opened out for the study of surveyors' reports to find what are the different precautions taken on behalf of the lending company to ensure that the property is safe and can readily be sold if default takes place.

The Legal Department. Questions of law constantly arise in many connections. A policyholder has assigned his policy and wishes to know how he can get it re-transferred to himself. Or he has taken out his policy in favour of his wife and she has died. What is he to do? A member dies and it is found that he has pledged the interest in his policy in security to one man, with a second charge upon it to another. How are their claims to be adjusted? A man dies without leaving a will How is the company to know to whom to pay the sum due under his policy? A junior clerk of an inquiring turn of mind will find pleasure in searching for the correct answers to these questions in handbooks on the law of life insurance, or in perusing a well-formed judgment expressed in a letter from the solicitors of his company bearing on a special case.

There are a number of special Acts of Parliament to be studied in connection with life assurance. The following are the most important.

The Gambling Act, 1774.

The Policies of Assurance Act, 1867.

Life Assurance Companies Acts, 1870 to 1872.

Married Women's Property Act, 1870 (Sec. 10).

Married Women's Policies of Assurance (Scotland) Act, 1880.

Married Women's Property Act, 1882 (Sec. 11).

In the latest edition of Bunyon's book on the law of life assurance the chief points are dealt with, and the student should study this book, especially with regard to any particular case which may arise in the office.

Agency Department. A life office never grows very quickly and is often in danger of dwindling to small proportions unless it has an active agency department for securing a fresh access of new life proposals; and the young man who wishes to succeed in other than actuarial departments will find quick promotion if he is able to introduce new assurers, either by his own personal influence or by his skill in stimulating agents.

Life proposals are generally secured by personal canvassing. An outdoor man must have confidence in himself and in his company, good address, and plenty of perseverance. He must be ready in securing introductions, and ingenious in bringing a tardy client to the insuring point. If a clerk shows canvassing ability, he will receive every encouragement to act as an *Inspector of Agents*, and will be on the high road to a post as branch secretary when he can point to a good record of business. Our rising man in the outdoor department will concern himself with methods of advertising the company, and of encouraging the public, by circularising and otherwise, to apply for a prospectus. He must learn how to secure business without paying extravagant commissions, and how to encourage agents to keep constantly on the look-out for fresh insurers.

The Chief Schemes for Life Insurance. It is sometimes bewildering to the outsider to find in how many different ways life insurance can be applied. New schemes are constantly being issued by the companies, but these are often meant for ingenious advertising rather than planned for any great practical good. The student will find that the great bulk of life insurance is done under one or other of the following heads.

1. Whole Life Assurance.

2. Whole Life Assurance with Premiums limited to ten, fifteen, or twenty payments.

3. Endowment Assurance. Sum assured payable at death or at an agreed age like fifty or sixty.

4. Joint Life. Sum assured payable at the death of the first of two lives; perhaps a husband and wife, or two partners in business.

5. Short Term Insurance, covering perhaps one year only, or five, ten, or twenty years, protection ceasing at the expiration of the term.

6. Children's Assurances. Sum assured payable only on the life reaching age of twenty-one, or risk beginning at age twenty-one, and sum assured payable at death or at an age like fifty or sixty, or previous death.

7. Annuities. A sum of money is paid down to secure an annual allowance until the death of one or more lives.

Bonuses. Policies may be taken out with or without profits (or bonuses). In the latter case a man receives the largest possible cover for the smallest possible premium. In the case of policies sharing in profits the offices are most liberal in granting at each period of distribution a very large share—generally nine-tenths—of all profits earned by the company, including any profits made on non-bonus policies, so that in a well-managed society a life policy may not only be a very fine form of protecting the family, but may also prove a capital investment, giving a rate of compound interest higher than could be had from Government securities. First-class life offices pay very substantial bonuses, but a comparison between the profits declared by first-rate companies and those granted by offices not so well managed and financed will form an interesting study.

Survival Bonuses. Of special interest is the method of only granting bonuses should the assured survive for, say, twenty years. This method appeals to some, because it contains a speculative element, and, of course, the bonuses in such a case ought to be about double those granted by the companies who divide profits every five years or thereabouts. As a matter of experience, however, it is found that the ordinary British offices' bonuses at the end of twenty years often amount to more than the tontines bonuses declared at the end of that period in some inferior office, while valuable additions to the sum insured by way of profits have been made by the first-class offices during the intervening years.

Re-assurances. Offices have a limit to the amount which they will insure on any one life. It happens constantly that wealthy men apply for large insurances in one office. It will be the duty of an official to arrange for re-assuring the surplus portion of the risk with one or more other offices. To do this copies of the proposal, medical, and all other reports and papers bearing on the case are submitted to the office approached. The rate offered to the re-assuring company may be that of either office.

If the risk be accepted, a copy of the policy is generally supplied to the company sharing the risk, and on this copy a guarantee is endorsed, agreeing to accept so much of the insurance within described. Sometimes the guarantee is by direct policy, the company which accepts part risk agreeing to follow the terms and conditions of the original assurance.

A separate register is kept in which to enter all re-insurances and also a book showing on one side how much in sums assured and premiums has been given off to each office, and how much in sums assured and premiums has been received in return. It is desirable to see that other offices do not get too great a share of surplus lives without giving adequate business in return.

Industrial Insurance. The rise and progress of industrial insurance might be fitly studied by reading the history and development of the Prudential Assurance Company. The Prudential is the oldest and largest industrial company, and it has justified its existence in many admirable ways. By close attention to the needs of the poor, by skilfully constructed tables, by careful selection of outdoor inspectors and constant supervision through local and district superintendents, the Prudential has attained its present position.

The distinguishing features of industrial assurance are these: premiums are met by weekly payments, generally called for by the company's canvassers at the houses of the working classes, the sums assured being determined upon the basis of how much can be secured for a penny a week and upwards. The expense of working industrial insurance is about 40 per cent. This certainly appears very high, but it is fully justified by the enormous trouble to which the collectors are put.

In this class of insurance there is generally no medical examination, the agent being relied upon to use his judgment and discretion before accepting a risk. There are now many attractive positions occupied in the industrial insurance world by men who began as door to door canvassers, and through energy and success have been promoted, first to the position of assistant superintendant, and then to the desirable post of superintendent or district manager.

Importance of Actuarial Knowledge. It is, of course, impossible, even undesirable, that the whole staff of a life office should become actuaries; but the fact that his duties are non-actuarial is no excuse for ignorance on the part of any official regarding the elementary principles on which life assurance is based. To the branch secretary, agency inspector, and to outdoor men generally, a knowledge of the principles of life assurance is of the greatest assistance, enabling them to answer inquiries from probable assurers, to understand the schemes of rival companies, and in many cases preventing waste of time on undesirable cases. Such officials should make a point of solving each difficulty as it presents itself, and they will then find in a comparatively short time that their knowledge is really considerable. They should seek for information principally in the "Transactions of the Federation of Insurance Institutes," the papers therein being both useful and interesting. Other books which will also be found very useful are "Life Assurance Explained" (Schooling); "Practical Information for Life Assurance Agents" (Wm. Hughes); and "Insurance" (T. E. Young).

Actuarial Symbols. At the outset the actuarial symbols met with appear to be very imposing, and are calculated to dishearten those to whom they are unfamiliar. In reality they represent merely a system akin, let us say, to Pitman's shorthand. For example, the symbol ax may be said to be the "actuarial shorthand" for the value of an annuity of 1 per annum, payable at the end of each year during the life of a person aged x. Similarly Ax is "the value of, or the single premium for, an assurance of 1 payable at the end of the year of death of a life now aged x; and Px is the annual premium, payable at the beginning of each year during the life of x, which will provide a similar assurance of 1. The notation employed is entirely arbitrary, and the only way to understand it is to commit it to memory. The system will be found in the beginning of the "Institute of Actuaries Text-book," Part II; and as it is most graphic, the task of learning it is really an easy one.

Many of the simpler relationships employed in actuarial work can be established verbally, without reference to the algebraic qualities of the symbols employed. For example:

$$Ax = (P + Pax) \text{ or } P\,(1 + Ax).$$

It is evident in view of the above definitions that Ax, the single premium for an assurance of 1, ought to be the equivalent of the annual premium multiplied by Ax (the value of an annuity of 1 per annum payable at the end of each year) plus, in addition, Px, the first annual premium. Of course, either Px or Ax has, in practice, to be increased, or "loaded," by an amount sufficient to cover expenses and profit.

Again, a policy value or a policy reserve can be easily explained. At the issue of a policy the present value of the benefit is equivalent to the present value of the future premiums (leaving the "loading" out of account), but afterwards the value of the benefit exceeds the value of the future contributions, and the difference is the policy value.

This can be well expressed in the form of an account:

Present value of sum assured after n years, $x + n$ being then the attained age	$= Ax + n$	Present value of future premiums	$= Px(1 + Ax + n)$
		Balance is policy value represented by	$n\,Vx$
	$Ax + n$		$Ax + n$

and therefore $n\ Vx = Ax + n - Px(1 + Ax + n)$; or, as stated above, the policy value equals the value of the benefits less the value of the future contributions.

Other points on which information is useful are the various defects in family and personal history on account of which extra premiums are imposed; the merits or demerits of various bases of valuation, and the rationale of surrender values. Information on these and other points will be found in the literature referred to in such a form that little difficulty will be experienced in assimilating it.

All actuarial tables are given in decimals, and it is well to learn how to turn these readily into shillings and pence, and vice versâ.

It must be borne in mind that, however clearly the symbols employed may be understood, no one is competent to judge when a table is suitable for use unless he thoroughly understands the methods and data employed in its construction.

and this point cannot be too strongly emphasised.

Typical Examination Questions. The following questions on life assurance and life office work set at one of the examinations will give some idea of the knowledge which a life official, though not an actuary, ought to possess:

(*a*) A policy-holder, under a whole life policy by annual payments payable during life, desires to commute the future premiums to ten further payments, and has paid the first increased premium of £10. The premiums are due on April 1st. Draft a form of endorsement to be placed on the policy.

(*b*) State what you know as to the different systems of insuring lives without medical examinations.

(*c*) An annuitant desires to surrender his annuity. Should this be agreed to, and if so, under what conditions ?

(*d*) A policy is payable to an assured's executors, administrators, or assignees, and has not been dealt with in any way. What is the title in England, Scotland, and Ireland (1) when the assured has left a will; (2) when no will has been left ?

(*e*) When does the liability of an insurance company under a life policy commence ?

(*f*) What special allowance for income tax does an insurer receive from the Government ?

(*g*) What are the stamp duties on (1) a policy of life insurance ; (2) an annuity bond ; (3) a mortgage ; (4) an absolute assignment ; (5) a memorandum of deposit ; (6) an assignment to marriage contract trustees ?

(*h*) A policy has become a claim. It has been assigned. What is the procedure as regards delivery and custody of the deed of assignment in England :

(1) When the deed also conveys a policy on the deceased's life with another office ?

(2) When there are other effects conveyed ?

(*i*) Should a loan be granted to a policy-holder on security of his policy if he has lost it ? Should a surrender value be granted ? What is the procedure in such a case when the policy becomes a claim ?

(*j*) A policy-holder who has been insured for some years wishes to surrender. He points out that since his insurance has involved no loss to the office he considers he should get a return of at least all the premiums paid, since the office has had the benefit of the interest on the premiums. Draft a reply.

(*k*) An agent has been so frequently in arrear in the rendering and payment of his accounts that the office has decided to collect the premiums in his agency direct, crediting him with the commission. Draft a letter telling him of the office's decision, and one to the policy-holders in his agency informing them of the new arrangement.

(*l*) Explain fully any three bonus systems, and the advantages and disadvantages of each.

(*m*) A policy for £500 is effected in April, 1905, in an office which divides its surplus quinquennially, the next investigation taking place in December, 1908. On the basis of a compound bonus of 30s. per cent, per annum for each premium paid, with an intermediate addition of 25s. per cent., state what the amount payable would be in the event of death in November, 1915.

How to Become an Actuary. An actuary is one who has to solve for insurance companies, friendly societies, and similar institutions, financial questions that involve a consideration of the separate and combined effects of interest and probability in connection with the duration of human life, sickness, marriage and other contingent events ; or, more generally, an expert in the application of the doctrine of chance to monetary affairs, more particularly in respect of the insurance of life. Hence his chief duties are to make the computations necessary to determine the value of contingent liabilities, the compilation of mortality and other statistical tables, and the calculation of premiums.

On such calculations depends the practice of life assurance, and it is therefore evident that a skilled actuary is of final importance to the successful conduct of an office engaged in life insurance and annuity business. The governing authorities are, in England, the Institute of Actuaries, founded in 1848, and incorporated by Royal charter in 1884, and, in Scotland, the Faculty of Actuaries, formed at Edinburgh in 1856 and incorporated by Royal charter in 1868.

There are two principal ways for the "junior" in a life assurance office to gain promotion ; he may either become an actuary or a good "field" worker and organiser. No man, however, is put to outdoor work until he has had a number of years' experience in office routine ; and these years may with advantage be devoted to the attainment of actuarial training and experience. Both the outdoor man and the actuary are necessary to the life assurance office, and the man who is doubly qualified stands a better chance of reaching the highest position.

Preliminary Steps. The first step which the future actuary must take is to get himself enrolled either as a probationer of the Institute, or as a student of the Faculty. These are kindred institutions, and a resident in England, Ireland, or the Colonies would probably join the Institute, and a resident in Scotland the Faculty. Those who wish to join the Institute should write to the Assistant Secretary, Staple Inn Hall, Holborn, W.C., asking for a form of application for admission to the class of probationer and for a syllabus of the examinations. This form must be filled up and signed by two members of the Institute, either Fellows or Associates. Probably there will be in the applicant's own office at least one official of either status, but, should this not be the case, he should get his principal to assist him in obtaining the necessary introductions. Those who wish to join the Faculty should write to the Secretary, 24, George Street, Edinburgh, for an application form and syllabus. In this case the application has to be recommended by two Fellows of the Faculty.

The Institute requires the candidate to pass four examinations, known as Parts I., II., III., and IV., held in April of each year, before admitting

him to the class of Fellow (F.I.A.), although passing Parts I. and II. only will admit him to the class of Associate (A.I.A.). The Institute examinations are held at these centres: London, Edinburgh, Dublin, Adelaide, Melbourne, Sydney, Wellington, Montreal, Toronto, and Ottawa.

The Faculty requires the candidate to pass three examinations, also held annually in April, but only in Edinburgh for the first, and only in Edinburgh and London for the second and final examinations, before admitting him to the class of Associate, and thereafter admits him to the class of Fellow (F.F.A.) without further examination.

Graduates in mathematical honours of any university in the United Kingdom are exempt from the first examination in the case of both the Institute and the Faculty. Also in both cases admission to the class either of Associate or Fellow cannot be obtained before the age of twenty-one years, although the examinations may be passed earlier.

The Institute examinations involve the study of a larger number of subjects than do those of the Faculty, and in this course attention will mainly be devoted to the former, the differences between the two syllabuses, however, being indicated.

It may be well to state at this point that a resident in England, especially if connected with an English company, would be ill-advised to join the Faculty. The absence from the Faculty syllabus of certain items appearing in that of the Institute detracts materially from the value in England of the Scottish qualification. Obviously, too, a student residing in England can derive little benefit from a library in Edinburgh, and has no opportunity of meeting with other members of the institution; and, further, if he resides in London, he will lose the great advantage of being able to attend the classes provided by the institute.

The Institute of Actuaries Examinations. Assuming, then, that the candidate is enrolled as a probationer of the Institute, we give a concise description of the subjects which he will have to study, of the classes he should attend, and of the principal books he should read. [See also Schedule herewith.]

Examination Part I.

The Institute provides a tutor for Part I. of the examinations, and the probationer living in London should certainly join his class. Probably, for most students, this will be sufficient coaching for the first examination; but the class is generally a large one, and a student who feels that he requires special attention will do well to go to some other tutor in addition.

The Institute issues this initial regulation: "For admission to the class in Part I. the candidate must possess a fair knowledge of algebra up to and including quadratic equations."

This indicates the minimum amount of mathematics which the probationer must know, and enables any student to decide for himself whether he requires a preliminary course of study. The official class not being available to probationers resident in the provinces or abroad (unless they choose to come to London for the purpose), they must procure the services of a tutor; but, since there is nothing technical about the examination in Part I., any competent mathematician will suffice. If the tutor chosen has had no experience in preparing students for this examination, he should obtain copies of previous papers in order to ascertain the probable character and standard of the questions. The beginner, however, will, in many cases, be able to study under a qualified actuary, who will be conversant with these points.

Every candidate will receive advice as to the opening of the class, which is held in the evening, and he has then merely to attend the first meeting and pay his fees to the Assistant-Secretary. [See Schedule.]

The books which should be read in preparation for the first examination are Hall and Knight's "Higher Algebra" (Macmillan, 7s. 6d.); the introduction to some standard book of logarithmic tables; "Elements of Finite Differences," by Burn and Brown (C. & E. Layton, 7s. 6d.); and the chapters in Part II. of the "Institute Text Book" dealing with the fourth division of the syllabus. The theory of probabilities is dealt with in Hall and Knight's "Higher Algebra," but the student should also read some other work on the subject. Messrs. Ackland and Hardy's "Exercises and Examples" (C. & E. Layton, 10s. 6d.) will be found of great use in preparing both for this examination and the examination in Part II. A knowledge of the game of whist is very desirable. A game of cards not infrequently forms a setting for a problem on probabilities, and whist is invariably the game selected. The following question, set in 1905, illustrates this point and is a good example of a problem on probabilities. "In a game of whist, the dealer found, on turning up the last card, that he had the ace, king, queen, knave, ten and three other trumps in his hand; find the chance that this would occur." Here the essential point is that the dealer, having turned up the last card, must have at least one trump, which, of course, materially affects the probability or chance required.

Examination Part II.

Coming now to Part II. of the examinations, the Institute has published this reminder: "Candidates for the class in Part II. should have read the 'Institute of Actuaries' Text Book, Part I.'"

This book deals with subjects not comprised in the syllabus for Part I., and it is therefore necessary to study it in the interval between passing the first examination in April and joining the Part II. class, which is held during the winter months. Most men will find that they require no special assistance for this, but some may feel the need for a tutor, who, since the subject is technical, should certainly be an actuary. No doubt the tutor for the class in Part II. would not ignore Part I. of the "Institute Text Book," but he is entitled to assume that the members of his class have some knowledge of its contents.

SCHEDULE OF EXAMINATIONS FOR ACTUARIES

Examining Body, Grades, Time and Place of Examinations	Subjects of Examinations	Fees
INSTITUTE OF ACTUARIES. Students. Associate.	**Part I.**—Arithmetic and Algebra. The Theory and use of Logarithms. The Elements of the Theory of Probabilities. The Elements of the Calculus of Finite Differences, including Interpolation and Summation.	£1 1 0
	Part II.—Compound Interest and Annuities-certain. The Application of the Theory of Probabilities to Life Contingencies. The Theory of Annuities and Assurances on Lives and Survivorships. The elementary application of the Calculus of Finite Differences, and of the Differential and Integral Calculus, to Life Contingencies. Expressions for the Law of Mortality. The principles (as distinguished from the methods) of the construction of Mortality Tables (excluding graduation); and the principles and methods of the construction of monetary and other Tables involving the Contingencies of Life.	£1 1 0
Fellow.	**Part III.**—The methods of constructing and graduating Mortality, Sickness and other Tables. The history and distinctive features of existing Tables. The valuation of the Liabilities and Assets of Life Assurance Companies. The Distribution of Surplus. The Calculation of Office Rates of Premium for Assurance, Annuity, Sickness and other risks, excluding Pension Funds and Widows' and Orphans' Funds. The practical valuation of Life Interests and Reversions, and of Policies for surrender or purchase	£1 1 0
April. London, etc. (see text).	**Part IV.**—The Elements of the Law of Real and Personal Property. The Law relating to Life Assurance Companies and Life Assurance Contracts. The Constitution, Valuation, and Calculation of Rates of Contribution of Friendly Societies, Pension Funds, and Widows' and Orphans' Funds; and the Laws relating to such Institutions. Life Assurance Bookkeeping; preparation of Schedules, Statements and Reports. The Principles of Banking and Finance, including a knowledge of the Constitution and Operations of the Bank of England, and of the National and Local Debts of the United Kingdom. The Investments of Life Assurance Companies.	£1 1 0
Graduates in Mathematical Honours of any University in the British Empire may, at the discretion of the Council, be exempted from Examination in Part I. of the Syllabus.		
FACULTY OF ACTUARIES. Student. Associates and Fellows.	**First Examination.**—Arithmetic. Equations. Series. Permutations and Combinations. Binomial Theorem. Theory and use of Logarithms. Elements of the Calculus of Finite Differences. Theory of Probabilities.	No fee on first sending in name for examination, but £1 1s. on each subsequent occasion.
	Second Examination.—Interest and Annuities-certain, with Construction of Monetary Tables. Probabilities of Life and of Survivorship. Theory of Life Contingencies, including Annuities and Assurances, with construction of relative Tables. History and Characteristics of Mortality Tables. Application of the Calculus of Finite Differences to Life Contingencies. Elements of Differential and Integral Calculus.	
April. London and Edinburgh (see text).	**Third Examination.**—Mortality, Marriage and Sickness Investigations, including Construction of Tables from actual or from hypothetical data. Graduation of Tables. Formulas for Summation and Interpolation. Application of the Differential and Integral Calculus to Life Contingencies. Life Assurance Finance and Practice, namely: Calculation of Premiums. Valuation of Assets and Liabilities. Distribution of Surplus. Surrender and Conversion of Policies and Bonuses. Book-keeping and Accounts. Investments. Miscellaneous Questions. Law of Life Assurance. Reversions, Life Interests and other Contingencies. Widows' Funds, Superannuation Funds, and Friendly Societies—Calculation of Rates, and Valuations.	

QUALIFICATIONS WHICH SECURE EXEMPTION FROM THE ABOVE EXAMINATIONS

Any student who has taken a degree at one of the Universities of Great Britain or Ireland, Mathematics being one of the special subjects of examination for such degree, being 21 years of age, may, in the discretion of the Council, be exempt from the first of the examinations mentioned above.

The syllabus for the examination in Part II. may be roughly summed up by saying that it consists of the Algebra of Actuarial Science and of the Principles of the Construction of Tables of Mortality and other tables. [See Schedule]

The principal books to be read are the "Institute Text Book," Parts I. and II. (obtainable at the Institute, 10s. 6d. and 31s. 6d. respectively). King's "Theory of Finance" (C. & E. Layton. 4s.) may also be read with advantage, although, since the same ground is covered by Part I. of the "Text Book," it is not essential. It will also be necessary to read some book on the Differential and Integral Calculus, and whatever textbook is chosen the student will find a knowledge of Trigonometry useful. [See MATHEMATICS.]

The Principles of the Construction of Mortality Tables is the only remaining subject in the syllabus for this examination. The "Institute Text Book" deals with the subject, and many papers besides have appeared in the "Journal of the Institute of Actuaries." Although the construction of Mortality Tables is explicitly excluded from the syllabus of Part II. and appears under Part III., yet it is difficult to study the Principles of Construction apart from the actual construction. The student is recommended to study the construction of certain representative tables, but to bear in mind whilst so doing that he will be examined only on the principles underlying that construction.

The student should read the following papers in the "Journal of the Institute of Actuaries": Volume IX., on the "Healthy English" Table, and on the "Peerage" Table; Volume XVIII. on the "Carlisle" Table; three papers in Volume XXXI., by Sprague, Meikle, and Whittall, dealing with various methods and tables: and in Volume XXXIII. the paper by Ackland. He should also read the Introduction to Farr's "English Life Table No. 3"; Finlaison's "Report on Government Annuitants, 1883," and

Sprague's criticism thereon; the introduction to the "Institute Mortality Experience," and, most important of all, the "Account of Principles and Methods" adopted in the construction of the British offices' life tables. The student for Part II. should ignore all portions of these books which are concerned with graduation.

Examination Part III.

The Institute does not at present provide a tutor for either Part III. or Part IV. In recent years, however, a course of lectures by an expert has generally been held upon some subject which comes within the scope of the syllabus. These lectures have been printed and are of great assistance. Lectures are also delivered at the London School of Economics on various insurance subjects, and those courses which meet his requirements should be attended by the student. Notwithstanding this aid the student is more dependent upon private coaching than when preparing for Parts I. and II., and the best advice which can be given him is to join the class of a well-known tutor and, so far as possible, make no change until both Parts III. and IV. have been passed.

A certain amount of work towards the subject under the first heading in the syllabus for Part III. has necessarily been done in preparing for the second examination. Sickness tables, however, have not yet been studied, and this is the student's first introduction to the subject of Graduation.

Graduation. When a mortality table is constructed it is found that there are certain irregularities, arising from various causes, which would interfere with the practical value of the table. These irregularities require adjustment, and it is to this adjustment of the original observations that the term "graduation" is applied.

In preparation for the examination in Part III. there are numerous papers and letters in the "Journal of the Institute of Actuaries" which should be read, and also papers in the "Transactions of the Actuarial Society of Edinburgh," in the "Journal of the Statistical Society," and in the "Transactions of the Faculty of Actuaries."

The student should also read (in addition to the books mentioned in connection with the Principles of the Construction of Mortality Tables under Part II.), the introduction to Sutton's "Sickness Tables"; Watson's "Manchester Unity Sickness Tables"; the Annual Reports of the Registrar-General, especially those issued on completion of the decennial censuses; Bowley's Lectures on the "Measurement of Groups," G. F. Hardy's Lectures on "Graduation"; and the "Report on the Mortality of London" issued by the London County Council.

Valuations and Distribution of Surplus. In connection with items 3 and 4 of the syllabus, every student should make himself familiar with the methods of valuation and distribution of the disclosed surplus in use amongst life offices at the present time. This can best be done by studying the blue-books issued by the Board of Trade each year, which contain the Returns made by the Companies under the Life Assurance Companies Act, 1870. It should be particularly noticed how each method of distribution affects the incidence of the bonuses declared.

In order to acquire practice and facility in the valuation of reversions and life interests the student, unless he makes such calculations frequently in the course of his office work, should value such interests as he sees advertised for sale by auction and compare his results with the prices obtained.

Examination Part IV.

This examination may be taken the same year as Part III., but, having regard to the amount of reading which has to be done in preparation for Part III. only a really brilliant man has much chance of passing both parts together. On the other hand, Part III. being disposed of, a single winter's work should bring almost certain success in Part IV., and to take each part separately appears in most cases to be preferable.

The syllabus of the Examination in Part IV. consists largely of subjects which are not purely actuarial, but a knowledge of which is very necessary to the actuary. [See Schedule.]

Books to Read. The following books should be read: Strahan's "Law of Property" (Stevens & Sons. 12s. 6d.), or, if the student has time to read a full exposition on the subject, "Williams on Real and Personal Property"; Lectures by Wood Hill on "The Law of Real Property," by Hayter on "The Law of Mortgage" and by Clauson on "The Companies Acts" (obtainable at the Institute, 1s. each); and Indermaur and Thwaites' "Guide to Real and Personal Property" (Stevens & Haynes. 10s.). The last mentioned book will be found invaluable for revising the student's knowledge of the subject. Bunyon's "Law of Life Assurance" should be read, and certain Acts of Parliament, such as the Life Assurance Companies Acts, 1870-2; the Friendly and Collecting Societies Acts, 1896; Companies Act, 1900; and the Finance Act, 1894, must receive special attention.

A small book, entitled "How to Read the Money Article," by C. Duguid (Effingham & Wilson), is an admirable introduction to the financial part of the work. Clare's "Money Market Primer," "A.B.C. of the Exchanges," and also his "Lectures on the London Daily Stock and Share List," and some works on bimetallism and mono-metallism, should be studied. The student should read regularly the financial articles in one of the leading morning papers, and should also make a point of seeing regularly one of the financial weeklies, "The Economist" for preference.

No textbook can adequately deal with the subject of investments, knowledge of which can only come with experience. What the student should strive to acquire is a knowledge of the principal securities and investments, and a *thorough knowledge of the characteristics and special points* connected with the various classes

into which the investments of a life assurance company can be divided. Burdett's "Official Intelligence" and "The Stock Exchange Year Book" are the great mines of information concerning Stock Exchange securities. The student should attend any available lectures on the subject of investments, and should read Gunn's "Stock Exchange Securities," and Nicoll's paper entitled "Description of Certain Stock Exchange Securities," as well as Clare's lectures already referred to. As regards investments made by way of loans, the proposal forms used by the office with which the student is connected should be carefully studied to see on what points information is deemed essential. The correspondence in such cases is also important. There are, in addition to the books and articles already mentioned, a number of papers in the "Journal of the Institute of Actuaries," and of the other insurance institutes, which should be read.

The Student's Library. The student will find it difficult and expensive to purchase all the books mentioned, especially the earlier numbers of "The Journal of the Institute of Actuaries." He will, however, be able to borrow some of them from the library of his office, and others from the library of the Institute; he can thus, in most cases, reduce his purchases to a minimum.

In endeavouring to indicate the work which the actuarial student has to do before he becomes fully qualified, we have kept in view principally those who are not familiar with the subjects dealt with. On this account an exhaustive list of reading has not been attempted, though nothing of importance has been omitted. For fuller information, including the papers in the various journals which should be read, the student is referred to an admirable article, entitled "Hints on Reading for Actuarial Students," which appeared in the "Post Magazine" in 1903 from the pen of a well-known coach.

The general aim of the Institute, and also of the Faculty, examinations appears to be to educate the student first in pure mathematics, next in the theory of Actuarial Science, then in the practical application of that science, and finally in various subjects not strictly actuarial, but a knowledge of which is nevertheless necessary to the actuary. The foundation of the whole scheme is mathematics, and parents who wish their sons to enter the actuarial profession should see that a considerable portion of their time at school is devoted to algebra, trigonometry, and kindred subjects; and, further, should not allow a lengthy period to elapse between leaving school and beginning serious work. This is too often allowed, and it is no exaggeration to say that in many cases it is fatal, for the habit of studying is broken, and much useful information forgotten in the interval.

As already mentioned, a certain aptitude is necessary. The examinations are far from easy, and great application is required to get through such an enormous amount of reading when the days are spent in an office and only the spare hours of the evening are available for study.

The Faculty Examinations. The first examination of the Faculty corresponds very closely with Part I. of the Institute examinations. The second differs mainly from Part II. of the Institute in that the History and Characteristics of Mortality Tables takes the place of the Principles of the Construction of Mortality Tables, and other tables involving the contingencies of life. The third examination involves all the subjects in Parts III. and IV., with the exception of "The Elements of the Law of Real and Personal Property," and "The Principles of Banking and Finance."

The subscriptions to the two Institutes are very reasonable. We give the figures:

THE INSTITUTE OF ACTUARIES

Probationer, entrance fee, 10s. 6d.; annual subscription, 10s. 6d.

Student, further entrance fee, 10s. 6d.; annual subscription, £1 1s.

Associate, annual subscription, £2 2s.

Fellow, annual subscription, £3 3s.

FEES for class in Part I. or Part II., £2 2s. per session, from October to April.

FACULTY OF ACTUARIES

Students, entrance fee, £1 1s.; annual subscription, 2s. 6d.

Associates, futher entrance fee, £2 2s.; annual subscription, £1 1s.

Fellows, further entrance fee, £2 2s.; annual subscription, £2 2s.

It is impossible to give an idea of what a tutor would charge for individual attention, but where the student is one of a private class the fee charged for a winter session for Part III. or IV. will be found not to exceed £10 10s., and for Part I. or II. will be considerably less. The fees charged by the London School of Economics vary according to the course, but will in every case be found very moderate.

Actuarial Work in the Office. Probably the first actuarial work which the student will be required to do in his office will be the calculation of ordinary rates of premium, surrender values, paid-up policies, etc. The formulas employed are all laid down in advance by the actuary of the company, and the work is therefore not particularly difficult. At a later stage will come special calculations in connection with risks of various kinds which do not proceed on definite lines, and are consequently of greater interest. There are also valuations of reversions and life interests, either for purchase or for the purpose of determining their suitability as security for loans. Statistical work in connection with various Government returns, and for office information, also falls on the actuarial staff. All these branches of work will be done under the supervision of the chief actuary, who will also be responsible for the preparation of new schemes, acceptances of risks, settlement of claims, valuation of liabilities and assets, the distribution of the surplus disclosed by the valuation, and, if he be also the manager, the investment of the funds of the company.

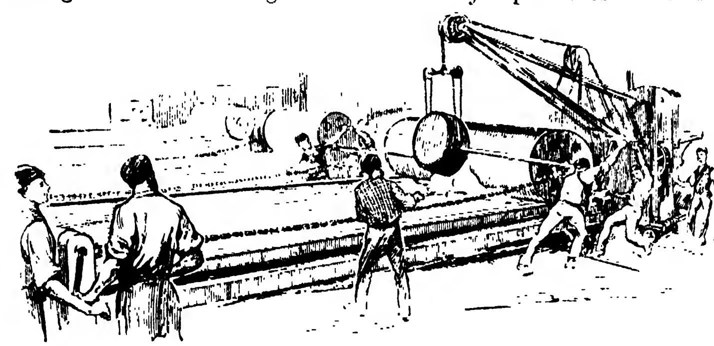
Continued from page 4534

PLATE GLASS AND BOTTLES

Making, Grinding, and Polishing Plate Glass. Perforated and Wired Glass. Blowing Bottles and Tumblers. Making Glass Tubes and Rods

Plate Glass. Plate glass is made by pouring molten glass on to an iron table, flattening it by passing an iron roller over it, and, after annealing the sheet of glass, grinding the surfaces flat, and polishing. The materials used are the purest obtainable, as freedom from colour is most necessary. The melting is done in pots, which serve also for pouring, the melted glass being for this purpose lifted bodily out of the furnace. The furnaces, on this account, are constructed with sliding doors made of iron frames, filled with firebrick, so that the pots can be readily taken out. The melting-pots having been filled with material, are lifted in place, the doors of the furnace closed, and the producer gas admitted. In about 15 hours the glass is ready for pouring. The door is then lifted, and a large wrought-iron balanced pair of tongs is swung into the furnace by a travelling crane. The pot is withdrawn and brought to the casting table. The casting table is a carefully



9. ROLLING PLATE GLASS

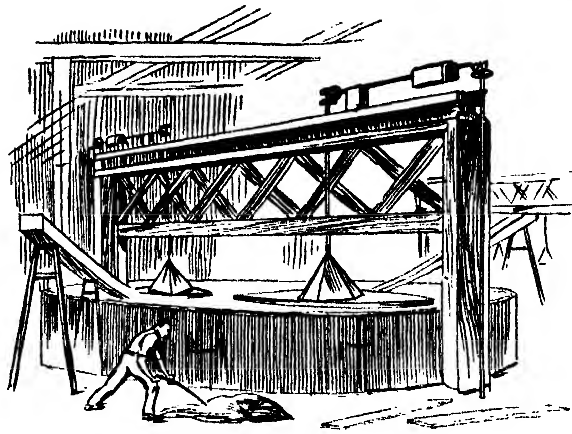
trued surface of cast iron or bronze. The surface is not in one piece, but consists of small sections, the object being to neutralise the warping which would take place if one large sheet of metal were heated on one surface only.

On one end of the table is a hollow cast-iron roller, extending entirely across the table. Down each edge of the table is laid a strip of iron, ½ in. in thickness, upon which the roller travels. Round each end of the roller is wound a chain, which is carried to the opposite end of the table to the drum of a hand winch. An overhead electrical crane carries a pot of molten glass up to the line of the annealing furnace, where it is set down and picked up by a small jib locomotive crane, which travels on a track that runs the full length of the annealing furnaces. By this crane the pot of metal is carried to the casting table, where the contents are poured out in front of the roller [9]. The roller is then drawn forward, and as it is raised above the table by half an inch, the molten glass is rolled out to just that thickness. By the time it has been rolled out the glass has cooled sufficiently to be moved to the annealing furnace. This furnace is raised to a temperature higher than that of the glass, and as soon as the plate has been introduced, the door is shut and the plate left to cool slowly for from four to five days. The cooling is assisted by passing cold air into flues below the annealing furnace.

Grinding the Plate. When removed from the oven, the plate is rough, and is submitted to the processes of grinding and polishing. The ½ in. plate in these operations becomes reduced to ¼ in., an ⅛ in. being lost from each side of the plate. The rough grinding is done between series of grinding tables arranged in groups of three, each group consisting of a lower and two upper tables. The lower table is a large cast-iron rotating disc, which has been faced and carefully trued up. The plate is laid upon this and embedded in plaster of Paris. Bearing upon the glass plate are two circular runners, one of which is 12 ft. and the other 14 ft. in diameter. The two runners are journalled in a trussed frame which extends across the top of the machine, and they are driven by means of mitre gears and shafting. The bottom face of the runners is shod with a number of parallel cast-iron serrated bars, which are spaced about 3 in. apart. The grinding [10] is started at slow speed, the runners moving at the rate of about two revolutions per minute. As it proceeds, the speed is increased until it reaches 30 revolutions per minute. Sharp sand and water are fed to the plate, and as not merely the runners, but the table below, are constantly rotating, the grinding is perfectly even over the whole surface of the glass, and thus a true surface is obtained. When about ⅛ in. has been taken off, the plate is turned over, and the rough grinding repeated on the opposite side. As the sand and water flow from the grinders, it is carried to a series of grading boxes and prepared for use again.

The Polishing Process. The plate, as it comes from the rough grinders, is like ground glass, and it is necessary to submit it to a polishing process. The polishing is done upon a large number of low tables. Down the full length of each table extends a cast-iron girder, to which is attached at intervals of about 20 in. a series of transverse wrought-iron bars [11]. Through the end of each of these bars extend the vertical

shafts of a series of felt-covered polishing discs. The pressure upon these discs is regulated by means of cup-shaped weights. which are placed upon their vertical spindles. The polishers are fed with rouge or oxide of iron, obtained by igniting sulphate of iron at a white heat for 36 hours. This rouge, mixed with water, is squirted on to the plate during the polishing operation. The longitudinal girders referred to above are connected to the crank-arms of a series of spur wheels driven by a 75-horse power engine, and by this means an oscillatory movement is given to the whole series of polishers. It takes twelve hours, six hours each side, to give the proper finish to a plate of glass. After polishing, the glass is sorted over for faults, and cut up into the desired size by a diamond.

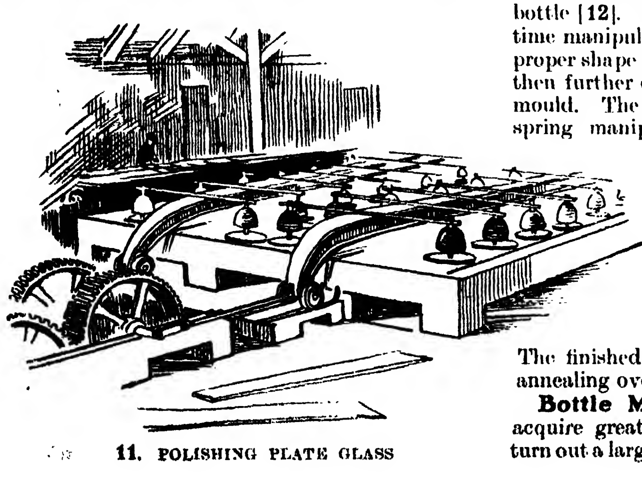


10. GRINDING PLATE GLASS

Rolled Plate. Unpolished plate glass is used for roofing purposes, but is frequently impressed with a design of fine lines, grooves, or squares, and in this condition is very largely used where obscured light is desired. The metal is ladled direct from the pot on to the table and rolled in the ordinary manner, but each ladleful is poured out at the end of the preceding quantity, as it is not so important in this case to avoid air bubbles. The rolled plate can also be annealed by piling on edge, as practised in annealing sheet glass, thus avoiding the use of the costly annealing furnaces required in the case of plate glass, where only one to three plates can be treated at a time. A method of making rolled plate practised by Messrs. Chance, of Birmingham, is to pass molten glass between a pair of rollers down an inclined plane. The glass is thereby rolled into a sheet, this sheet being then carried on an inclined plane to the annealing furnace. Additional rollers with patterns upon them are also employed. *Rippled glass* is made by the same firm by making the roller alternately rise and fall by means of a tooth edge on the side of the table.

Perforated and Wired Glass. A *perforated glass* for ventilating purposes is made on a casting table furnished with projections, so that on rolling holes are made in the glass, or the glass is so thinned at the spots that it can be easily drilled. The holes can be made by drilling with sand and water.

With the idea of increasing the strength of rolled glass, and preventing the scattering of the glass in case of breakage, it has become customary to enclose wire netting for certain kinds of glass. A layer of rolled glass of half the usual thickness is prepared; on this is spread the wire network, and then another layer of glass is rolled upon the netting. The wire is thus entirely enclosed and cannot rust. *Wired glass* is specially adapted for skylights, as wire protectors can be dispensed with. The glass is also to a certain degree burglar-proof, as it cannot be cut through with a diamond.



11. POLISHING PLATE GLASS

Bottle-making. The manufacture of glass bottles is a blowing operation, whether done by a workman or by a machine using compressed air. Moulds are used for shaping the bottle, and are made of cast iron or brass. A workman takes up on the blowpipe from the glass tank a sufficient quantity of the molten metal, called a *gathering*, and hands it to the "blower," who blows the mass into a pear-shaped bottle [12]. This embryo bottle is at the same time manipulated on a *marver*, and when of the proper shape is placed in the bottle mould and then further distended by blowing till it fills the mould. The mould is opened and closed by a spring manipulated by pressure of the foot. The bottle is released from the mould and separated from the blowing rod by touching the neck with a wet tool. A workman then forms the lip of the bottle by affixing a ring of molten glass which is moulded to the proper shape by a necking-tool, some varieties of which are shown in 13. The finished bottles are taken at once to the annealing oven.

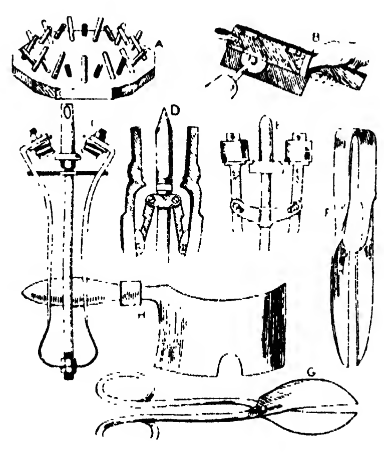
Bottle Machines. Although workmen acquire great dexterity in making bottles, and turn out a large number of these useful receptacles,

it is not surprising that efforts have been made to make the process quicker and surer by means of automatic machinery. Mr. H. M. Ashley in 1886 patented his bottle-making machine, which has since been modified and improved. Mr. Ashley's description of his machine is as follows: A quantity of molten glass is poured into a cup-shaped mould termed a *parison mould*, the lower part of which is made the counterpart of the shape which the head and neck of the bottle are intended to have. While the glass is still in a plastic state in the bloom or parison mould, a *punch* or *plunger* is pushed up into the body of the glass and withdrawn, thus forming a cylindrical cavity in the glass. The parison mould is then inverted and withdrawn, the neck mould, or that part which embraces the head and neck, being still left in position, so that the parison, or bulb of glass, remains suspended by the head and neck; this bulb, being still plastic and tending to elongate itself by gravity, is then enclosed within a mould which is a counterpart of the finished shape which the bottle is intended to have. Air or gas under pressure is then admitted into the interior of the glass bulb through a perforation in the punch or plunger, and the glass is thus distended so as to take the shape of the mould enclosing it. This mould being then removed, the bottle remains suspended by the head and neck, and that part of the mould being then opened the finished bottle is released and is conveyed away to be annealed.

12. GLASS-BLOWING

Several sets of apparatus are arranged on a revolving frame provided with means of performing successive movements automatically.

Since Mr. Ashley's machine was introduced, many variations have been brought out by other inventors, most of them being equally adaptable for narrow-necked bottles and wide-mouthed jars.



13. GLASSWORKERS' TOOLS
a. Northwood's scolloping tool for shaping edges of vases *b*. Richardson's wineglass foot mould, "Pacella" *c*, *d*, and *e*. Three forms of tongs for shaping the necks of bottles (*c* shows the complete tool) *f*. "Tool" for regulating the form of a blown glass vessel *g*. Shears for trimming edges of vessels *h*. The "whip," for forming necks and cleaning away surplus glass

Blown Glass. By a combination of blowing and clever manipulation with simple tools [13], the glassblower forms variously shaped vessels out of molten glass. Table glass, except the commonest, is blown glass. A *tumbler* is a simple form of the glassblower's art, but in making it a special rotary motion is given either to the blow-tube or the mould, which requires considerable practice. A *wineglass* is a more elaborate production. The bowl is first made, the stem and the foot being subsequently added and shaped.

Pressed Glass. Another form of hollow glassware is that known as *pressed glass*, which is made chiefly at Gateshead in England and Pittsburg in the United States. The glass used is *flint glass* (lead glass) on account of its superior brilliancy, but the cheaper *baryta glass* is being increasingly employed. The process is manipulated by either hand or steam, the small hand presses being sufficient for small articles. The moulds are of iron or gunmetal, and a quantity of molten glass having been introduced, a plunger descends and forces the glass into all parts of the mould, thus shaping the outside and the inside of the vessel at the same time. The Appert process is a modern development in the manufacture of pressed glass which seeks to overcome the cooling effect of the mould, and to make the process automatic. The moulding is effected by successive stages so that the glass only touches as small a surface of metal at one time as possible.

Fire Polishing. The surfaces of the pressed glass article are not so smooth as blown glass, but this defect is overcome by what is known as *fire polishing*. This consists in reheating the articles in an oil furnace with a steam blast so that the outer surfaces of the glass are melted, a brilliant surface being the result. The method was invented by Sowerby in 1886, and improved in 1896. The furnace receives the heat from injectors at one or both ends, the glass article being held on a *snap*, which has the ends lined with asbestos to prevent cracking.

Glass Tube and Rod. Tubing or rod of glass is made by gathering metal on a blowpipe, rolling it on the marver, attaching a metal rod to the opposite side of the lump of glass, and drawing the two rods apart. If the lump of glass has been formed into a hollow bulb, tubing results. The rods are held by different workmen, who walk backwards away from each other, assistants watching the process to give warning of any thinning of the tube in parts. Glass buttons are pinched off glass rods while still soft, the pincers having moulds on the gripping surfaces. Glass marbles are also cut off glass rods while soft, but are then placed into an iron drum with kaolin and rapidly revolved, when the pieces of glass assume globular shape. A recent application of glass rod is seen in the prismatic globes used for covering electric light bulbs. The glass rod is softened by a blowpipe flame, and coiled upon a revolving mandrel of the required form. Glass tubing is used in the manufacture of beads, a short account of which is given in the next lesson.

PROBLEMS IN THE CONE

Effects of Height. The Shapes of Envelopes. Conic Frusta. Oblique Cones. Effect of Varying Planes of Truncation. Plates for Fire-boxes

continued from page 4526

By JOSEPH G. HORNER

CONICAL figures and portions of the same divide importance about equally with pyramidal forms, and they occur in right and oblique varieties. Their construction is not difficult, either by direct reference to the apex or by the method of triangulation.

The Elements of the Cone. In **41**, AB is the vertical height of the cone, AC its slant height, BC its radius, and DE the diameter of its base. Hence the meaning of the statement that a right cone is formed by the revolution of a right-angled triangle round one of the sides contained in the right angle, and that the hypotenuse in its revolution develops the surface of the cone.

In **42** and **43** the triangle is dotted on one side of the axis and the cone drawn on the other. The axis of revolution, therefore, is the side *a* in **42**, and the side *b* of the triangle in **43**. The hypotenuse *c* measures the same length, *c*, in each case, but the difference in the diameter of the base and the difference in the steepness, or slant height, and the vertical height are most marked. Not the least value of an object lesson like this is to introduce a mental exercise which the workman constantly finds himself making. When in doubt about the possible resulting shape of a development, greatly exaggerate it mentally, and the issue often becomes obvious.

To obtain one dimension from others, lay down the known dimensions to scale, or to full size, and measure off the others. Thus, in **42** and **43** the heights *de* and radii *ef* being known, the length of the slant edge, *df*, is obtainable. Or, if radii *ef* and slant *df* are given, the heights *de* can be obtained. The construction is too obvious to need further description, and of course the same method applies to conic frusta.

Cases arise in which it is not practicable to draw the entire triangle, and then the rules of geometry may be used thus: if the lengths of the sides be known, add the squares of these, and the square root of the sum will be the length of the hypotenuse. The lengths of the sides are the equivalent of the perpendicular height, and the radius of the base of a cone and the hypotenuse is the equivalent of the slant height.

It is not necessary in all right circular cones to draw the circle of the base in plan, as it was essential to draw the base of a pyramid in plan in our first article. The bases of **42** and **43** are circles of radii *ef*, *ef*, which we know must be the case. But in many cases it is necessary to draw the circle, not to obtain the shape, but to get other dimensions and relations on.

Marking Out the Envelope of a Right Cone. In marking out the complete envelope of a cone, therefore, the length of the slant edge *c* [**42** and **43**], or AD, AE [**41**] is taken for a radius, the length of the circular edge of the envelope is made equal to the circumference of the base, and lines are drawn from the termination to the centre, corresponding with the apex, thus:

Taking the cone in **42**: To obtain the length round the circumference, calculation based on diam. × 3·14159 is not so convenient as stepping round with a large number of very short chords, because of the difficulty of bending a rule round. These steps of division may be as numerous as desired. The distance round *f* is more conveniently obtained by drawing a quadrant of the circle, as in **44**, or a semi-diameter, as shown below **42**, and dividing either into any convenient number of equal parts. Four times the number of divisions in the first [**44**], or twice the number in the second [**42**], will give the total length round the circumference of the base of the cone. The larger the number of divisions the more nearly will the chord measurements be the equivalent of arc measurements. Now, these divisions have to be stepped round an arc, not of radius *ef* [**42**], but of radius *df*, as in **45**. Then, starting from *f* [**45**], step round 16 parts and connect the sixteenth with *d*, and the envelope is obtained which will cover the cone in **42**.

Just to fix this in the mind, see what the development of **43** would give us. Divide a quadrant of **43** into, say, 10 equal parts as shown. With the slant height *df* for radius, strike an arc [**46**], and divide it round four times 10, and connect the fortieth division with *d*. The resemblance to the development in **45** is hardly obvious. We learn, therefore, that the flat cone cuts into more material than a steep one, for the sheet is almost a complete disc. The relations between slant height and vertical height are also much more apparent than in steep cones.

The Conic Frustum. The envelope of the frustum of a cone is obtained by the same kind of construction as that of the complete cone. In **47** the elements of a conic frustum are shown, with the cone of which it forms a section completed by dotted outlines, in order to determine the shape and proportions of the frustum.

In **47**, AB is the perpendicular height of the cone, and B*b* that of the frustum. BC is the radius of revolution of the base, sweeping round the diameter DE; *bc* is the corresponding radius in the plane of truncation, sweeping the diameter *de*. The slant height of the complete cone being AE, that of the frustum is *e*E. We have therefore two planes, DE and *de*, separated by

a slant dimension *e*E, for which the circumferences of the sheet to form the envelope have to be obtained, as in **48** and **49**, thus:

Draw the required frustum, D*de*E [**48**], and complete the cone to the apex A. Take the slant height AE as a radius, and strike a circular arc [**49**], with radius AE. Take the radius BE of the base of **48**, and strike a quadrant E*f*, and divide it into any convenient number of parts, say six. Transfer these four times in succession to the curve E in **49**, which will then be practically equivalent in length to the circumference of the base DE in **48**. Connect EA24 [**49**], which will complete the boundaries of the entire conical figure in **48**. As the article required is for the envelope of the frustum, it is only necessary to take the curve corresponding with the plane of truncation from the slant edge, and carry it as far as the radial lines, so completing the envelope without any dividing round. Thus the slant height A*e* [**48**] is taken, and a curve *ed* struck from A in **49**. The sheet E*ed*24 in **49** will be the correct envelope for the body of the frustum in **48**. The bottom and top are obviously circles of diameters DE and *de* respectively.

The developments represent the exact envelopes only, to which extras for joints, soldered, riveted, or otherwise, as the case may be, have to be added on the completion of the exact developments.

A Frustum with a Distant Apex. Taking next an article [**50**] in which a conical frustum occurs, where the apex would be situated at too long a distance away to admit of the use of compasses, the triangulation method illustrated in our first lesson again comes in. Such problems occur very frequently, both in complete figures and in the curved corners of flaring objects, or those having sloping sides or "flue."

Figs. **51, 52** show the marking out of the pattern for the frustum in **50**. First take the radii A, B from **50**, and strike them both in plan [**51**] from centre, *o*. Divide a quadrant on A into any convenient number of equal parts, and prolong lines thence to the centre, *o*, cutting the curve B so that both arcs A and B are divided proportionately. These divisions correspond with those of quadrants of the circles of the base and the plane of truncation in **50**; but we now have to obtain the width corresponding with the slant face C in **50** and the curves of the developed plate, obtained thus:

Raise a line [**51**] *a*D, perpendicular to the line A*a* joining the points A*a*, and measure off on it the length *a*D, equal to the perpendicular height D in **50**. Join AD, which will be the actual length of the line A*a*, measured up the slant face C in **50**.

From these the plate is developed as in **52**. Draw a line AB equal in length to the slant height C [**50**]. Take the divisions A1, B*a*, in **51**, and set them off by small arcs A1, B*a*, in **52**. Take the length AD in **51** for a radius, and from the points A and B in **52** as centres strike arcs intersecting those, 1 and *a*, just marked. Next, taking 1 and *a* as centres, proceed as just described from A and B, striking arcs with radius AD [**51**], repeating the process from each new set of centres obtained, as 2 and *b*, 3 and *c*, 4 and *d*, 5 and *e*, to 6 and *f*. Curves drawn through the successive centres as shown will give the outline of the sheet required. Fig. **52** is, of course, only a quadrant, which has to be repeated four times to produce the entire envelope for **50**.

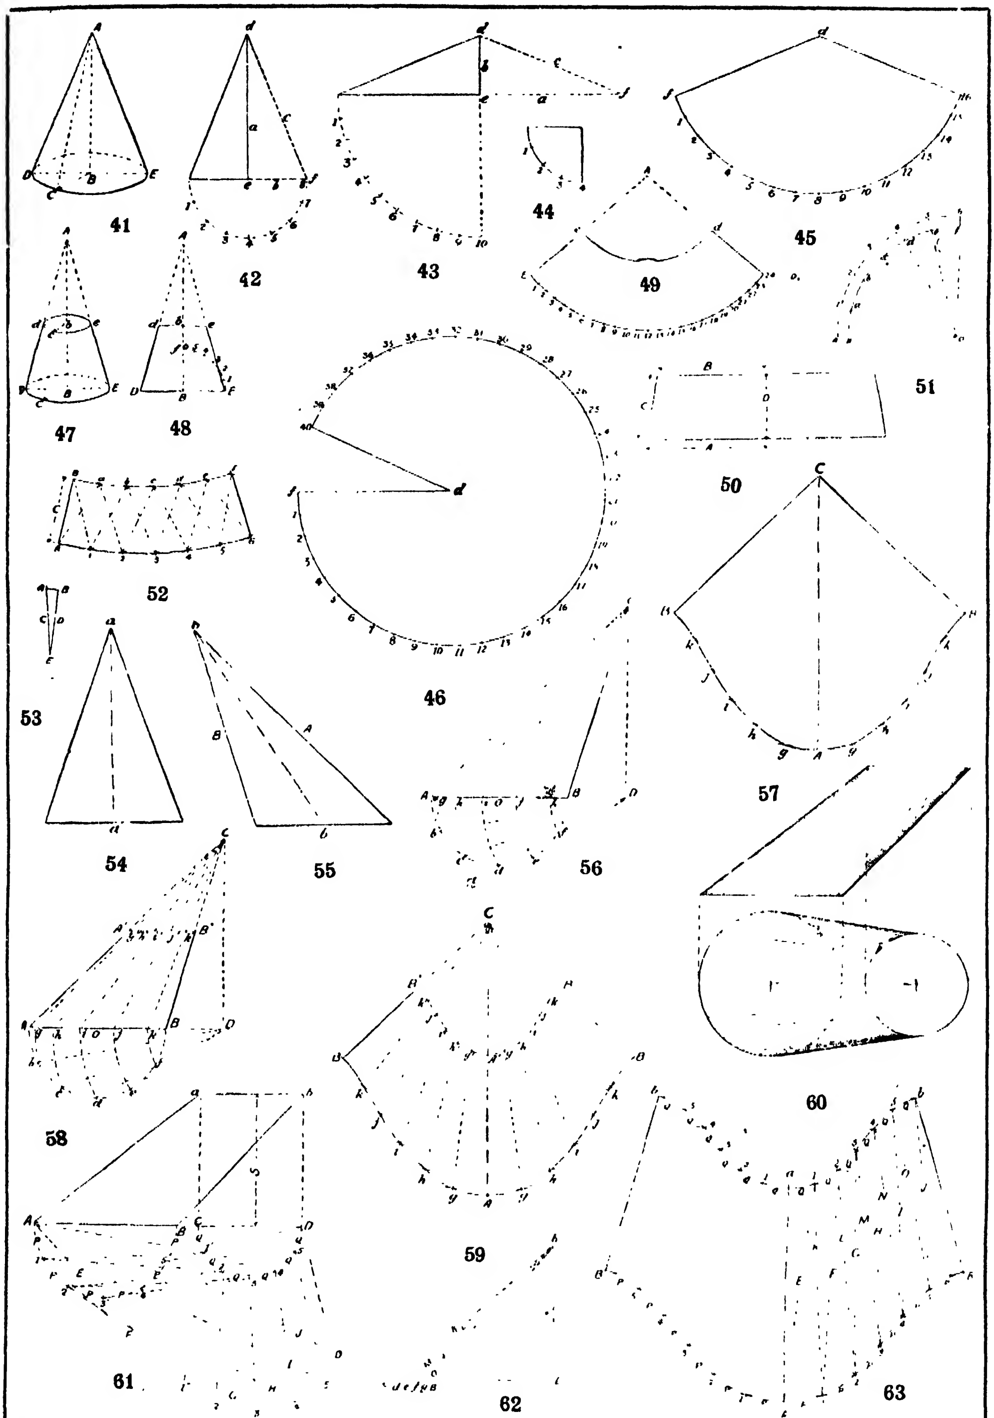
It may often happen that the vertical height only, D [**50**], of the conic frustum is known, and not that of the slant C. Then the latter can be obtained as in **53**. The distances corresponding with the difference in radii on top and bottom being given, AB, a line BE is raised perpendicularly to a line connecting the radii. The length BE is measured off equal to the perpendicular height D, in **50**, and a diagonal AE will give the slant height C.

Oblique Cones. Oblique cones are those in which the apex is not situated over the centre of the base. As, therefore, the right cone is developed by the revolution of a hypotenuse of constant length and angle round one side of the right angle, so the oblique cone is the result of the revolution of a hypotenuse of *varying* length round angles that vary constantly. Two views of an oblique cone are shown by **54** and **55** taken at right angles to each other. Only on opposite sides of the plane *aa* do the angles and lengths correspond. On the opposite sides of the plane *bb* there is an infinite gradation from the maximum slant A to the minimum ditto B.

Oblique cones are drawn by the same principle as the oblique pyramids in the previous lesson. In fact, if we regard a cone as a pyramid with all the angles obliterated, the construction is identical. In drawing cones, divisions and lines are taken at intervals just as in pyramids.

To develop the envelope of a complete cone [**56**] let AB represent the base of the cone, C its apex, and O the centre of the base. From O as a centre describe a semicircle of diameter AB. Divide this into any convenient number of parts, as shown. Drop a perpendicular from C to meet the line AB, prolonged at D. Draw lines from *b*, *c*, *d*, *e*, *f* to D. These will represent the cone divided in plan. Using D as a centre, draw radii from *b*, *c*, *d*, *e*, *f* to cut the line AB at *g*, *h*, *i*, *j*, *k* respectively, and join *g*, *h*, *i*, *j*, *k* to the apex C. The lines C*g*, C*h*, C*i*, C*j*, C*k* are the actual lengths of the lines *b*D, *c*D, *d*D, *e*D, *f*D respectively drawn in plan, and are therefore the working lines.

Fig. **57** shows the development of the envelope, supposing the seam to occur along the line CB in **56**. From a centre C [**57**] strike radii CA, C*g*, C*h*, C*i*, C*j*, C*k*, CB equal respectively to the radii similarly lettered in **56**. Take in **56** the distance A*b*, or *bc*, *cd*, etc., these divisions being equal, and set off the same distances from A to *g*, *g* to *h*, *h* to *i*, etc., to B and B in **57**. Join B and B to C to obtain the sides for the seam, and draw a curve through the various points of intersection, as shown, to produce the envelope corresponding with the base.



THE CONE AND ITS DEVELOPMENT

41. Elements of the cone 42, 43. Effect of difference in heig'' of cones and envelopes of same 44, 45, 46. Stepping round chord divisions for lengths of arcs 47. Elements for conic frustum 48, 49. Envelope of conic frustum 50. Conic frustum with little slant 51 52. Envelope obtained by triangulation 53. Problem when the slant is not known 54, 55. Oblique cone 56, 57. Envelopes of oblique cones 58. Truncated oblique cone 59. Development of truncated oblique cone 60. Cone with apex inaccessible 61, 62, 63. Envelopes of cone with apex inaccessible

Truncated Oblique Cones. Truncated cones also may be cut both at base and top, parallel with the true base of the cone, or, as is frequently done, at an angle therewith. They may also be developed with compasses, or by triangulation. The cone may also vary much in its degree of obliquity, until one side may stand vertically.

If the frustum be truncated in a plane parallel with the base, the projection of the lines from the base to the plane of the truncation gives the radii at once for a second set of arcs, drawn in **58**. Also a semicircle equal in radius to that at the plane of truncation, divided round into the same number of equal parts as the base gives the points of division on the corresponding arcs, through which the curve of development is drawn for the small end of the frusta thus:

In **58** let AA′B′B be the elevation of the frustum. The construction of the development of the base is the same as that shown in **56** and **57**, and the same reference letters being employed in the two figures, it is not necessary to repeat the instructions there given. The *additional* lines required for the construction of the top of the frustum are obtained thus: The lines which pass from the points of division in the base to the apex cut the plane of the frustum at the points *g*′, *h*′, *i*′, *j*′, *k*′ [**58**], and the lines thence to the apex C give the true lengths of the several generating lines in the frustum. To obtain the developed form, mark the curve for the base as shown in **59** similarly to that shown in **57**. Then for the curve for the top of the frustum; with the radius CA′ [**58**], strike the curve CA′ [**59**]; with the radius CB′ [**58**], strike the curve CB′ [**59**]; and so on with the radii C*g*′, C*h*′, etc., in **58** transferred to **59**. Through the points of intersection of these arcs with the radial lines previously obtained draw the curve B′A′B′, then the outline BAB B′A′B′ will be that of the development of the frustum.

The so-called oblique truncated cone occurs frequently. Its chief value lies in connecting cylindrical bodies, the axes of which are not perpendicular, hence the base and plane of truncation are generally circles. If a right cone were tilted, and its base and top cut at an angle, the section would be an ellipse, as we shall see later, and then the plans would have to be developed as ellipses. But in speaking of oblique cones, the base and truncation, when parallel with the base, are taken as circles. These relations are shown in **60**, where the plan of base and top are drawn perpendicularly to their elevations. We see also that the degree of slant may often be such that the apex might be inaccessible, so that the method of **58** could not be applied. We now take, therefore, such a case and show its development without radii from the apex.

Conic Frustum with Distant Apex. To obtain the pattern for such a frustum, first proceed as in **61**. On a base line draw semicircles AB, CD, equal in radius respectively to that of the base AB and truncated top of the cone *ab*, the latter being perpendicular from the top as shown. If angles of slant only are given, draw lines A*a*, B*b*, and draw the semi-diameters thence. Divide these semi-diameters into any convenient number of equal parts, 1, 2, 3, 4, 5, B, 1′, 2′, 3′, 4′, 5′, D, taking care that the number of divisions shall give a central division, as 3′3′. Connect these points of division by lines 1 1′, 2 2′, 3 3′, 4 4′, 5, 5′. These will represent the lengths of lines of development in plan, but they are obviously not the actual lengths required for setting out the pattern. The lengths of the sloping edges A*a* and B*b* are those taken directly on the elevation. But as the actual lengths of the lines 1 1′, 2 2′, 3 3′, 4 4′, 5 5′ are not the same as those drawn in plan, they must be obtained by projection to the elevation, thus:

As the point D is dropped perpendicularly from *b*, the length DB bears the same relation to the slant length B*b* that the lengths of the lines 1 1′, 2 2′, etc., do to their real lengths. Thus, starting from D as a point to mark from [**62**], take the length 1 1′ from the plan [**61**] and set it off from D to *c* [**62**]. Then *cb* will be the real length of 1 1′. Next take 2 2′ from the plan and set it off from D to *d*, and *db* will be the real length of 2 2′, and so on, to get the positions *e*, *f*, *g*.

To obtain the true diagonal lengths required for triangulation [**61**]. From 1′ draw 1′1″ perpendicular to A1′, and measure off 1′1″ equal in length to the height S of the frustum. Then the length A1″ will be the true length of the line A1′. Also, having connected 2, 3, 4, 5 to 2′, 3′, 4′, 5′, from 2′, 3′, 4′, 5′, D, draw lines 2′2″, 3′3″, 4′4″, 5′5″, DD″ perpendicular to 1 2′, 2 3′, 3 4′, 4 5′, and 5 D, respectively, and all equal in length to the height S. Joining 1 2″, 2 3″, 3 4″, 4 5″, 5 D″ will give the true diagonal lengths required for triangulation.

Envelope of Frustum. We have now, therefore, the true lengths [**62**] of the lines of division taken on the planes of the semicircles for base and crown. Also the real lengths of the diagonals in **61** required for setting out the development by triangulation.

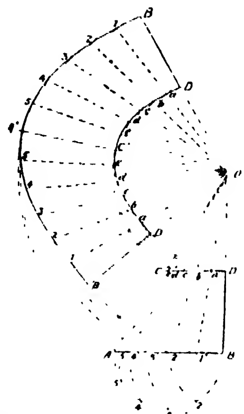
To describe the envelope [**63**], draw the line A*a*, equal in length to the line A*a* in **61**, and use A and *a* as centres, as follows. (But as it is very confusing to bear all these letterings in mind, capital letters are introduced in addition, to represent the lines themselves, so that by comparing those in **61** and **62** with **63** the corresponding relations are seen at a glance.)

From A as a centre [**63**] with the radius A1″ [**61**] (length E), strike an arc. From *a* as centre and with radius C1′ [**61**] (length Q) strike an arc cutting this at 1′ [**63**]. Then from A as centre and radius A1 [**61**] (length P) strike an arc; and from 1′ as centre, and radius *cb* [**62**] (length K) strike an arc cutting this at 1 [**63**]; 1 and 1′ [**63**] are now new loci or points of intersection whence 2 and 2′ are obtained from the next pair of elements in **61** thus: From 1′ [**63**] as a centre, and radius 1′2′ (length Q) [**61**] strike an arc. From 1 [**63**], with radius 1 2″ (length F) [**61**], strike an arc intersecting this at 2′ [**63**]. Then from 2′ [**63**] with radius *db* [**62**] (length L) strike an arc [**63**], and from 1 with radius 1 2″ (length F) [**61**], strike an arc intersecting this at 2 [**63**]. Then 2 and 2′ are points of intersection from which with respective radii 2 3″ and 2′ 3′ [**61**] the

next points of intersection, 3 3′ [63], are found. From 3′ and 3 as centres, and respective radii *eb* [62] (length M), and 3 4″ 4′ [61] (length H) describe arcs intersecting at 4 4, and so on until the figure required is completed, the pattern being symmetrical about the centre A*a*.

Oblique Cone with One Side Vertical. A variation in the oblique cone occurs when one side is perpendicular, BD in **64**. Draw a semicircle on the base AB, and divide it round equally as convenient, 1, 2, 3, 4, 5, A. From B as centre strike radii from these points of division to cut AB at 1′, 2′, 3′, 4′, 5′. Prolong these lines to the apex *o* of the completed cone, cutting the plane of truncation CD at *a, b, c, d, e*. The developed pattern is shown to the left in **64**, obtained as follows:

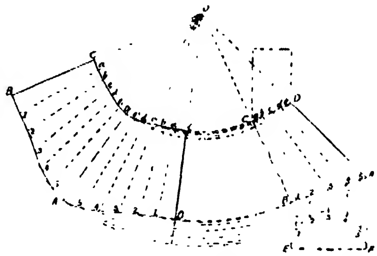
From *o* as a centre, draw arcs starting from A, 5′, 4′, 3′, 2′, 1′, B, and another series of arcs from C, *e, d, c, b, a*, D. Set the compass to one of the equal divisions 1, 2, 3, on the semicircle, and from A′ as a centre step off these divisions from one arc to that adjacent in the manner shown, 5, 4, 3 etc., and the edge of the envelope corresponding with the base is then drawn through these points of intersection. Prolong lines from all these points of intersection to the centre *o*. For the edge of the truncated face, the points of intersection of the radial lines just drawn, with the successive circles *e, d, c, b, a*, will give the required development, the edges BA′BDC′D completing the outlines



64. OBLIQUE CONE WITH ONE SIDE VERTICAL

Different Planes of Truncation. Conic frusta are often cut both along the base and along the plane of truncation in planes that are neither horizontal nor parallel. To draw the envelope of an oblique conic frustum ABCD [**65**], to join two vertical cylinders, proceed as shown, the cylindrical portions being indicated by dotted outlines.

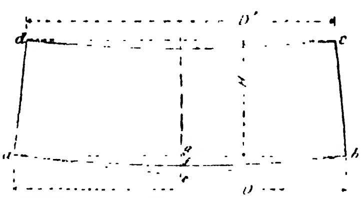
In the lower portion draw a semicircle, EF, to represent half the lower cylinder in plan, and divide it round into any number of equal parts, 1, 2, 3, 4, 5 and F. Project lines up from these to cut the base of the cone at the line of its joint with the cylinder 1′2′3′4′5′. Prolong lines from these points to the apex, *o*, of the cone completed, intersecting the plane of truncation CD, or that where the upper cylinder is to be united, at *a, b, c, d, e*.



65. ENVELOPE FOR VARYING PLANES OF TRUNCATION.

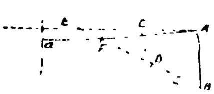
Now, from the apex *o* as a centre, draw arcs from these lines of intersection on both planes, starting from all the points of intersection, and the bounding lines, as B, 1′, 2′, 3′, etc., C, *a, b, c*, etc. Draw a centre line *o*A, anywhere [left hand of **65**], and to right and left of this step off distances A, 5, 4, 3, etc., equal to the divisions 1, 2, 3, 4, 5, on the semicircle EF. Draw radial lines thence to *o*. Through the successive points of intersection of the radial lines and curved lines draw the curves of the envelope at the large and small ends, as shown on left.

Conical Fire-boxes. Some problems in constant use differ from the foregoing in the fact that the amount of slant or taper is very slight, amounting to 3 in. or 4 in. difference in diameter at top and bottom. Neither trammels nor triangulation are adaptable in these cases. Two rules in regular use are here given for the plates of conical fire-boxes. One is shown in **66**. First set out the lengths D, D′, equal to the circumference of the plate required to complete the fire-box, on the lines *ab, dc*, the distance H, by which these lines are separated, being equal to the height of the fire-box. To obtain the top and bottom curves, first draw two lines starting from the edges *a, b*, and perpendicular to the edges *ad, bc*, meeting on the centre line at *e*. A point *f*, taken nearly midway between *e* and *g* will be a point in the curvature required for the bottom edge. It is often taken midway, but is more accurate if *f* be brought nearer to *g* than *e*, in the proportion of 4 to 5. The curve is drawn by bending a strip through the points *a, f, b*, and the top curve is afterwards drawn parallel with the first. Width of seam for riveting is added to *ad* and *bc*.



66. DEVELOPMENT FOR A CONICAL FIRE-BOX

Fig. **67** shows another method. From a centre A, with a radius less than one-fourth the length of the shorter edge of the plate, strike a quadrant BC. From B, with the same radius cut BC in D. Draw a line BE through BD. From D, and still with the same radius, cut BE in F. A line drawn from A, through F, cutting the centre line at *a*, will give the middle point in the curve required. The other edge will be cut parallel with the first as in the alternative method described in the preceding paragraph.



67. ANOTHER METHOD OF **66**

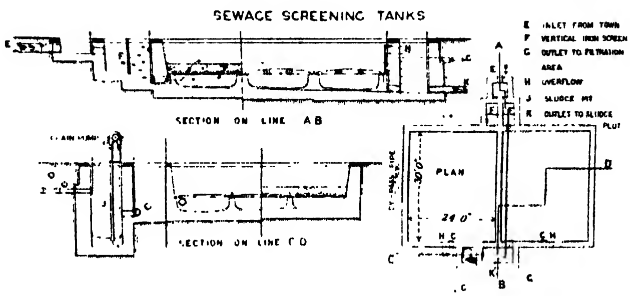
BACTERIAL TREATMENT OF SEWAGE

Various Bacterial Systems and What They Have Taught. The Contact System and Contact Beds

By Professor HENRY ROBINSON

THE bacteria which effect the purification of sewage are divided into two classes, (1) the aerobe, which requires air; (2) the anaerobe, which acts without air or light. The latter liquefies the organic solid matter in sewage as is seen in the ordinary cesspool, where only inorganic solid deposits will be found when it is cleaned out. The writer had an experience of this when he had to dispose of the sewage of a town on too small an area of land for irrigation to be possible. He wished to avoid the expense of chemical precipitation, and adopted an upward filtration system, by which the solids were arrested before the sewage passed on to the land. The diagram [38] shows the filter as actually carried out.

It will be seen that the tanks had false bottoms, covered with a bed of coarse stones. The sewage from the outfall passed slowly upwards through the filter, leaving the larger suspended solids in the false bottom, where they became liquefied by what is called *septic action*, as in a cesspool. The liquid sludge was pumped at intervals out of the bottom of the tanks, carted away, and disposed of on adjoining land with excellent agricultural results.



38. UPWARD FILTRATION SYSTEM

In designing a sedimentation tank, through which the crude sewage is to pass to deposit inorganic (and some organic) solids before the liquid is applied to bacteria beds, the capacity of the tank must be such as to insure no excessive velocity whereby the solids would be carried through it.

Bacterial Systems. The organic solid matters in suspension, or pseudo-solution, which flow from the sedimentation tank (after passing a screen to arrest large solid matters) to the bacterial beds are those which have to be acted upon by either aerobic or anaerobic germs, and the systems which have been adopted to perfect their action and to convert foul fluid into a good effluent will be described.

In 1895, Mr. Cameron, of Exeter, brought into prominence the results which he had obtained there by passing crude sewage through a septic tank, by which the solid organic matters were liquefied as already described. This form of tank was closed, but experience has shown that an open tank will enable the liquefying organisms to act. The point of admission of the sewage into the tank should be below the top of the fluid in the chamber, and the resultant septicised liquid should be drawn off at a point below the top level. A scum forms on the surface, which it is useful to preserve, and the writer, in employing tanks of this kind, has adopted a simple covering to protect the scum from the action of the wind and rain.

Birmingham Experience. An interesting paper was read in 1906 by Mr. Watson, of Birmingham, before the Incorporated Association of Municipal and County Engineers, in which he gives the liquefying action of septic tanks on the solids of the sewage of Birmingham. The composition of the sewage was as follows:

Dissolved Solids.	Suspended Solids. Total.	Suspended Solids. Organic.	Free Saline Ammonia	Albuminoid Ammonia.	Chlorine.	Nitrates and Nitrites as Nitrogen.	Oxygen Absorbed. Unfiltered.	Oxygen Absorbed. Filtered
119·3	74·3	44·9	4·05	1·57	20·2	0·92	27·56	15·79

He found that the sludge from the septic tanks was practically inodorous, but on being pumped on to the land it had to be mixed with earth in a ratio of one-fourth of the residuum to black earth before a satisfactory crop could be grown. It was also found that if the roughing tanks, which are provided to get rid of the detritus, were of such capacity as to sediment too much of the solids, the septic action in the tanks following them suffered, and it was necessary to pump a volume equal to 30 per cent. of the liquid sludge from the roughing tanks into the septic tanks daily to restore their fermentative quality. With the Birmingham sewage it was found that only about 10 per cent. of the sludge—which is considerably below the results at Manchester and other places—was liquefied in the septic tanks. It must, however,

be borne in mind that these places have a considerable quantity of trade waste to deal with, and it has been proved that with purely domestic sewage this percentage would be considerably augmented. • The chief point, however, that requires attention appears to be the condition of effluent coming away from the septic tanks. In order to get the maximum liquefaction of the solids it becomes necessary to have a very foul effluent coming away from the tanks, owing to the flow through the tanks being slow, thus tending to make the treatment of the same a danger as far as nuisance is concerned. The resultant sludge, however, as has been shown, is not offensive. If, on the other hand, a highly septicised sewage be not obtained, the sludge is more offensive, and greater care must be taken in dealing with it.

Contact System. In a paper before the same association, Mr. Dibdin dealt with the purification of sewage on biological lines by means of "contact" beds (referred to hereafter) filled with slate debris, supported on suitable slate blocks, the distance between the slates being about 2 in. He claims that a bed filled on this principle doubled its holding capacity, while the accumulations of mineral matter, which clog bacteria beds of clinker, stones, etc., can be flushed from the surfaces of the slates, and the bed restored to its original capacity. At Devizes, where some experiments were carried out, the capacity was found to be 87 per cent. of the total holding capacity of the beds. After 14 months this was reduced to 50 per cent., which, after being hose-flushed, was again increased to 82 per cent. It will thus be seen that beds filled on this principle have a very much greater holding capacity than with contact beds filled with ordinary clinker. It does not, however, appear practicable on a large scale, as the flushing of the beds would be almost impossible.

In covering a septic tank care must be taken to ensure ventilation, as the bacterial changes which take place in the sewage from anaerobic action liberate marsh gas, which is liable to explode, as has been the case in several instances.

GOVERNMENT HOUSE EXPERIMENTAL BACTERIAL INSTALLATION.

Areas and depths of filter material in filter beds, and amounts of tank effluent passed through beds in connection with samples taken for the purpose of analysis on May 28th, 1902.

No. of Filter	I.	II.	III.	IV.	V.		VII.

Australian Experiment. The Australian Government had some valuable experiments carried out with the sewage of Perth, Fremantle, and the various suburbs under their chief engineer, Mr. Palmer. The results were communicated by him to the Public Health Engineer in 1905. The sewage was described by Mr. Mann, the Government analyst, as being of a far higher strength than would usually be found in a town sewage, while the percentage of purification was higher than he had seen recorded. The preceding table shows the construction of the seven filter beds that were used for the experiments.

On the day when the samples were taken for analysis the volume of sewage that was being delivered to the beds was noted as follows:

No. of Filter.	Gallons passed through the filter on May 28th, 1902
I.	110
V.	120
II.	120
III.	120
VI.	90
IV.	120
VII.	50

Bed No. 1 was used from 7 a.m. to 8.30 a.m., and again from 3 p.m. to 4 p.m. Two samples of bed No. 1 were therefore taken.

Beds Nos. 5 and 6 are kept as reserve beds and are used when one of the regular beds fills before its proper time.

Bed No. 5 was used between 8 30 a.m. and 9 a.m. and, not being full, was again used between 10 a.m. and 11.30 a.m. before being let off and the first sample of filtrate taken.

Bed No. 5 was used again from 4.10 p.m. to 5 p.m. and, after standing full, a second sample was taken from this bed.

Bed No. 6 was used between 12.30 p.m. and 1 p.m. and, not being full, was used again between 2.30 p.m. and 3 p.m. before being let off and a sample of filtrate taken.

There are, therefore, two samples of bed No. 1, and also of bed No. 5, and one sample each of beds Nos. 2, 3, 4, 6, and 7. [See table on next page.]

The result of much observation at different outfalls where tanks have been employed to work on the septic principle leads to the conclusion that their capacity should be sufficient to hold from one to one and a half days' dry weather flow.

Hydrolitic Tank. At Hampton-on-Thames what is called a *hydrolitic tank* forms a useful part of the system that has been adopted for the bacterial treatment of sewage, the Shone Ejector being used to collect and deliver the sewage at the outfall.

The sewage, after leaving detritus tanks, enters the centre of a transverse channel, which conveys it into the sedimentary chambers of the hydrolitic tank, which consists of two parts. The first portion is divided into three compartments by means of light division walls formed of flagstones. Of these compartments, the two outer are the sedimentary

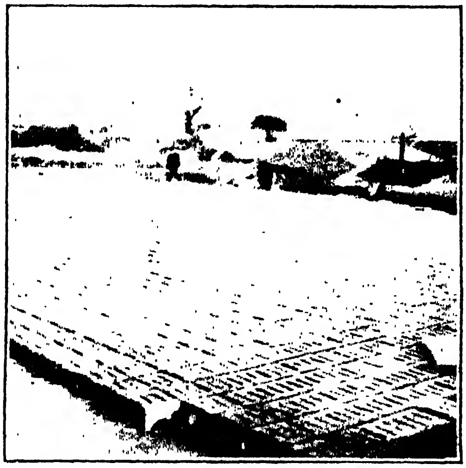
chambers and the central the liquefying chamber. Along the bottom of the sedimentary chambers are narrow openings which lead into the liquefying chamber, and form the only means of liquid communication between these chambers.



39. FALSE FLOOR FOR BACTERIA BED

False Floor for Bacteria Beds. Messrs. Stiff make a false floor for bacteria beds with channels to carry off quickly the fluid that has passed through the bed to the bottom of it. **Fig. 39** shows one of these in course of construction. It will be seen that the material composing the bed rests on the top of a perforated surface which lets the fluid pass rapidly through the false floor and away, carrying any suspended matters with it, and leaving the empty spaces to assist aeration. Before sewage is delivered on to any kind of bacteria bed it is essential that as much solid matter as possible should be arrested by sedimentation to prevent the beds clogging and the interstices being choked with matter which cannot possibly be acted upon by bacteria. Much of the data as to the purification or disposal of sewage by filtration shows that the failure, or inefficiency, of the beds to continue their successful working for long periods has been due entirely to non-compliance with this essential condition.

Contact Beds. Another system which depends on the action of bacteria for the treatment of sewage is that called the *contact bed*, with which the name of Mr. Dibdin will always be associated. The principle on which they are worked is to pass sewage into a chamber containing suitable filtering material until it is filled, then leaving the sewage at rest for a time in the filled chamber, after which the filtrate is run off, and the empty tank is left at rest for a time, during which the aeration of the interstices is effected.

The annual report of the Manchester Corporation Rivers Department for the year ending March 29th, 1905, contains a great deal of information regarding the results of both the experimental and permanent works which have been carried out to deal with the sewage of Manchester and adjacent places.

The following useful information is given with reference to the treatment of the sewage in open septic tanks and bacteria beds.

The total flow through the septic tanks during the year amounted to 6,189,995,000 gallons, or an average of about 17,000,000 gallons per day.

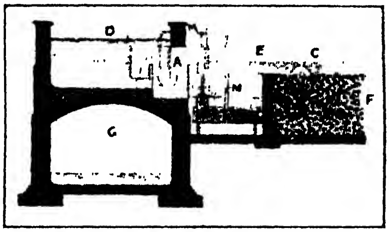
The total amount of sludge removed from the septic tanks—namely, 72,310 tons—is equal to 11 tons 14 cwt. per million gallons. The corresponding figure for the previous year was 6 tons, the average for the two years thus being 8 tons 27 cwt. of sludge per million gallons, as compared with 18 tons 2 cwt., the average amount of sludge per million gallons obtained by chemical treatment from 1899 to 1901. Or, taking the total production of sludge, including that deposited in the settlement tanks, the average for the last two years is 2,860 tons per week, as against 3,902 for the years 1899 to 1901.

At the date of the report $42\frac{1}{2}$ acres of beds were in operation, so that with the completion of the remaining seven beds the whole area of primary beds will be available. The quantities dealt with are obtained by the use of the following sliding scale of capacities.

Number of fillings.	Capacity of bed.
0 to 200	180,000
200 to 500	160,000
500 to 750	150,000
750 to 1,000	140,000
1,000 to 1,200	130,000
1,200 to 1,500	110,000
1,500 +	100,000

Aeration of Contact Beds. After careful observation at the Manchester sewage outfall Dr. Fowler, who had charge of the works, came to the conclusion that the period of resting the contact bed when empty is more important than the time when the bed is left at rest full, and that generally it is not desirable for the latter time to exceed one hour. This is a useful experience to record. The aeration of the contact beds, when empty, is

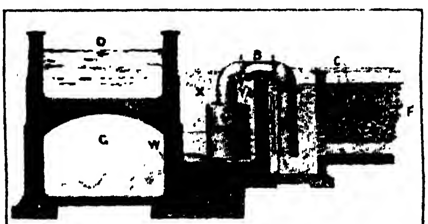
due to the organisms contained in them absorbing oxygen and producing carbon dioxide. The natural interchange of gases which takes place causes the aeration of the beds. It is generally found that the interstices between the material composing the beds is about one-third of the total capacity of the bed, so that if the basis of three fillings a day is adopted the volume that the beds are capable of dealing with would be represented by the actual capacity of the beds.



40. FILLING A CONTACT BED

The depth of the beds is governed to a great extent by the levels at which the sewage is delivered and discharged, dependent on local conditions. Shallow beds drain more rapidly and are, therefore, to be preferred. If the available area of the outfall plot is limited, deep beds would have to be used, whereas shallow ones could be employed on larger areas.

A Second Contact Bed. By using a second contact bed a higher degree of purity can be attained than with only one. The second one can be worked at twice the rate of the first, thus involving only one secondary bed for two primary ones. The filtering mediums used in every kind of sewage filter must be free from any fine matter which can tend to fill up the interstices. It should also be incapable of disintegration by exposure to the passage of the sewage through the filter. The material to be employed depends, to a large extent, on the locality, and may be hard coke breeze, coal, broken hard bricks, sifted and selected debris from stone or slate quarries, slag and clinker. As has been explained, it is necessary when adopting this system of sewage purification that the liquid must remain in contact with the filtering medium before being run off. In order that this may be accomplished automatically, various devices have been designed, among which may be mentioned that of Adams-Hydraulics, Limited [40 and 41].



41. EMPTYING A CONTACT BED

The illustrations show the air-lock feed and automatic methods of discharging a bed after it has been standing full for a time. Fig. 40 shows the method of filling; the sewage enters the bed, through a syphonic feed, A, and is conveyed by means of a distributing trough, C, to the bed. The liquid is admitted to M through a small syphon (not shown). As it rises, it compresses the air in the domes K and N; the compressed air in K forms an air lock in A, which automatically shuts off the supply, while the compressed air in N is connected to the feed of another bed, in order to break the air lock in that feed and allow filling to begin. The method of emptying a bed is shown in 41. The liquid in the bed has access through perforations to a chamber in which is a syphon, Z, and a bent pipe fitted with a cock, Y. This cock is adjusted to admit into the chamber X enough liquid to fill it in any required time; the syphon then comes into operation and empties the bed.

Percolation Beds. As the function of anaerobic bacteria are known to be best discharged without air, and those of aerobic bacteria depend on plenty of air, it is difficult to appreciate how a contact bed can be right, as the emptying, filling, and resting process appears incompatible with either requirement. The aim should be to let the sewage percolate, or trickle, over the largest surface in the presence of the maximum amount of air, by which the best oxidisation must be effected. The material used for filling these beds must comply with the conditions laid down as regards absence of substances that may choke or clog the bed.

As already stated the sewage, before passing to a percolating bed must have passed through some form of sedimentation chamber in which the solid inorganic matters will have been deposited, and a certain amount of liquefaction of organic solids will have taken place, depending upon the size of the chamber and the rate of flow through it.

The satisfactory results that have been obtained at a great many places by passing sewage over the surfaces of the material composing a percolating bed have established this system as one that affords a solution, although not necessarily the only one, of the problem of the disposal of sewage at outfalls, where irrigation is not possible, and where the cost of chemical precipitation is to be avoided.

THE MANUFACTURE OF STEEL

Constitution of Steel. Tempering and Temper. Alloys of Steel. Various Methods of Producing Steel. Armour Plate

By A. H. HIORNS

STEEL is an alloy of iron and carbon, and its peculiar characteristics have been known from very early times. Yet the phenomena of hardening, tempering, and annealing have been clearly indicated only in the last decade, owing chiefly to the revelations of the microscope and the pyrometer, combined with chemical analysis.

In the solid state the maximum amount of carbon that pure iron can retain is 4·23 per cent. The presence of foreign bodies raises or lowers this quantity according to their nature and amount. Three chief forms of carbon in iron are generally recognised—namely, *graphite carbon*, *cement carbon*, and *hardening carbon*. Graphite is comparatively rare in steels. Cement carbon is really carbide of iron. It exists in unhardened or annealed steels, and has the chemical formula Fe_3C. Hardening carbon is found in hardened steels, and the hardness, brittleness, and tenacity of the steels increase with the increase of hardening carbon up to the limit of about 1·3 per cent. of carbon as regards tenacity, and probably to 4·3 as regards hardness. In tempered steel some of the hardening carbon has been released, forming cement carbon, hence the diminution of hardness and brittlensss.

Hardening of Steel. When steels containing over 0·25 per cent. of carbon are suddenly quenched from a red heat they become *hardened*. The degree of hardness increases with the percentage of carbon, with the rise of temperature, and with the rapidity of cooling. The real cause of hardening is unknown, but according to the theory of Osmond, which is largely accepted, it is due to a hard allotropic modification of iron which exists at certain ranges of temperature, depending on the amount of carbon present. Whether the hardness be due to this cause or not is a matter of pure theory, but it is a fact that in mild steel and malleable iron there are three well-marked critical points. They are distinguished as described in this table:

	Beginning.	Maximum between.	Conclusion.
Ar. 3	845 C.	825° to 819° C.	800° C.
Ar. 2	755° C.	736° „ 725° C.	710° C.
Ar. 1	680° C.	662° „ 655° C.	645° C.

In medium steel the points Ar. 2 and Ar. 3 are combined into a single point, reaching a maximum at about 720° C., and the point Ar. 1 has a maxium at about 660° C. In high carbon steel there is only one break in the cooling of long duration, at 674° C. Ar. 1 is absent in pure iron, therefore it is a function of the carbon in steels corresponding to the change from hardening to cement carbon in cooling the steel. Ar. 2 is identical with the disappearance of magnetism. Osmond recognises the existence of three allotropic forms of iron. Above Ar. 3 the iron is in the *gamma* form. Between Ar. 2 and Ar. 3 the iron is in the *beta* form, and below Ar. 2 the iron is in the *alpha* form. According to this theory, beta and gamma iron are hard and alpha iron is soft. Hence, by suddenly quenching steel from above the point Ar. 2, the change is prevented and the steel remains hard.

By the carbon theory, hardening is due to the condition of the carbon above certain critical temperatures termed *hardening carbon*, which is retained in that state by sudden cooling and decomposed on slow cooling. It is probable that the phenomenon of hardening is due to both the allotropic form of iron and the hardening carbon.

Tempering. On cautiously reheating hardened steel to a certain point, the tension is released, some carbide is set free, the steel loses its brittleness and becomes softer and more elastic. This operation is termed *tempering*. The temperature for tempering varies with different articles, and is judged by the colour of the film of oxide on the brightened surface. The following table, from the writer's "Steel and Iron," shows the tempers for various articles:

Percentage of carbon.	Temperature.	Colour.	Article.
1·5	220° C.	Faint yellow ..	Surgical knives.
	230° C.	Straw yellow ..	Razors, knives, hammers, taps, and dies.
	255° C.	Brownish yellow	Scissors, hard chisels, shears.
1·3	265° C.	Purplish brown	Axes, planes.
	277° C.	Purple	Table knives.
	280° C.	Violet	Cold chisels for brass, punches, etc.
0·9	288° C.	Light blue ..	Swords, coiled springs.
	293° C.	Dark blue ..	Fine saws, augers.
0·8	316° C.	Blackish blue ..	Hand saws, cold chisels for copper and wrought iron.
0·6	400° C.	Black	Spiral springs.

Steels expand on hardening, varying with the amount of carbon present, and the higher the carbon the lower should be the temperature to which the steel is raised. Small tools are plunged into water or oil. Bulky articles are placed in water and deluged with a stream of water. Files must have their teeth protected with a fusible paste before heating. Saws are heated in an air or gas furnace and quenched in whale oil. They are tempered by burning off the oil. Hammer-heads and steel-faced articles have the other parts kept cool with a wet rag while the faces are heated.

Effect of Work. Ingot metal is improved by fagoting and welding. Up to a certain limit, and avoiding working at a blue heat, the tensile strength and elongation are increased by cold rolling and hammering. The elastic limit is raised and the area is reduced. If the sectional area of a piece of steel be reduced to 30 per cent. or 40 per cent. by hot working, each per cent. of diminution of area increases the tensile strength and elastic limit by about 0·2 per cent., and the elongation and contraction of area by about 1·5 per cent. Hot working expels slag, welds detached particles, closes pipes and blowholes, and prevents undue crystallisation. Hammering is generally superior to rolling in yielding the results mentioned.

COMPOSITION OF VARIOUS STEELS

	Carbon.	Silicon.	Manganese.	Phosphorus.	Sulphur.

SILICON. The amount of silicon in mild steel is generally very small, but amounts up to 0·05 per cent. do not impair strength and welding properties. In high carbon steel silicon is more hurtful.

SULPHUR. The influence of sulphur with less than 0·05 per cent. on the tenacity and ductility of steel is very slight, but beyond this amount it causes red-shortness. But manganese, which is usually present, neutralises the influence of sulphur to a great extent. Sulphur has a tendency to cause development of fine cracks.

PHOSPHOROUS. Small quantities under 0·1 per cent. do not effect the hot-rolling properties or the tensile strength, but phosphorus is very dangerous when the steel is subjected to vibration or sudden shock. In structural steel the phosphorus should not exceed 0·06 per cent., and in high carbon steel it should not be more than 1·01 per cent.

MANGANESE. This is an essential constituent of structural steel, but the less it contains above that required to produce soundness and freedom from red-shortness, due to sulphur, the better, and for these purposes 0·50 should be sufficient. Manganese tends to increase tenacity and reduce ductility. In high carbon steels the effect of manganese is more marked, and tends to produce fractures on quenching for hardening.

ARSENIC. In quantities of less than 0·15 per cent., arsenic has no effect on the mechanical properties of steel. Above this amount cold-shortness is noticeable, and prevents good welding.

COPPER. In small quantities, copper has no influence on the physical properties of steel.

Segregation. In considering the effect of impurities on steel, the temperatures of casting, reheating, and work put upon the metal must be considered. Moreover, the effect of an element on steel is modified by the simultaneous presence of other constituents. While it is easy to determine the influence of a single element on steel, it is very difficult when four or five elements are present. Another point of difficulty is the tendency of certain constituents to segregate, especially when the steel is slowly cooled. Howe divides bodies which tend to segregate into three groups: (*a*) compounds which differ from the rest in fusibility; (*b*) compounds which have a strong affinity for each other; (*c*) compounds which differ greatly in density from the rest of the mass. Carbon and phosphorus have a great affinity for manganese. Carbides, phosphides, and sulphides of iron are more fusible and have lower densities than alloys of iron and manganese. It is generally found that segregation of one impurity induces segregation of the rest. Sulphur, phosphorus, and their compounds are generally most unequally distributed. Carbon also very readily segregates. Chrome and tungsten steels are very liable to segregation, while nickel steels are remarkable for their uniformity.

Steel Alloys or Special Steels. The varieties of steel already considered are termed *carbon steels*, but special steels contain other metals alloyed with iron, with or without much carbon. The metals which chiefly influence the properties of steel and are used for industrial purposes are: *manganese, nickel, chromium, tungsten, aluminium, vanadium*, and *molybdenum*.

Manganese is generally present in commercial steels from 0·3 to 1 per cent. Manganese steel contains 12 to 14 per cent. of manganese and about 1 per cent. of carbon. It has a high tensile strength and elongation, is self hardening, and is used for various tools. It is non-magnetic, and offers great resistance to electricity.

Nickel forms with iron and carbon most valuable alloys, termed *nickel steels*. Steel with 3 per cent. of nickel and 0·2 per cent. of carbon has a tensile strength 10 per cent. greater than any ordinary carbon steel of the same quality, with an increase of 25 per cent. of elastic limit. The ratio of elastic limit to tensile strength increases up to 20 per cent. of nickel and then falls away rapidly. The hardening effect ceases with 10 per cent. of nickel. Above 1 per cent. the difficulty of welding increases. Steel with 25 per cent. of nickel is scarcely magnetic, but becomes so when cooled to −40° C., and does not regain its non-magnetic properties until heated to 600° C.

Steel containing 2 per cent. of nickel, 1 per cent. of chromium, and 0·4 per cent. of carbon is used for armour-piercing shells. The nickel toughens, while the chromium and carbon harden the steel. Nickel steel offers greater resistance to corrosion than wrought iron or mild steel.

Chromium does not impart hardness to steel, but in small quantities it raises the tensile strength and in large quantities the brittleness. Chromium does not of itself harden iron. Steel with 1 per cent. of carbon and 2 to 3 per cent. of chromium is used for projectiles, and with 1 to 2 per cent. of chromium for special files. Chrome steel is used for railway tyres and springs.

Tungsten is added to steel for self-hardening cutting tools and for magnets. Excellent tools can be made from steel with 1 per cent. of carbon and 7 per cent. of tungsten. A small percentage of tungsten in ordinary tool steel improves the wearing properties. Mushet steel contains 1·5 per cent. to 2 per cent. of carbon and 5 per cent. to 8 per cent. of tungsten. Tungsten is one of the constituents of high-speed tool steels.
